Average elevation (m)	National digital terrain model – zonal statistics to derive catchment average
Average slope (°)	National digital terrain model, processed for slope – zonal statistics to derive catchment average
Waste rock area (km²)	Based on processed Landmark data (see below) – zonal statistics to derive catchment total
Waste rock as percentage of catchment area	Based on above and water body catchment area
Average sediment Cd concentration (mg/kg)	GBASE data filtered for stream sediments only; spatial join to derive average (and count) based on number of GBASE sample points in each water body
Average sediment Cu concentration (mg/kg)	As above
Average sediment Pb concentration (mg/kg)	As above
Average sediment Zn concentration (mg/kg)	As above

Waste rock risk assessment

The identified potential metal mine waste rock heap polygons were subject to a range of analyses to assess the potential risk for delivering contaminated sediments into adjacent river systems, which may become remobilised in the water column. Waste rock features were then assigned a relative risk score based on a series of criteria. The boundaries for these criteria were set to give a roughly even distribution of features in each class. The Calculate Geometry Tool was used to determine the area of individual features (Table 2). Each polygon was then given a risk score based on proximity to the nearest watercourse (taken from the 1:50000 river network shapefile). Buffer distances and Risk Scores were obtained as per Turner *et al*. (2011) and are shown in Table 2.

Topographic Wetness Index (TWI) is a tool widely used in assessing slope stability in many geotechnical settings (e.g. railway embankments and cliffs). TWI is a function of local slope and the drainage area feeding an individual point on the slope (as a surrogate of potential soil moisture). We followed the method of Miller *et al.* (2012) to derive the TWI for all waste rock heaps based on 10m Digital Terrain Models (DTM) for the UK. TWI is given by the following:

$$TWI = \ln (\alpha / \tan \beta)$$

where α is the local upslope contributing are draining through a specific point and β is the local slope. The 10m DTM was used to create a Slope raster using the Slope Tool (Spatial Analyst), in degrees. Subsequently, a Flow Direction Raster was created, with the Flow Direction Tool (Spatial Analyst). The Flow Accumulation tool was then applied to determine the number of cells draining to every point of the 10m DTM (see Mayes et al. 2008).

Table 2 Risk Scores for each of the waste rock / landscape criteria

Risk Score	Area (m^2)	Distance to river (risk category)	TWI score
6	>100000	Direct contact : <2m (extreme risk)	<11
5	20001-100000	2 – 50m (very high)	11-12.5
4	10001-20000	50 – 100m (high)	12.5-13.5
3	5001-10000	100 – 250m (moderate)	13.5-14.5
2	2001-5000	250 – 500m (moderate-low)	14.5-15.5
1	301-2000	>500m (low)	>15.5

Average slope was calculated for each waste rock feature (using the Zonal Statistics Tool), while the maximum drainage area in km^2 was also calculated for each feature. TWI Risk Categories were then computed according to Table 2. It is worth noting that given the form of the TWI equation, a lower value equates to greater risk (i.e. increased slope or drainage area at a point).

After these steps, an overall Risk Score was derived for each polygon using the following equation:

> Risk Score (values between 3 – 18) = Area Risk Score (1-6) + Distance to stream Risk Score (1-6) + TWI Risk Score (1-6)

RESULTS AND DISCUSSION

Catchment descriptors

Of the catchment descriptors generated, those that are most revealing in terms of national generalisation on the extent of diffuse mining pollution sources are (a) catchment average sediment metal concentrations, and (b) the areal extent of waste rock in mine-affected catchments. The GBASE coverage covers 202 of the 264 Impacted / Probably Impacted catchments, however, a cursory examination of the available GBASE data highlights several patterns. Firstly, where data are available, the catchment average metal concentrations are usually derived from multiple instream samples (average of 11 samples per catchment; range from 1-169), which gives a reasonable level of resolution on which to consider sediment metal concentrations. Figure 1 shows the relationship between Pb and Zn (left panel) and Cd and Cu (right panel), which provide an indication of mining provenance and highlight the potential additive effects on biota of multiple metals in fluvial sediments. The relationships between the four metals are all positive and significant (r: 0.42-0.63; $P<0.05$ for all permutations). Similar patterns are seen in analysis of mine discharges themselves (e.g. Jones et al. 2013) and represent the nature of mineralisation in many of the UK orefields. The chief Pb ore (galena: PbS) is often found with sphalerite (ZnS) in many orefields (e.g. Dunham, 1985; 1990), while Cd is commonly found in sphalerite as an impurity (Dunham, 1990). Cu enrichment is less common across the orefields of England and Wales (hence

the weaker correlations), but peak concentrations found in the orefields of the Lake District and Cornwall and Devon are typically found in combination with other Zn and Pb minerals. Superimposed on Figure 1 are the respective Threshold Effects Levels (TEL – green line) and Predicted Effects Levels (PEL – red line) for fluvial sediment contamination (Buchman, 2008). These values, derived by Environment Canada (PLA, 2014), offer an initial screening tool to assess the likelihood of negative effects of metal concentrations on sediment-dwelling organisms in river systems. A value below the TEL would not be expected to impact on aquatic biota, whereas a value in excess of the PEL would be expected to result in negative impacts on sediment-dwelling organisms. The distribution of the catchment average sediment concentrations show that for Zn, Pb and Cd that the majority of catchments exceed TEL values (between 85 and 94% of catchments), with a significant portion of catchments above PEL values (between 17 (Cd) and 69% (Pb)). Elevated Cu concentrations are rarely an issue in most priority catchments with only 35% above TEL and 3% above PEL values. Comparisons with such preliminary screening tools should be undertaken with caution, however the data highlight that sediment metal concentrations (notably for Zn and Pb) are elevated at levels of potential concern for aquatic ecosystem health in most priority catchments. Screening for sediment metal concentrations in non-priority catchments shows TEL exceedance in less than 5% of cases (data not shown). While such a coarse-scale analysis cannot provide detail on the provenance of the metals, the body of evidence from smaller scale studies consistently highlight the importance of mining activity in elevating sediment metal concentrations above pre-mining levels (Environment Agency 2006). This would suggest that secondary diffuse metal pollution sources in fluvial sediments are widespread.

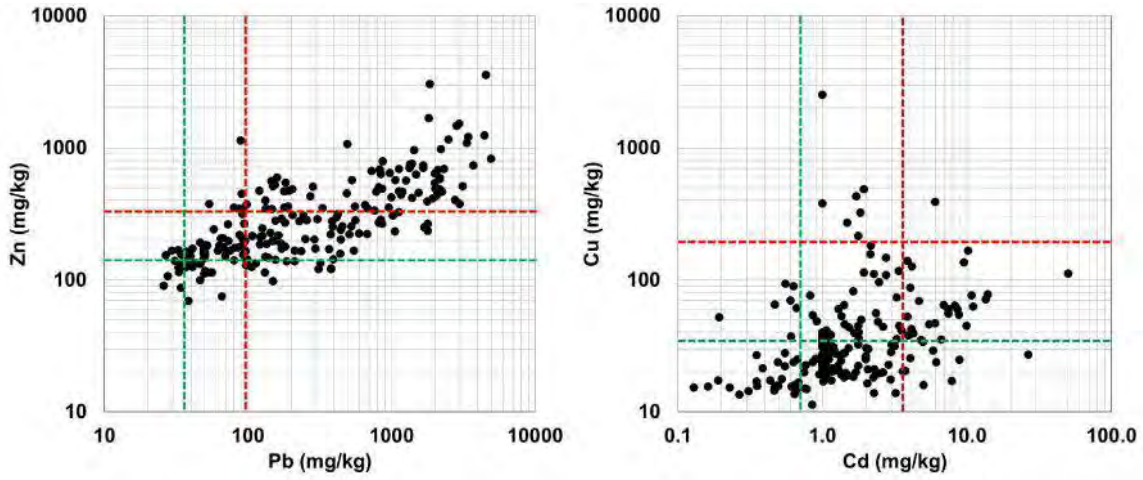

Figure 1 The relationship between Zn and Pb (left panel) and Cu and Cd (right panel). Green lines show respective Threshold Effects Levels (TEL), red lines show Predicted Effects Levels (PEL). Data from GBASE: Licence No.2012/069GB British Geological Survey © NERC

The waste rock cover data offer another good insight into key diffuse pollution sources. In the priority catchments the average areal extent of waste rock was 0.06 km^2. The maximum recorded extent of waste rock was up to 6.4km^2 in the upper Wharfe catchment in the Yorkshire Pennines. When the areal extent of waste rock is compared with catchment area, the average percentage cover of waste rock is 0.8%, with maximum values in four catchments where waste rock exceeded 25% of the entire catchment area (Hicks Mill Stream, Upper and Lower River Carnon in Cornwall and the

mid-reaches of the Lathkill in Derbyshire). Generally, those with the highest waste rock cover are dominated by catchments from the Pennines and South West of England. Whether this is a feature of more systematic mapping in some regions is uncertain (possibly those where mining was more recent and therefore better represented in spatial data, such as the extensive reworking of waste rock in Pennine catchments for fluorspar and barytes in the 1960s/70s: Dunham 1990) and warrants further investigation of the Landmark datasets.

Waste rock heap risk maps

The waste rock heap overall risk score effectively provide a relative risk assessment of metal delivery to the fluvial environment based on the parameters detailed above (slope, flow accumulation, proximity to stream, waste rock area). Figure 2 shows a screengrab of the layer in the Upper Tyne catchment. The waste rock areas with the higher risk scores are generally closer to, or overlap rivers on steep slopes, while those with the lower scores are typically on low gradient summit plateaux near catchment boundaries. This relative risk assessment provides a coarse-scale screening tool to focus more detailed remedial planning investigations. We envisage this layer to be used alongside point mine discharge data to (a) determine the most suitable positions for potential instream sample stations (e.g. upstream and downstream of major waste rock heaps) in catchment scale synoptic surveys (e.g. Gozzard et al. 2011), and (b) assist in interpreting catchment loading data, for example suggesting on which reaches diffuse input from riparian waste rock would be anticipated. During such catchment scale investigations field validation of the relative risk assessment (e.g. visual inspection for evidence of contaminated sediment delivery to surface waters) would provide the scope for future refinement of the spatial analyses.

Case study: the River South Tyne catchment

The River South Tyne, in north east England, has a catchment area of approximately 800 km^2. It drains a large section of the North Pennine orefield, which was heavily mined for several centuries, primarily for lead and zinc. The widespread abandoned mines in the area most severely impact the Rivers Nent, and East and West Allen (Figure 2). In addition to numerous point sources of mining pollution (there are 5 major discharges to the River Nent alone), diffuse pollution (both aqueous and particulate) adds a significant additional burden to the overall flux of metals to the River South Tyne (Gozzard et al. 2011; Rudall, 2012). The main metal of concern is zinc.

Figure 2 (yellow inset) shows the waste rock heap risk map for the River Nent, a major tributary of the River South Tyne. In particular, Figure 2 shows that there are extensive tracts of waste rock in the vicinity of the headwaters of the Nent, which are assigned a risk score of 12-13 according to the methodology described above. Sneddon et al (2008) estimated that 615 000 tonnes of waste rock material were dumped along the River Nent during the period of mining, containing 0.4 wt% Pb and 3.5 wt% Zn.

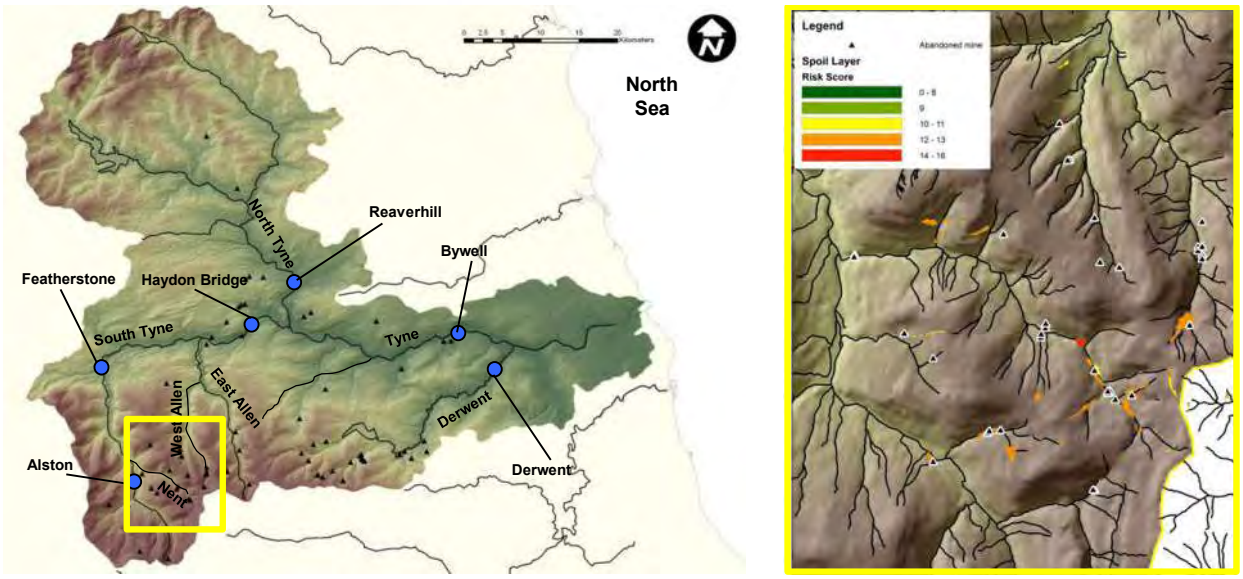

Figure 2 Screenshot of waste rock layer (with risk categories) and river network in the Upper Tyne catchment (yellow inset) and the broader Tyne catchment

The contribution of point sources of pollution to the overall flux of Zn in the River Nent is relatively constant. For example, an investigation during 1997 and 1998 suggested that the combined flux of Zn from the 5 point source discharges did not exceed 40 kg/d (in both particulate and aqueous fractions: Nuttall, 1999). More recent monitoring of Zn flux shows that this remains the case to this day. However, Zn flux monitoring in the River Nent, below the areas of waste rock, and also at two locations on the River South Tyne, downstream of the River Nent, shows that riverine fluxes of zinc are far in excess of that which can be accounted for by the point source discharges. Figure 3 shows zinc flux as a function of river flow-rate on the River Nent, and also on the River South Tyne at Featherstone and at Haydon Bridge, during 2010 and 2011. It is clear that there is a sharp increase in flux as flow increases on the River Nent, which is a result of waste rock heap runoff and remobilisation of secondary metal contamination associated with metal-rich instream sediments. The flux of Zn in the River South Tyne at Featherstone is attributable almost entirely to the metal pollution from the River Nent. Further downstream, at Haydon Bridge (Figure 2) Zn flux is greater than that at Featherstone during highest flows (up to a maximum of instantaneous flux of 1 678 kg Zn/d), and this is due to the contribution of zinc from the Rivers East and West Allen. Point source mining pollution is often the focus of remedial efforts, but observations such as those for the River South Tyne have major implications for the benefits of such remediation. Specifically, point source treatment may not result in downstream water and sediment quality objectives being met, particularly at higher river flows when diffuse source pollution is significant.

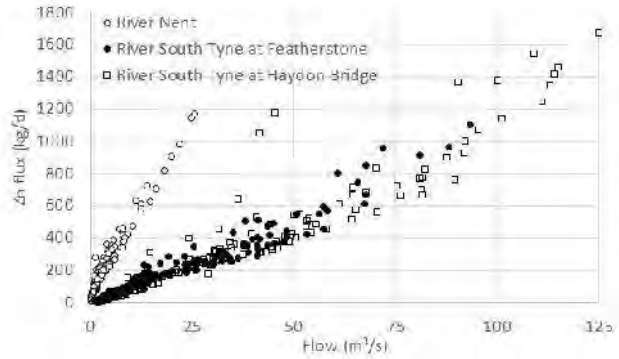

Figure 3 Zn flux in the River Nent and River South Tyne under varying hydrological conditions, illustrating the substantial contribution of diffuse sources of mining pollution

CONCLUSION

Diffuse sources of metal pollutants are ubiquitous in catchments in which extensive former metal mining has occurred. This includes both waste rock heaps, which total 91 km^2 in area and contaminated instream sediments. The analysis of fluvial sediment metal concentrations across the orefields of England and Wales shows in most catchments deemed priorities for remedial action, concentrations are often in excess of prescribed screening thresholds. The positive correlations between Zn, Cd, Pb and Cu highlights that contaminated sediments in mine-affected catchments typically contain a cocktail of numerous metals in high concentrations giving rise to the prospect of synergistic impacts on aquatic biota. The GIS screening exercises undertaken here provide environmental managers with datasets that can assist in catchment scale remedial planning. In the UK, this typically consists of catchment scale synoptic sampling of contaminant loads to identify the contribution of individual point and diffuse discharges to instream contamination. A case study of the River South Tyne illustrates how mapping waste rock coverage can highlight the potential importance of diffuse pollution, and guide the design of monitoring programmes to quantify the relative contributions of point and diffuse source pollution.

ACKNOWLEDGEMENTS

This work was funded by the UK Government Department for Environment, Food and Rural Affairs under Project WT0969. We are grateful to the project steering committee (Dr Abby Moorhouse, Dr Ian Watson, Victor Aguilera) for comments on the methodological approach. BGS GBASE data are used under licence 2010/069GCB. The views expressed in the paper of those of the authors and not necessarily those of the funding agency.

ABSTRACT

When assessing mine closure options, predicting mine waste effluent water quality is a particular challenge. Conventional static and kinetic tests on small sample volumes are typically used to assess if the mine wastes will be acid generating. However, using these small scale tests to assess if or when field-scale waste piles will release poor quality effluent requires recognizing scale-up issues between laboratory and field conditions. At the Diavik Diamond Mine, up to 42 million tonnes of fine processed kimberlite (FPK) will be deposited onsite for permanent storage. To evaluate the effectiveness of using lab scale experiments to predict mineral weathering and the evolution of porewater geochemistry from the FPK storage impoundment, testing was done to quantify the relationship between laboratory humidity cells and large field-scale tanks. Three fractions of FPK were used for the humidity cell experiments including fine, medium and coarse grained fractions of slurry-deposited FPK. Humidity cells representing the three grain sizes were run for 80 weeks in duplicate at 4°C and 20°C, following the ASTM method. Concurrently, three 5700 L high-density polyethylene tanks were filled with the same fractions of FPK material as the humidity cells. The three tanks were constructed to represent unsaturated conditions. Each tank was instrumented in detail to measure pore water geochemistry, gas-phase concentrations and oxygen diffusion, matrix pressure and flow, evolution of temperature, as well as to resolve mass and flow balances. Results from this study will be used for closure plans at Diavik and potentially other Diamond mines in the Canadian North.

Keywords: Sulfide oxidation, neutralization, processed kimberlite, humidity cells, scale-up

INTRODUCTION

Processed kimberlite (PK) is discharged by slurry to permanent tailings impoundments at diamond mines in Canada's arctic. The Diavik Diamond Mine (Diavik) is an operating mine with two completed open pits and an underground mine. Up to 42 million tonnes of slurry-deposited fine processed kimberlite is expected to be permanently retained on-site in the Processed Kimberlite Containment (PKC) facility. Slurry-deposited PK is defined by Diavik as the < 1 mm fraction of the PK stream and is referred to as fine PK (FPK). Diavik is located 300 km northeast of Yellowknife, NT, Canada (Figure 1) in the remote barren lands of the Canadian arctic. The area is dry and cold with a mean annual temperature, rainfall, snowfall and lake evaporation of -12°C, 164 mm, 187 mm and 271 mm, respectively.

Laboratory humidity cell experiments and *in situ* 5700 L tank experiments were initiated in 2012 to complement an on-going *in situ* PKC experiment at the Diavik Diamond Mine (Moncur and Smith, 2012) to understand better the complexities of using small-scale laboratory experiments for long-term predictions of seepage quality.

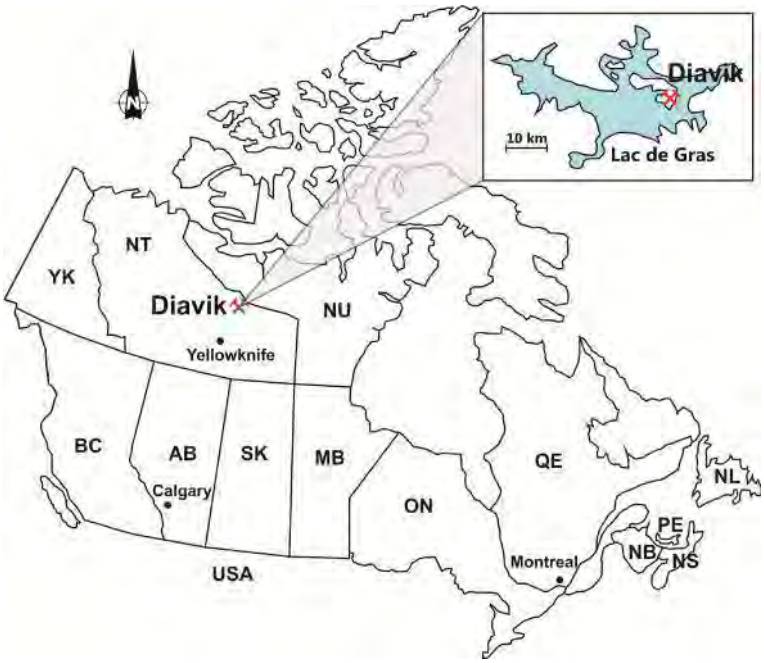

Figure 1 Location of Diavik Diamond Mines in NT, Canada.

METHODOLOGY

Processed kimberlite used for this study was deposited by slurry in 2011 on the East Beach of the PKC. Using a track hoe, FPK was excavated and transported by dump truck on August 2, 2012 to the experiment site. The coarse fraction of FPK (CT) was collected near the toe of the containment dam; the fine fraction of FPK (FT) was collected approximately 200 m from the dam, adjacent to the standing pond water; and the medium FPK fraction (MT) was collected mid-way between the pond

and the containment dam. During FPK excavation every attempt was made to remove the overlying unsaturated FPK to prevent the collection of previously weathered material. Material collected for the tanks was excavated from within the saturated and frost zones of the impoundment.

Tank design and construction

Instrumentation was selected to measure pore water geochemistry, gas-phase concentrations and oxygen diffusion, matrix pressure and flow, evolution of temperature, as well as to resolve mass and flow balances, developed after Smith et al. (2013).

Each tank was constructed from a 2 m in height by 2 m diameter 5700 L HDPE tank. The top of each tank was cut off at a 1.8 m and a 44.5 mm drainage hole was drilled in the wall of the tanks near the bottom for drainage. Water discharging from the bottom of each tank was channeled through a 37.5 mm schedule 40 PVC pipe into a sealed sample cell (Figure 2). Overflow from the sample cell discharged into a data-logging tipping bucket rain gauge so that a continuous record of flow could be maintained to provide bulk chemistry and volume of flow from each tank.

Figure 2 Photos showing (A) completed PK tanks, from left to right FT, MT, CT (B) tank bottom drain pipe discharging into the sample cell and tipping bucket (C) instrumentation on tank tops.

Soil water solution samplers (SWSS) were installed in each tank to provide point measurements of pore water solute concentrations by extracting pore water using applied suction from an area of influence around the probe tip. SWSS were installed at depths of 0.25, 0.5, 1.0, 1.5 and 1.7 m.

Decagon Devices ECH$_2$O-TE probes were installed in each tank at depths of 0.25, 0.5, 0.75, 1.0 and 1.5 m to provide discrete measurements of electrical conductivity (EC), volumetric water content and temperature. Measurements of volumetric water content through space and time can be used to monitor the wetting front propagation through each tank in which discontinuous zones of ice may form, and may indicate the locations and/or transient nature of any preferential flow paths. Continuous monitoring of EC at various depths will provide an understanding of the evolution of pore water during weathering, precipitation and freeze/thaw events. All ECH$_2$O probes were connected to a Decagon Devices EM50 data logger that continually records measurements every 4 hours.

A thermistor string consisting of 10 thermistors was installed at 0.0, 0.25, 0.5, 0.75, 1.0, 1.25, 1.5 and 1.75 m depths through each tank to allow the determination of spatial and temporal variations in permafrost formation, as well as the quantification of thermal contributions from exothermic sulfide oxidation reactions. Nine of the thermistors were attached to a 37.5 mm PVC stand pipe for support, with the bottom thermistor placed on the tank bottom. The PVC stand pipe was filled with FPK to prevent the conduction of air temperatures down the pipe annulus. Thermistor strings were connected to Lakewood Systems UltraLogger data loggers for continuous measurements.

Gas sampling lines consist of 0.63 mm I.D. low density polyethylene tubing installed at 0.1, 0.2, 0.3, 0.4, 0.5, 0.7, 0.9, 1.1, 1.3, 1.5 and 1.7 m depths within each tank. Internal gas compositions in each tank will be used to understand O_2 gas transport mechanisms, O_2 consumption rates from the oxidation of sulfide minerals, and CO_2 production or consumption rates from the dissolution or precipitation of carbonate minerals. Measured O_2 consumption rates can be used to determine sulfide mineral oxidation rates assuming sulfide oxidation is the only process consuming O_2 (Linklater, Sinclair and Brown, 2005).

Soil moisture 2725ARL Jet FI11 tensiometers were installed in the unsaturated zone of the tanks to measure pressure potential (matrix potential) in the FPK at depths of 0.25, 0.5, 1.0, 1.5 and 1.7 m. Pressure potential measurements will be used to calculate the gradient pressure in order to determine the rate of water movement through the unsaturated zone in the tanks.

Each tank was filled with the assigned FPK fraction in lifts of 0.3 to 0.4 m. Filling the tanks in lifts was necessary to accurately place the instruments and insure material was applied uniformly and compacted. Tanks were filled with FPK to a height of 1.7 m above the tank bottom. During filling of the tanks, a 20 L composite sample from each tank was collected for humidity tests and analyses of mineralogy, grain size, total sulfur and carbon, whole rock analyses, acid-base accounting and neutralization potential. All tanks were filled and instrumented on August 3, 2012 and remain exposed to ambient conditions year-round.

Sampling

Water sampling was initiated on August 28, 2012. Porewater was collected into SWSS by applying a vacuum of approximately 70 kPa two days prior to sampling. Water samples were collected from SWSS and drain sample cells using 60 mL polyethylene (PE) syringes. Measurements of pH, Eh and electrical conductivity (EC) were made on unfiltered samples in the field. The resulting water samples were passed through 0.45 μm filters and split into three aliquots. One aliquot of water was acidified with 12 *N* trace-metal grade HNO_3 to a pH of <1 for cation analysis, and another aliquot was left unacidified to use for anion analysis. The remaining water was used for alkalinity and NH_3 analyses. Water samples collected for anion and cation analyses were immediately refrigerated until analyses. Determination of major cations and trace elements was performed by inductively coupled plasma–optical emission spectroscopy (ICP–OES) and inductively coupled plasma-mass spectrometry (ICP–MS), respectively. Ion chromatography was used to measure inorganic anion concentrations. Concentrations of O_2 and CO_2 gas were measured from gas lines using a Grafton Model 902 O_2/CO_2 analyzer. Air temperature and precipitation data from site was provided by Diavik.

Humidity Cells

Two samples of each the fine-, medium- and coarse fractions of FPK were split from the tank material for an 80 week kinetic testing program. Kinetic testing followed the ASTM (1996) 5744-07

protocol, with the exception that samples were not crushed. Original size fractions were maintained in order to observe any geochemical variation caused by differences in grain size distributions. One set of fine, medium and coarse humidity cells was operated at room temperature (~22°C) and one set was operated at 4°C. The cells were subjected to a weekly cycle of a 3-day dry period (0% relative humidity), 3-day wet period (>95% relative humidity), and a 1-day flood leach with 500 mL of DI water. Effluent from each humidity cell was analyzed weekly for pH, ORP, acidity, alkalinity and SO_4. Dissolved metals, Cl and F were analyzed weekly from week 1-20, bi-weekly from week 20-40, and every six weeks from week 40-80.

RESULTS AND DISCUSSION

Mineralogy

The kimberlite pipes at Diavik are intrusions within supracrustal rocks and late Archean granitoids of the Slave structural province (Moss, Russell, and Andrews, 2008). The pipes are composed of bedded volcaniclastic kimberlite, consisting of both kimberlite and mudstone xenoliths. Processed kimberlite used for this study was composed of olivine, calcite, quartz, garnet, lizardite, biotite, albite, saponite, and both framboidal and massive pyrite. Pyrite grains are mostly encapsulated in fragments of serpentine and aluminosilicate clays. The acid generating potential (AP) and neutralizing potential (NP) of the FPK were calculated following the Modified ABA test described by MEND (1991). The AP values are similar among the three grain size fractions, 5.3 - 7.8 kg $CaCO_3$ eq/t, however not all of the AP would be available due to the occurrence of some pyrite as locked particles in other mineral fragments. The NP of the samples are similar, 165 - 218 kg $CaCO_3$ eq/t, and far exceed the acid generating potentials (Table 1). Olivine and calcite were the primary neutralizing minerals.

Sieve analyses using sieves +20, -20+35, -35+60, -60+100, -100+120, -120+200, -200+270 and -270 show the differences in grain size between the FPK in the three tanks and humidity cells (Table 1). The FPK from the FT and MT samples were similar with FT having slightly finer FPK, whereas the FPK from CT was coarser with a lower uniformity coefficient (Table 1).

Table 1 Grain size distribution, sulfur content, neutralization potential (NP), acid-generating potential (AP) and net neturalizing potential (NNP) for the tank and humidity cell experiments.

Tank	d10	d60	Uniformity Coefficient	Sulfur (%)	NP (kg $CaCO_3$ eq/t)	AP (kg $CaCO_3$ eq/t)	NNP (kg $CaCO_3$ eq/t)
FT	0.07	0.39	5.8	0.23	218.4	5.3	213
MT	0.08	0.44	5.3	0.34	203.1	7.8	195
CT	0.18	0.82	4.6	0.26	165.3	6.6	159

Processed kimberlite tanks

The pH from the tank drains were circumnetural to alkaline and showed little variation between tanks during the active period of June 1, 2013 to August 31, 2013 (Figure 3). The Eh and alkalinity trends were similar to that of pH, with all tanks exhibiting oxidized conditions and alkalinity typically >40 mg L^{-1} (as $CaCO_3$) (Figure 3), consistent with calculated NNP. Concentrations of SO_4 remained relatively constant for each tank but with the FT tank drain having much lower concentrations (Figure 3). The CT tank had slightly higher concentrations than the MT tank (Figure 3). The EC trends for the tanks mirror the SO_4 concentration trends with the highest concentration of dissolved SO_4 observed from the CT tank and the lowest from the FT tank (Figure 3).

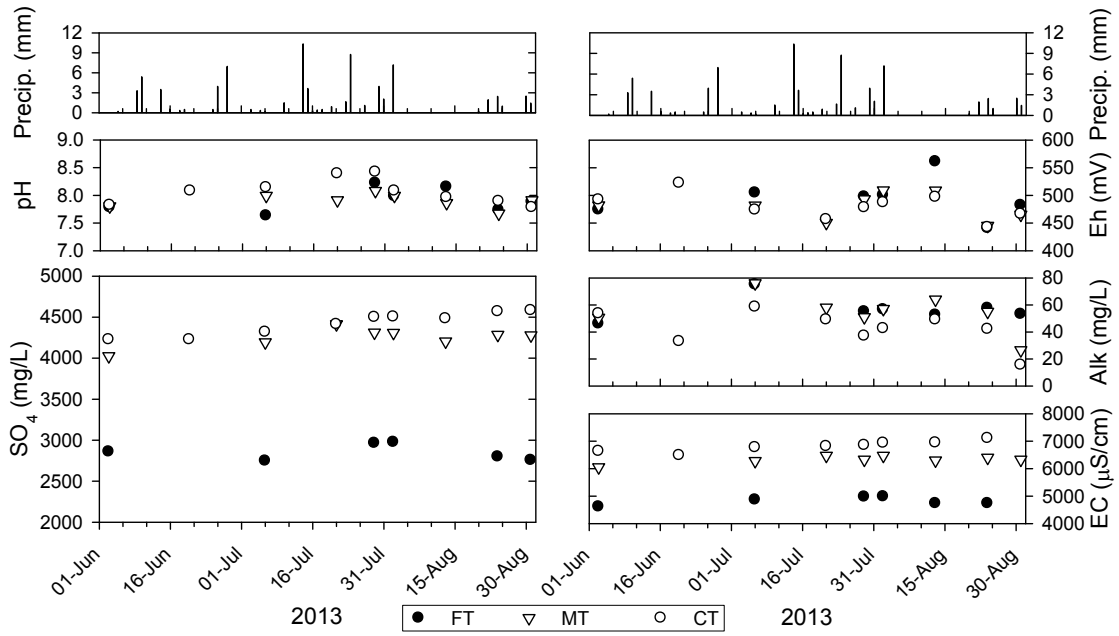

Figure3 Temporal variation of precipitation, pH, SO_4, Eh, alkalinity and EC from the PK tanks between June 1, 2013 and August 31, 2013.

The pH in the SWSS from all three tanks remained circumneutral to alkaline at all depths and was slightly higher in the MT and CT tanks for 2013 than for 2012 (Figure 4), possibly as accumulated reaction products began to flush through the tanks. Similarly, alkalinity concentrations in all tanks at all depths remained similar for both 2012 and 2013 (Figure 4), consistent with calculated NP values and alkalinity concentrations measured in porewater from the unsaturated zone at the PK facility (Moncur and Smith, 2012). Dissolved sulfate concentration in PK slurry water from the end-of-pipe ranged from 59 to 380 mg/L. Porewater concentrations of dissolved sulfate in the tanks approached 5000 mg L^{-1} and remained relatively constant between 2012 and 2013 sampling events (Figure 4). These elevated dissolved sulfate concentrations suggest that sulfide oxidation is likely occurring throughout the tanks (Lindsay et al., 2015). Depletions in O_2 in the FT and MT tanks were observed for 2012, but O_2 concentrations remained near atmospheric levels in 2013 and for both years in the CT tank (Figure 4). Volumetric water content (VWC) was typically higher in 2012 than in 2013 but varied with depth. The similar peaks and trends between sample years suggest the changes in VMC are not an artefact of sample timing dates (i.e. sampling during a particularly dry or wet time) and may suggest compositional differences by depths that affect wetting front propagation.

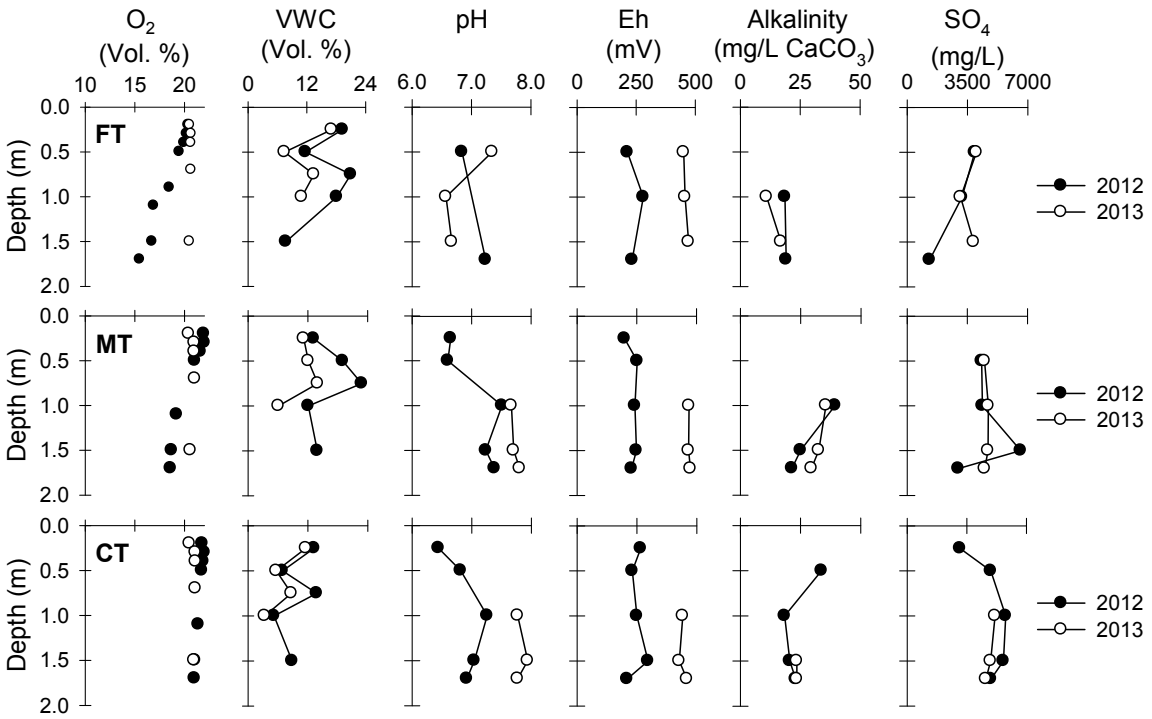

Figure 4 Depth profiles of oxygen gas, volumetric water content (VWC) and selected porewater chemistry from the PK tanks measured in 2012 and 2013.

Humidity cells

The pH in all humidity cell charges remained circumneutral to alkaline for the duration of the experiment with pH values ranging from 7.1 to 8.4 (Figure 5). The cells in the cold room consistently exhibited higher pH compared to the corresponding cell at room temperature. The room temperature cell with CT material exhibited lower pH and erratic fluctuations compared to the other five cells, possibly as a result of preferential flow paths reducing contact and reaction time with the cell material. However, alkalinity measurements from the same cell did not exhibit the same erratic behavior. Alkalinity remained >60 mg/L (as $CaCO_3$), for the duration of the experiment (Figure 5). Conditions within all cells remained oxidized with ORP ranging from 300 to 450 mV, consistent with the tank data.

Sulfate release rates were slightly higher for room temperature cells than for cells operated at 4°C, and in descending order, FT, MT and CT cells (Figure 5). Data from the first three weeks represent flushing of accumulated reaction products. Release rates from week 4 – 24 declined rapidly, and then declined at a more moderate rate from week 24 – 55. Sulfate release rates become more stable after week 55 until the end of the experiment at week 80 (Figure 5). Mass calculations suggest 77-85% of total sulfur and 73-81% of sulfides remain in the test charges after the 80 week experiment; however the decreasing rates suggest available sulfide surfaces are becoming limited by a reduction of available free grains, sulfide armoring or other limiting processes within the test cells.

Preliminary pH and alkalinity tank data are typically consistent with both the humidity cell experiments and the static tests which indicate that there is an excess of neutralization potential

over acid-generating potential. On-going monitoring of the tanks will determine if SO_4 release rates in the tanks follow the observed humidity cell trends of rapidly declining release rates despite >70% of measured sulfides remaining in the samples. Though not directly comparable, the difference between tanks in drain SO_4 concentration trends from humidity cell release rate trends suggest additional processes are occurring *in situ*. These processes need to be identified and evaluated for any scaling calculations.

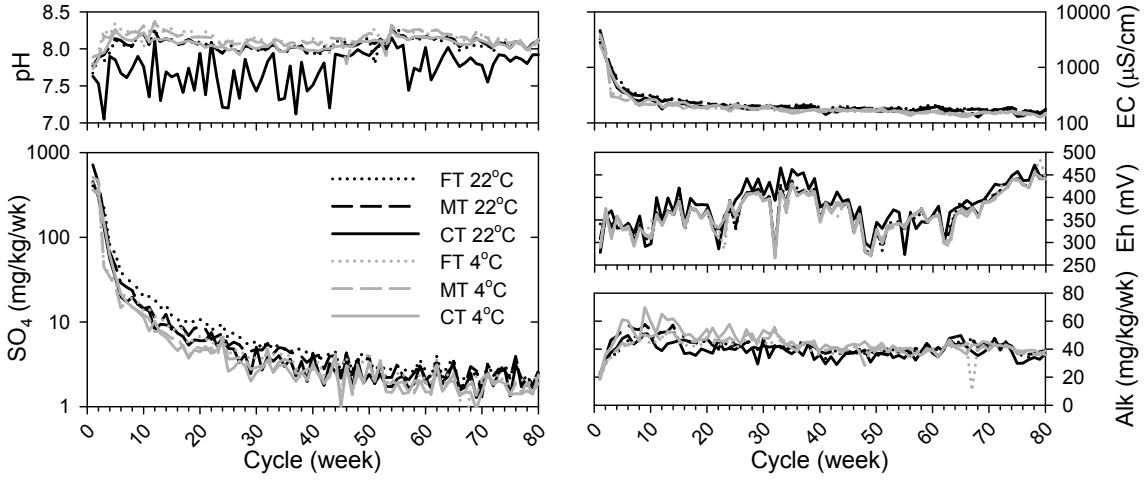

Figure 5 Temporal variation of pH, SO_4, EC, Eh and alkalinity of leachate from the FT, MT and CT humidity cells at 22°C and 4°C.

CONCLUSION

Comparing humidity cell reaction rates to the *in situ* tank experiment results are preliminary because the low amount of precipitation and infiltration and short thaw season limits the release of reaction products from the tanks and products are expected to take more than one thaw year to flush from the tanks. On-going monitoring of the tank experiments will permit the calculation of an *in situ* sulfate release rate(s) that accounts for local climatic factors that affect sulfide oxidation. Tank release rates can then be compared to humidity cell release rates to determine the applicability of using the small-scale tests to predict long-term seepage quality from the PKC facility. Diavik will use the results from the tank and humidity cell experiments to predict and refine long-term seepage quality from the PKC facility.

ACKNOWLEDGEMENTS

We would like to thank David Blowes, Kevin Tattrie, Jeff Bain, Sean Sinclair, Kent Richardson, David Wilson, Gord Macdonald, Emily Taylor, and the Diavik Environment team for their advice and technical assistance. This project was funded by Rio Tinto-DDMI. We thank an anonymous reviewer for their constructive evaluation of this manuscript. The use of trade names is for descriptive purposes only.

ABSTRACT

The Mount Isa mines have been active for more than 90 years and have played a significant role in the economy of Queensland. Process tailings from both copper and lead-zinc production streams are deposited in a large valley fill tailings storage facility which currently has an approximate surface area of 14 km^2. The site is a world class sedimentary deposit with climatic conditions typified by prolonged dry seasons with relatively short, high intensity wet seasons. This paper discusses the mineralogical and geochemical characterization of the tailings, and the assessment of the potential for metal leaching, to aid mine closure planning.

Historical tailings at Mount Isa are generally non-acid forming based on conventional acid base accounting, mineralogical examination, and kinetic testing. However, modern tailings are characterized by higher sulfide and associated trace element content, and lower carbonate mineral content than historical tailings. Changes in tailings composition are likely attributable to changes in ore and mineral processing methods, and time since tailings deposition. Strategies are currently being developed for the placement of a suitable cover system to reduce surface water – tailings interaction following decommissioning of the TSF. This study demonstrates the benefit of integrating detailed geochemical characterization into closure and rehabilitation planning.

Keywords: Mount Isa Mine, tailings, seepage

INTRODUCTION

Mount Isa is located in North-West Queensland, Australia, approximately 360 km south from the Gulf of Carpentaria and 960 km west of the Coral Sea (20° 43' S, 139° 29' E) (Figure 1). Mineralization in the Mount Isa region was first discovered in 1923 and subsequently a large number of mining leases were established with ore extracted through numerous shallow open pit operations. In 1924, Mount Isa Mines was incorporated, consolidating a number of the major leases and initiating the development of an underground mining operation. Today, ore is sourced from both underground and open pit mines. Copper ore is mined and processed separately from lead and zinc ore. The ore is concentrated by grinding and flotation, followed by smelting. Typically 30% of the combined copper and lead-zinc tailings stream is utilized as hydraulic fill in underground mine operations and the remaining portion is sent to a tailings storage facility (TSF).

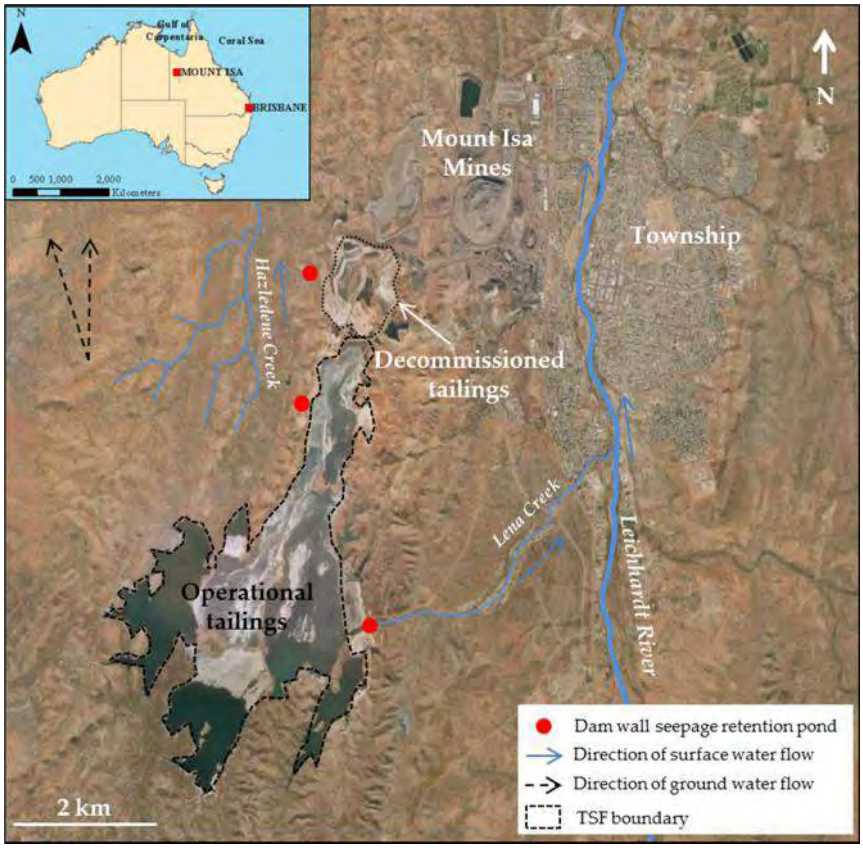

Figure 1 Site locality

The TSF is approximately 14 km² in surface area. The area is contained by three visible dam walls, with a further two dam walls buried under a waste rock dump to the north. Toe seepage emanates from the base of the dam walls at rates of less than 1 to 5 L/s and is captured in retention ponds prior to being pumped back to the TSF. It is characterized by neutral pH (7.3 to 8.2) and elevated sulfate (3100 to 8400 mg/L SO_4), with concentrations of arsenic, boron, cadmium, cobalt, copper, lead, manganese, and zinc slightly elevated in comparison to Australian National Water Quality Guidelines for 95% aquatic ecosystem protection (ANZECC, 2000) and regional surface and ground waters.

The TSF is composed of decommissioned cells to the north, and operational cells to the south (Figure 1). Decommissioned cells were operational from the early 1950s to the mid-1960s. Tailings within the decommissioned cells (hereon referred to as 'decommissioned tailings') have been exposed to approximately 40 years of weathering and exposure. Since decommissioning of the northern cells, tailings have been actively deposited within the operational cells ('operational tailings'). Tailings deposition is cycled through the different operational cells so that the operational tailings sampled by this study had been exposed for less than two years.

This paper discusses the mineralogical and geochemical characterization of the tailings, and the potential release of metals and acidity due to long-term mineralogical weathering.

Climate and Geology

The climate of Mount Isa is semi-arid and subtropical, characterized by average annual pan evaporation (3100 mm) exceeding average annual rainfall (430 mm), and warm to hot temperatures (19 to 32 °C mean monthly minimum and maximum) (BoM, 2012). On average, 75% of annual rainfall occurs between the months of December and March ('wet season') with the intervening months of April to November typified as the 'dry season'.

The Mount Isa Mines' ore deposits are located within the Mount Isa Inlier; an area of more than 50,000 km^2 of Early and Middle Proterozoic rocks host to economically significant quantities of lead-zinc, copper, uranium, cobalt, and gold (Blake *et al.*, 1990). Mount Isa shares some geological similarities to other well-known shale-hosted massive sulfide deposits, such as the Red Dog and Lik deposits in Alaska (Kelley *et al.*, 1995; Kelley and Taylor, 1997), and McArthur River and Broken Hill deposits in Australia (Huston *et al.*, 2006).

A distinct feature of Mount Isa is the occurrence of spatially separate lead-zinc and copper ore bodies. Both occur within the Urquhart Shale, a unit of metamorphosed pyritic and dolomitic shale approximately 1000 m thick at the mine. The main economic sulfides within lead-zinc ore are galena (PbS) and sphalerite (ZnS) with minor amounts of silver occurring in close association with galena. Copper ore principally occurs as chalcopyrite ($CuFeS_2$). The main gangue sulfide is pyrite (FeS_2). The main carbonates are dolomite ($CaMg(CO_3)_2$) and calcite ($CaCO_3$), with ankerite ($Ca(Fe,Mg)(CO_3)_2$) and siderite ($FeCO_3$) also present. Other gangue minerals include quartz, chlorite, K-feldspar, muscovite, biotite, albite, rutile, and carbonaceous material (Heinrich *et al.*, 1995; Chapman, 2004).

METHODOLOGY

Sample Collection

Decommissioned and operational tailings were sampled to less than 1 m depth with the assistance of an excavator, and to depth using a truck-mounted drill rig equipped with a push-in piston sampler. Drill cores were sub-sampled at 1 m intervals from 0 to 3 m below the tailings surface, and at 3 m intervals to bedrock (typically 27.5 m below surface). A total of 20 samples from four locations within decommissioned tailings, and 30 samples from 10 locations within operational tailings were collected.

The selection of sample sites at Mount Isa was ultimately constrained by accessibility. The unconsolidated nature of operational tailings restricted sampling to areas accessible by internal roads that run the length of the TSF. Analytical data were interpreted with supporting information

from secondary sources including aerial photography, ore geology and mineral processing publications, concentrator records, annual Xstrata sustainability reports, and personal communication with long-term mine staff.

Mineralogy

The mineral composition of tailings samples was determined using X-ray diffraction, optical microscopy, Scanning Electron Microscopy coupled with Energy Dispersive Spectroscopy (SEM-EDS), and Mineral Liberation Analysis (MLA). All analyses were undertaken at the University of Queensland.

Static Testing

Tailings were analyzed for acid base accounting (ABA) (AMIRA International, 2002) and elemental composition by four-acid digestion and ICP-MS analysis. Maximum Potential Acidity (MPA) was calculated using sulfide sulfur corrected for non-acid generating forms of sulfide, specifically sphalerite and galena using zinc and lead concentrations, respectively. Acid Neutralization Capacity (ANC) was measured using the Sobek method modified to oxidize and hydrolyze dissolved ferrous iron during the titration step (AMIRA International, 2002). Analyses were undertaken at the University of Queensland and a commercial laboratory (ALS) in Brisbane, Australia. Quality checking and assurance consisted of duplicate, certified reference material, and method blank inclusion in each sample batch.

Column Leaching

Three decommissioned and three operational tailings column samples were extracted from in-situ, near-surface (0 to 1 m depth) deposited tailings. The samples were collected intact with minimal disturbance to stratigraphy by inserting the column tubing housed within a soil corer directly into the tailings profile. The columns were 125 mm in length and 70 mm in internal diameter. The tailings were leached with deionized water supplied under constant head pressure using a Mariotte-type design. A flow rate of 2 to 5 mL/hr was targeted as this allowed the accumulation of leachate sufficient in volume to be collected at least once every two days. The columns were subject to four phases (Figure 2):

a) Saturated leach 1. Deionized water was slowly introduced from the column base over the course of one to two weeks to exclude air from pore spaces while minimizing loss of pore structure from increasing pressure, and then leached under saturated conditions until electrical conductivity showed little variation between collected samples (typically two to three months).
b) Suction and aeration. Drying was induced within the columns by applying suction (-15 to -60 kPa). The concept was to empty pores of water and increase oxygen ingress. Compressed air was fed directly into the tailings via an inlet on the side of each column for a period of one week. This was to encourage oxidation reactions and to hasten the mineral weathering process.
c) Saturated leaching 2. Deionized water was re-introduced in order to mobilize any soluble constituents released as a result of the suction and aeration step.
d) End of leach characterization. A non-reactive tracer test (KCl) was conducted to estimate solute transport parameters. Chloride break-through curve data were modelled using a non-equilibrium dual porosity, Mobile-Immobile Model within Hydrus-1D (Version 4.14) (Simunek *et al.* 2008). Further method detail is provided by Forsyth *et al.* (2013).

Collected leachate was analyzed for pH, electrical conductivity, oxidation-reduction potential, sulfate, chloride, major cations by ICP-AES, and trace elements by ICP-MS. Element release rates (mg/kg/day) were calculated for leach phases 1, 2a, and 2b as shown in Figure 2.

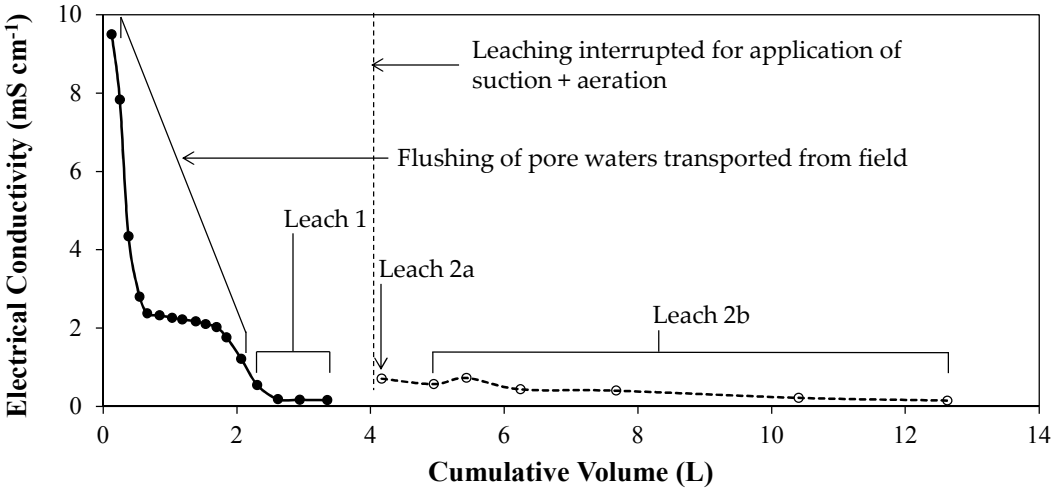

Figure 2 Column leach phases

RESULTS AND DISCUSSION

Tailings Characterization

Mineralogy

Bulk mineralogy was similar between decommissioned and operational tailings. The main minerals were quartz, K-feldspar, chlorite, muscovite, dolomite, calcite, and pyrite. Quantitative XRD showed that operational tailings contained more pyrite (12 to 15 wt. %) and less dolomite (6 to 16 wt. %) than decommissioned tailings (1 to 2 wt. % and 11 to 18 wt. %, respectively). Pyrrhotite, chalcopyrite, galena, sphalerite, ankerite, and siderite were observed in low abundance (less than 2 wt. %) in both tailings types.

Secondary minerals within decommissioned tailings included goethite and gypsum in sub-surface samples, and gypsum, hexahydrite, jarosite, melanterite/rozenite, chalcanthite, and poitevinite in surface samples. SEM-EDS analysis on decommissioned tailings indicated the presence of poorly crystalline iron (oxy)hydroxides, iron oxyhydroxysulfates, and a calcium-iron-silica gel of variable chemical composition. Secondary mineralization in operational tailings was restricted to gypsum.

Acid Base Accounting

ABA classifications were defined using ANC/MPA ratios (Figure 3), with samples forming four groups reflective of their origin within the TSF:

a) Group 1: decommissioned tailings, 0 to 1 m depth below surface. Samples within this group were depleted in ANC (geometric mean 110 kg H_2SO_4/t) and MPA (20 kg H_2SO_4/t) as a result of over 40 years of mineral weathering and exposure.

b) Group 2: decommissioned tailings, 1 to 27.5 m depth below surface. Samples within this group contained high ANC (320 kg H_2SO_4/t) and low MPA (120 kg H_2SO_4/t), and were classified as non-acid forming (NAF) or uncertain.
c) Group 3: operational tailings, 0 to 12 m depth below surface. Samples within this group typically contained less ANC (160 kg H_2SO_4/t) and more MPA (200 kg H_2SO_4/t) than operational tailings below 12 m depth, and were classified as potentially acid forming (PAF) or uncertain.
d) Group 4: operational tailings, 12 to 27.5 m depth below surface. Samples within this group were characterized by ANC (240 kg H_2SO_4/t) intermediate to that of group 2 and 3, and low MPA (120 kg H_2SO_4/t), and were classified as uncertain.

No samples were acidic. Paste pH ranged from 6.0 to 8.0, with group 3 samples at the lower end of the range (pH 6.0 to 7.4).

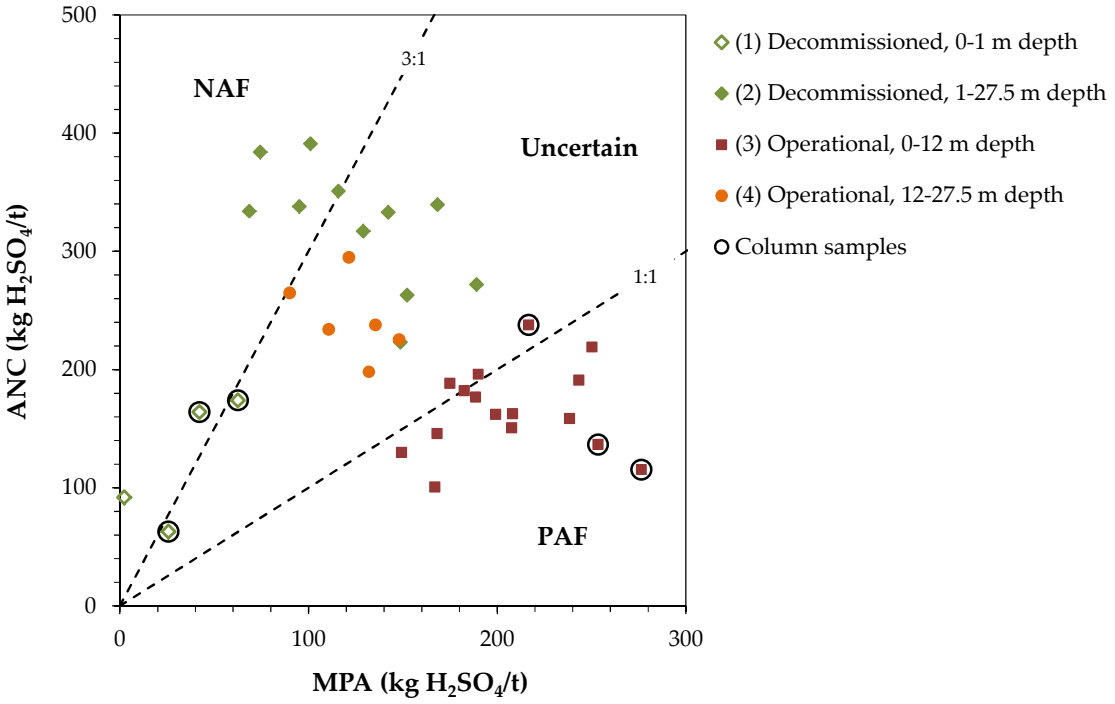

Figure 3 Acid base account plot for decommissioned and operational tailings

Trace Element Analysis

A comparison of decommissioned and operational tailings using a two-sample t-test indicated that operational tailings from 0 to 12 m depth contained significantly ($p \leq 0.01$) greater concentrations of trace elements commonly associated with mineral sulfides, including arsenic, copper, lead, molybdenum, nickel, and zinc (Table 1). Slightly elevated concentrations of some metals were observed in near-surface decommissioned tailings, including copper, molybdenum, nickel, and zinc (Table 1). These metals are likely to occur in association with efflorescent sulfate salts.

Table 1 Element concentrations by four-acid digestion summarized as the geometric mean with minimum and maximum values in parentheses

Tailings Group	As	Cu	Pb	Mo	Ni	Zn
	mg/kg	mg/kg	mg/kg	mg/kg	mg/kg	mg/kg
Decommissioned 0-1 m depth (n = 7)	480 (200, 790)	1900 (1000, 4600)	4200 (3200, 5700)	4 (2, 100)	22 (15, 32)	5500 (4400, 6800)
Decommissioned 1-27.5 m depth (n = 11)	330 (210, 460)	960 (790, 2000)	2800 (1800, 6100)	1 (1, 2)	11 (8, 14)	3700 (2200, 5900)
Operational 0-12 m depth (n = 21)	810 (610, 1400)	2200 (1300, 6100)	5400 (2400, 8500)	26 (3, 220)	26 (19, 35)	8600 (3400,20000)
Operational 12-27.5 m depth (n = 6)	540 (440, 800)	1200 (690, 1500)	4000 (2600, 6600)	2 (2, 3)	16 (12, 22)	4800 (4300, 7100)

Note: All values are reported to two significant figures.

Changes in Mine Operation Influencing Tailings Composition

In comparison to historical tailings, the modern tailings stream at Mount Isa, represented by operational tailings from 0 to 12 m depth, is characterized by higher sulfide and associated trace element content, and less carbonate. Information from secondary sources suggests changes in tailings composition are likely attributable to changes in ore source and processing.

Decommissioned tailings were primarily derived from the processing of shallow copper ore bodies (200, 400, 500 and 600 mRL) which are predominantly dolomitic in composition (Wilde *et al.*, 2006), and lead-zinc ore from the Mount Isa underground mine. In contrast, operational tailings were derived from the processing of deeper, more siliceous copper ore bodies (1100, 1900, 3000 and 3500 mRL), and lead-zinc ore from George Fisher underground and Handlebar Hill and Black Star open pit mines.

The introduction of ore preconcentration and ultra-fine grinding technologies such as the IsaMill allowed the processing of lower grade ores (Gao *et al.*, 2002), which contain more pyrite, and resulted in a finer, higher sulfide tailings stream.

Mineral Reaction Rates

Column Leaching

Leachate pH remained near-neutral throughout the experiment with little difference between the ranges of decommissioned (pH 7.5 to 8.3) and operational tailings (pH 7.3 to 8.4). Major ions were dominated by calcium and sulfate, with leachate from two of the three decommissioned tailings remaining supersaturated with respect to gypsum throughout the experiment.

The columns were characterized by long pore water residence times (15 to 53 hours) and high water retention with 84 to 98% of pores remaining water-filled after the application of -60 kPa pressure. However, this small change in water content in operational tailings was sufficient to increase sulfate, and calcium and magnesium release rates (indicative of sulfide mineral oxidation and acid neutralization, respectively), and release rates for certain trace elements, including manganese, cobalt, and zinc (for example, operational tailings column 2, Table 2). The increase in element release rates from operational tailings was accompanied by a 0.4 to 0.7 unit decrease in leachate pH.

Saturated hydraulic conductivity (Ks) under constant head increased during the experiment (Table 2). In two columns, this was attributed to the formation of fine vertical cracks observed after the application of suction. In other columns, it was attributed to the slow dissolution of soluble phases (particularly gypsum) resulting in more pores contributing to water flow.

Sulfate, calcium, and magnesium release rates were used to calculate rates of acid generation and neutralization, whereby:

$$\text{Sulfide oxidation rate (kg } H_2SO_4\text{/t/day)} = SO_4 \text{ production rate (kg/t/day)} \times \frac{98.08}{96.06} \quad \textbf{(1)}$$

$$\text{ANC consumption rate (kg } H_2SO_4\text{/t/day)} = \text{sulfide oxidation rate (kg } H_2SO_4\text{/t/day)} \times \frac{[Ca\ (mol)+Mg(mol)]}{SO_4(mol)} \quad \textbf{(2)}$$

Leachate solutions saturated and/or supersaturated with respect to gypsum were excluded from the calculations.

A comparison of the calculated rates (Table 3) indicated that ANC would likely be consumed before the acid-generating sulfides in operational tailings 1 and 2 under all test conditions, which supports a PAF classification. Conversely, ANC was unlikely to be consumed before the acid-generating sulfides in decommissioned tailings, which supports a NAF classification. Operational tailings 3 were classified as uncertain using static ABA. Kinetic testing suggests this sample has the potential to become acid generating if conditions were to remain unsaturated and highly oxidizing.

CONCLUSIONS

Modern tailings at Mount Isa are characterized by higher sulfide and associated trace element content, and lower carbonate mineral content than historical tailings. Changes in tailings composition are likely attributable to changes in ore and mineral processing methods, and time since tailings deposition.

Strategies are currently being developed for placement of a suitable cover system to reduce surface water – tailings interaction following decommissioning of the TSF. It is anticipated that covering the surface tailings would potentially limit the accumulation of efflorescent sulfate salts on the tailings surface, which if allowed to accumulate, would be subject to dissolution and transportation during wet season rain events. Infiltrated water that passes through the oxidation zone is expected to be readily neutralized by ANC in the tailings below. Modification of the final tailings layer prior to deposition to remove or pacify pyrite could also potentially be considered as an alternative to a suitable cover system.

Table 2 Element release rates from operational tailings column 2

Leach Phase[a]	Water Content	pH	SO_4	Ca	Mg	Mn	Co	Zn
	cm^3/cm^3		mg/kg/day	mg/kg/day	mg/kg/day	mg/kg/day	mg/kg/day	mg/kg/day

Investigation of Pore Gas Oxygen and Internal Temperature in a Waste Rock Dump, Antamina Mine, Peru

Maria Eliana Lorca, Ulrich Mayer and Roger Beckie
Department of Earth, Ocean and Atmospheric Sciences, University of British Columbia, Canada

ABSTRACT

Sulfide mineral oxidation in waste rock dumps tends to increase internal temperatures and may lead to oxygen depletion. The objective of this study is to address how waste rock heterogeneity affects dump-internal gas and temperature distributions. Waste rock dumps built by end dumping are characterized by a high degree of grain size segregation, where coarse rock fragments rest at the bottom, and smaller particles remain near the surface. Due to truck traffic, the fine-grained material located near the surface is compacted. In addition, chemical heterogeneity, in particular sulfide content, also affects internal reactivity and oxygen demand. A drilling program was initiated at Antamina to investigate pore gas and temperature distribution within one of the operating dumps. The investigated dump is 400 m tall and the material is geochemically highly heterogeneous, containing waste rock composed of skarn, hornfels, marbles and intrusives. Two sites where drilled: At Site 1 a shallow borehole was completed, and at Site 3 a shallow and a deep borehole were completed. The sulfur content of the drilled material showed a high degree of chemical heterogeneity with depth; the average sulfur content is 2.5%, but some of the intervals present sulfur content higher than 10%. A thermistor string and oxygen probes were inserted in the boreholes for monitoring of in-situ sulfide mineral oxidation. Areas of increased reactivity (elevated temperature and low pore gas oxygen) correspond to intervals of waste rock with high sulfur content. Regarding the overall reactivity, Site 1 is warmer than Site 3 and shows a higher degree of oxygen depletion. The nature of temperature and oxygen profiles in the deep borehole (Site 3) indicates the presence of reactive hotspots and complex pore gas and pore water migration patterns. These results highlight the role that physical and chemical heterogeneities have on waste rock reactivity.

Keywords: Waste Rock; Oxidation; Heterogeneity, Heat Generation

INTRODUCTION

In this study we investigate the effect of waste rock heterogeneity on dump-internal oxygen concentration and temperature distributions. Sulfide mineral oxidation in waste rock dumps increases internal temperatures, due to the exothermic nature of the sulfide mineral oxidation, and reduces oxygen concentration in the pore gas with respect to atmospheric levels.

Waste rock dumps built by end dumping are characterized by a high degree of grain size segregation, where coarse rock fragments rest at the bottom, and smaller particles remain near the surface (Smith and Beckie 2003; Amos et al. 2014). Due to truck traffic, the fine grained material located near the surface is compacted. (Lefebvre et al. 2001; Amos et al. 2014; Wels, Lefebvre, and Robertson 2003). Laboratory reactivity studies have shown that pyrite oxidation is higher with decreasing particle size (Stromberg and Banwart 1999; Hollings et al. 2001).

In addition, chemical heterogeneity, in particular sulfide content of the dump also affects internal reactivity and oxygen demand. Everything else being equal, zones of the dump where the sulfide minerals are abundant will present increased reactivity, elevated temperature and lower oxygen concentration.

The ingress of fresh air from the atmosphere brings oxygen to supply the reaction. This air can be drawn into the dump by advection/convection due to pressure and/or temperature gradients, but diffusion will also supply oxygen in presence of concentration gradients. Wels et al. (2003) provide an overview of gas flow in waste rock dumps. The main processes are depicted in Figure 1.

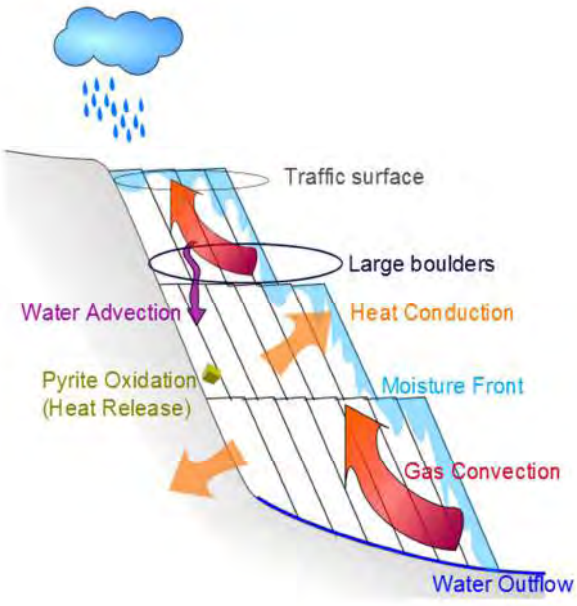

Figure 1 Conceptual model of the processes affecting oxygen transport within waste rock dumps.

Boreholes provide an opportunity to monitor the interior of waste dumps. Borehole construction is difficult and expensive, often limiting installation possibilities. In the past, some waste rock dumps and coal spoils have been successfully drilled, instrumented and monitored (Harries and Ritchie 1981; Lefebvre et al. 2001; Milczarek et al. 2009).

The traditional model of waste rock dump weathering considers that the oxidation processes occur in the exterior of the piles, whereas the interior stays oxygen deprived (Ritchie 2003). Numerical models show that bulk convection can occur in some dumps, where sulfide oxidation rates are high and permeability and diffusion are enhanced, allowing the ingress of oxygen deep into the dump.

METHODS

Site Description

The Antamina mine is located approximately 270 km northeast of Lima, Peru in the department of Ancash. It is located in the high Andes, at an elevation ranging between 4200 and 4700 m.a.s.l. There are two marked wet and dry seasons, the annual precipitation ranges between 1200 and 1500 mm, and the average annual temperature ranges between 5.4 and 8.5°C (Harrison et al. 2012).

Antamina is a polymetallic skarn deposit. It produces copper, zinc, and molybdenum concentrates, and silver and lead concentrates as by-products. The intrusion that produced the mineralization is hosted in sedimentary carbonate sequences (Love, Clark, and Glover 2004). There are five major lithologies in the mine: intrusive, skarn, hornfels, marble and limestone.

Drilling and Instrumentation

A drilling program was initiated at Antamina in conjunction with UBC to investigate pore gas and temperature distribution within one of the operational waste dumps. The investigated dump is 400 m tall and the material is geochemically highly heterogeneous, containing waste rock composed of skarn, hornfels, marbles and intrusives. A photograph of the dump with the location of the boreholes is shown in Figure 2. Two sites where drilled: At Site 1 a shallow borehole was completed, and at Site 3 a shallow and a deep borehole were completed 10 m apart from each other. The two sites are 1 km apart.

The boreholes were drilled with a percussion hammer (Casagrande C3 drill rig). The samples were retrieved by reverse air circulation using a cyclone, and there was neither use of drilling lubricants nor water. Casing was advanced using approximately 2 m lengths of welded steel casing. The percussion hammer breaks the rocks into smaller pieces therefore the particle size distribution of the samples is not representative of the deposit.

Solid phase analysis and ABA testing was done at ALS Peru. In this paper we present data on sulfur content. Analysis of secondary minerals for selected intervals of boreholes from site 1 is presented by Laurenzi el al. (2015).

After the borehole drilling was completed the instrumentation was installed in the borehole by attaching it to a central pipe (steel for the deep borehole and PVC for the shallow ones). A Geokon thermistor string and KE-50 Figaro oxygen probes were inserted in the borehole for monitoring of in-situ sulfide mineral oxidation.

Figure 2 Drilling sites. Arrows point to the monitoring borehole sites

To complete the installation, the borehole was backfilled with either silica sand/gravel, waste rock or bentonite using a tremie pipe. Each interval of the casing was retrieved one meter at a time during backfilling. Bentonite intervals were wetted with water to ensure proper sealing. The sensors were surrounded with material selected to optimize data collection, in the case of the oxygen readings, the probes were surrounded with quartz pea gravel.

Limitations

The construction of the boreholes was more difficult than initially anticipated. The height of the Antamina dump, the drilling method and the wide range in material size posed challenges for the successful completion of the installation. In particular, a deep borehole was considered to be included on site 1, but because of the difficulties this borehole was not completed at the time. The site 3 deep borehole has 2 sections of trapped casing underground (25 – 45 m and 100 – 120 m). These sections could not be brought back to the surface because the welds broke at the moment of casing retrieval.

RESULTS AND DISCUSSIONS

The sulfur content of the drilled material showed a high degree of heterogeneity with depth; the average sulfur content was 2.5%, but some of the intervals presented sulfur content up to 20%. The distribution of high sulfur content intervals is random, linked to the original lithology of the deposit. At Antamina, the abundance of carbonate rocks leads to acid-base-accounting (ABA) results that are mostly indicative of neutral drainage conditions, with a few exceptions in the high sulfur intervals.

The deep and shallow boreholes on site 3 (BH3d and BH3s respectively) show moderate oxygen depletion (i.e., about 10%-15% O_2) whereas the shallow borehole from site 1 (BH1s) shows steadily declining oxygen concentrations with depth to almost complete depletion at 20m depth (Figure **4**).

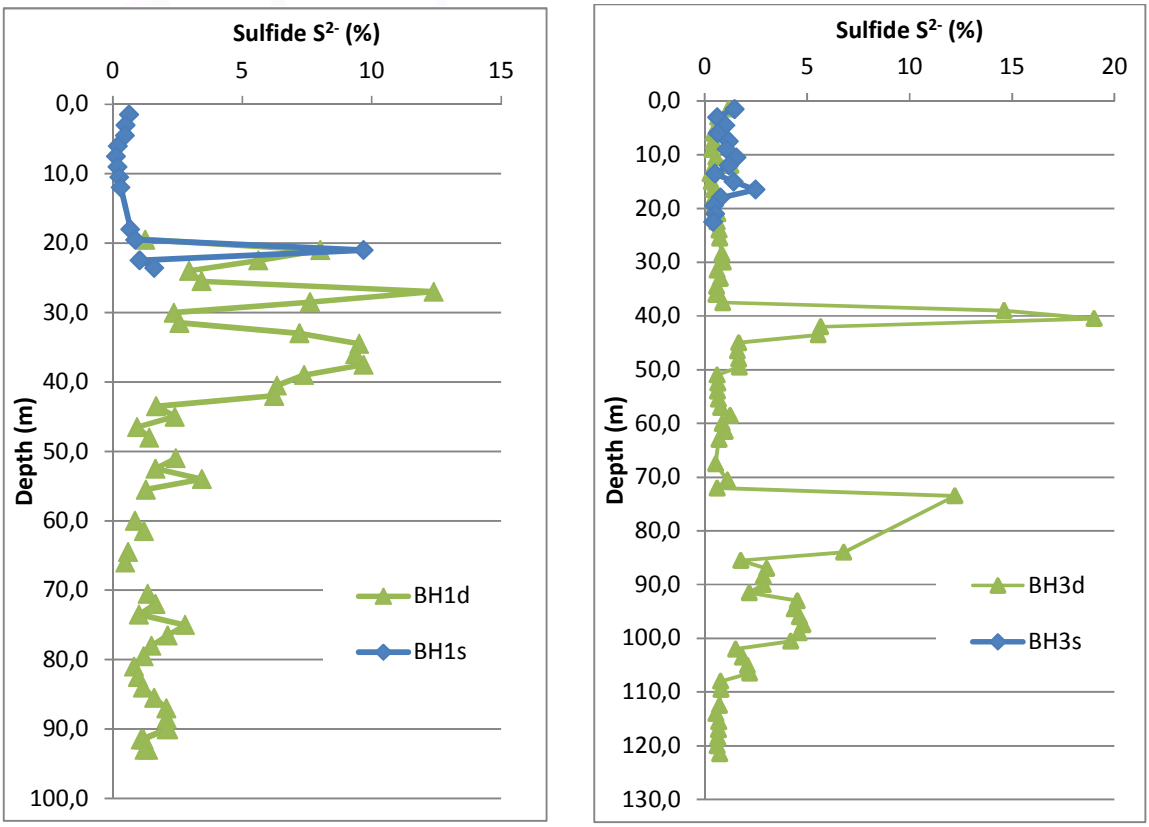

Figure 3 Sulfur content of the solid phase samples

Site 1 is warmer than Site 3, shows a higher degree of oxygen depletion and presents several intervals with higher than average sulfur content which could explain the increased reactivity. Nevertheless, higher overall sulfur content is observed in specific intervals at Site 3, .

The deep hole at Site 3 shows an increase in temperature at 40 m depth and then a decrease at 65 m. The same pattern is repeated at the bottom of the borehole. The lower temperature zones are correlated with the base of the lifts on which the dump was constructed. These zones are presumed to be a result of the lower reactivity of the boulders that rest at the base of each lift.

Waste rock dumps built by end dumping are segregated with coarse material resting the bottom, producing high permeability areas for oxygen ingress, similar to what Wels et al. describe as the "chimney effect". In the case of the borehole BH3d it is observed that O_2 content is higher in the location where coarse fragments are located (60-70 m), but rapidly decreases again in the new lift, where it is expected that fine material is present, but also there is an increase in sulfur content at 75 m.b.g.s.

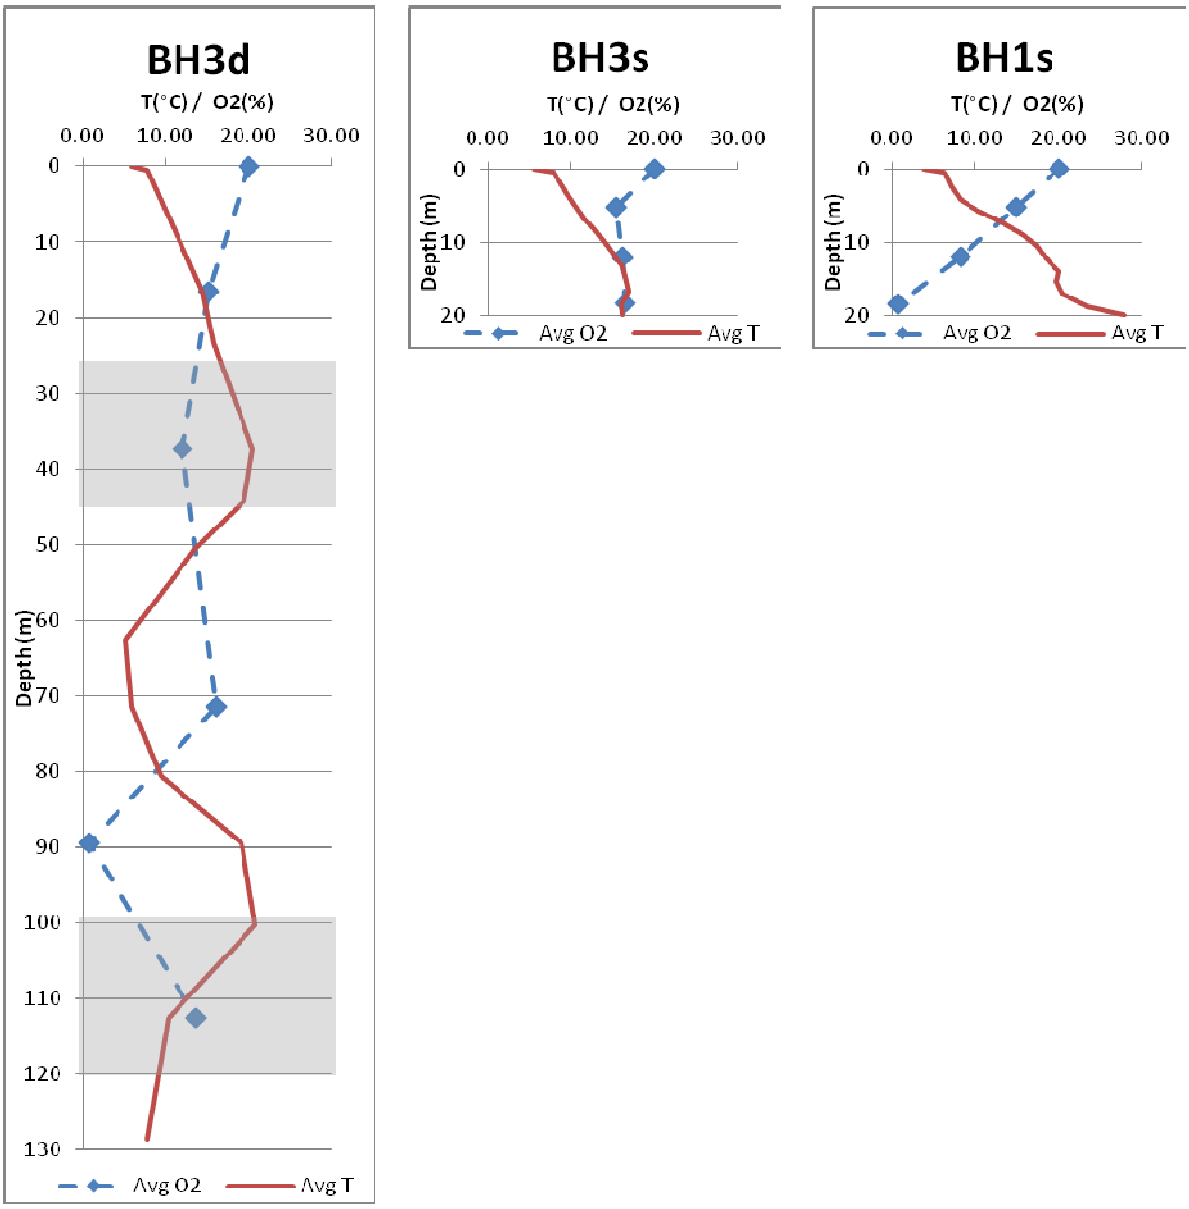

Figure 4 Average O_2 and T profiles for the boreholes. The shaded areas for BH3d represent the trapped casing

When oxygen is supplied by 1D-diffusion only, the oxygen concentration at depth can be solved analytically (Ritchie and Miskelly, 2000):

$$u(x) = \frac{\cosh(\varepsilon(x-1))}{\cosh \varepsilon} \tag{1}$$

$$\varepsilon = \sqrt{\frac{h^2 S_o}{D C_o}} \tag{2}$$

$$X_l = \sqrt{\frac{2 D C_o}{S_o}} \tag{3}$$

where u is the oxygen concentration as a function of $x = z/h$, z is the depth, h is the height of the pile, S_o is the intrinsic oxidation rate, D is the effective diffusion coefficient, C_o is the oxygen concentration at the surface and X_l is the diffusion length. The oxygen concentrations expected using these equations are shown in Figure 5.

The oxygen concentration profiles differ from an expected diffusion profile, and this could be explained because of either heterogeneity leading to complex diffusion patterns in three dimensions or gas migration processes other than diffusion, namely convection/advection. The isolated zones of high temperatures and low oxygen in the deep borehole (Site 3) indicates the presence of reactive hotspots and complex pore gas migration patterns that are not consistent with 1D-diffusion as explained by Ritchie and Miskelly (2000).

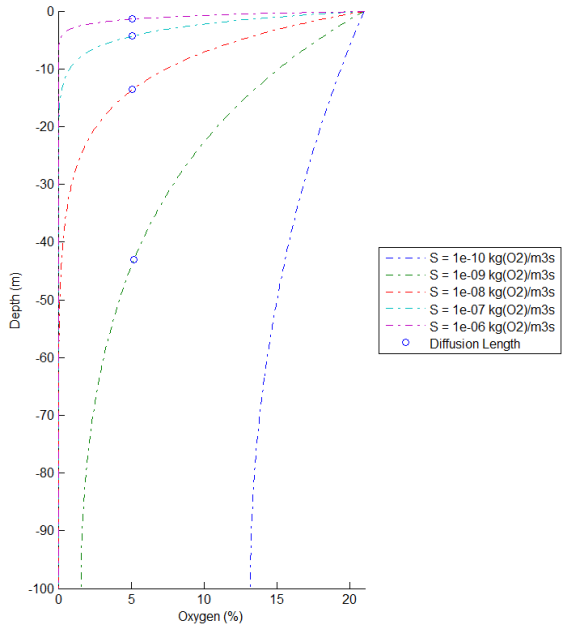

Figure 5 Expected oxygen concentration profiles for varying range of intrinsic oxidation (S) in a hypothetical 100 m tall dump considering homogeneous oxidation rate and 1D-diffusion as the only oxygen supplying mechanism

A previous study in an 10 m high experimental waste rock pile at Antamina showed decreased oxygen concentration down to 7% (Singurindy et al. 2012). The temperature increase at the experimental pile scale was up to 13.3 °C. It was observed at the experimental pile scale that the zones of greatest oxygen depletion were well correlated with the traffic surface, whereas at the operating dump scale zones in the interior of the dump show the highest degree of oxygen depletion. The experimental pile material is comprised of sulfur up to 4.6% which is lower than the high sulfur intervals of the dump.

Based on these results, the chemical and physical heterogeneity play important roles in the oxygen demand and distribution within waste rock dumps. Other factors, such as moisture content will affect fluid transport; increasing moisture content limits the ingress of fresh air into the dump by decreasing the air permeability and diffusivity.

CONCLUSIONS

We measured oxygen concentration and internal temperature within an operational waste rock dump. There is evidence of sulfide mineral oxidation at the two investigated locations. Areas of increased reactivity (elevated temperature and low pore gas oxygen) corresponded to intervals of waste rock with high sulfur content. Oxygen content and temperature were highly variable within the investigated dump, inconsistent with a 1D-diffusion – dominated system. The nature of temperature and oxygen profiles indicates the presence of reactive hotspots and complex pore gas and pore water migration patterns. It is often conceived that gas distribution in waste dumps is relatively smooth. This might be the case in relatively homogeneous dumps, however we show that in the presence of geochemical and physical heterogeneity this conventional view is not applicable. Because of the variability of waste rock, we recommend site-specific investigations.

ACKNOWLEDGMENTS

We thank Laura Laurenzi and Mehrnoush Javadi from UBC. The design of the boreholes and instrumentation was developed in conjunction with GeoSystems SA. We appreciate the support provided by Bevin Harrison, Celedonio Aranda, Edsael Sanchez, Bartolome Vargas, and Haydee Aguirre from Antamina. The funding for this project was provided by Compañia Minera Antamina.

Comparison of Pre-Mining Geochemical Predictions to Operating Conditions for New Afton Tailings

Emily O'Hara and Scott Davidson
New Afton Mine, Canada

ABSTRACT

New Afton is a block cave mine that sustains processing of an average of 14000 tonnes per day of ore. The mine produces an average of 80,000 ounces of gold and 750,000 pounds of copper annually over a 12 year mine life. New Afton is located near Kamloops, BC which is hosted by a grassland ecosystem classified as semi-arid, with annual average precipitation of 305mm and evaporation of 608mm.

Prediction of acid rock drainage (ARD) and metal leaching (ML) for tailings supernatant and leachate is typically carried out early in the permitting process when access to tailings samples is often limited to those generated from metallurgical testing programs which often do not reflect the range of geological conditions that are present in an ore body or surrounding waste rock. Early prediction of potential effects, is essential to ensure mitigation programs can be effectively developed and implemented. New Afton has a variety of practices available to understand and control potential effects of ARD or ML. With 2 years of operating conditions, comparisons are now being carried out to reflect on the predicted versus actual conditions. This paper examines the comparison of pre-mining geochemical predictions with actual observed conditions while also commenting on some of the challenges in linking the two.

The New Afton ore body is classified as having low acid generating potential, with a high neutralizing capacity. The predicted Net Neutralizing Potential (NNP) for tailings samples is between 177 and 263 tCaCO3/1000t, with paste pH between 8 and 8.6. Predicted tailings supernatant ranged between 7.85 and 9.28 and actual supernatant at the Tailings Storage Facility (TSF) has ranged between 7.83 and 9.79, over the last 2 years of operation. Additional tailings samples have been taken based on "actual" conditions, and humidity cell tests (HCTs) are in progress to determine the variability between the pilot plant samples. The two original humidity cells generated from metallurgical testing have been running for 6 years with no evidence of acidic conditions and pH results between 7.81 and 8.33. However, humidity cells, and tailings supernatant indicate that low level metal leaching may occur under neutral or high pH conditions.

Keywords: Tailings, Permitting, ARD, ML

INTRODUCTION

New Afton is located approximately 10km west of Kamloops in British Columbia, on the historic Afton Mine site. Kamloops is approximately 350km North East of Vancouver. The site is within the Interior Plateau region of British Columbia that lies in the rain shadow of the Coastal Mountains (Rescan, 2007). Precipitation in this area is very low, on average receiving 305mm per year with annual evaporation rate of 608mm (Environment Canada, 2014). The New Afton site is zero discharge, with all runoff being contained onsite. New Afton uses the "block cave" mining method.

The New Afton ore body is an alkalic porphyry copper-gold deposit comprised predominately of hypogene mineralization, with lesser amounts of supergene mineralization and intermediate mesogene mineralogy located in upper elevations of the deposit. The hypogene type ore has constituted over 85% of the mill feed to date, as the block cave mining sequence extracts ore from the lower levels of the current mining lift. The proportion of mesogene ore and supergene ores has gradually increased, as ore from higher levels in the block cave are extracted.

Pyrite is the main sulphide gangue mineral with the concentration of up to 0.5% in hypogene ore. Mesogene samples include higher proportion of carbonates (13% compared to 2-3% for the other ore types). A pyrite "halo" surrounds the ore zone, with sulphur values ranging between 0.02% and 8.1% (Rescan, 2006). Arsenic mineralization in the ore is found to be primarily tennantite with some tetrahedrite, and only trace amounts of arsenopyrite.

New Afton does not suffer from significant ARD/ML issues due to three main factors; low precipitation, low acid generating capacity and high neutralizing capacity. The block cave mining method does not generate significant waste rock, and all waste rock bought to surface is disposed of in the old Afton Pit. As waste rock generation is low, and disposal is fully controlled, the primary geochemical focus is acid rock draining and metal leaching (ARD/ML) potential of the tailings. While ARD potential for the tailings is very low, some metal leaching has been seen to occur at neutral or higher pH.

Tailings Dam Design

The New Afton tailings storage facility (TSF) is made up of five dams. Two dams were constructed at final elevation, and three were constructed as started dams to be raised throughout the mine life. The three construction dams use the centerline method of dam construction. New Afton also has the ability to use Pothook Pit for tailings deposition. Seepage ponds are located at the base of each of these dams, with pumping capacity to return water to the tailings impoundment.

The relevance to TSF design to geochemistry is the use of tailings sands as construction material. Raw tailings are processed using cyclones to produce a not acid generating (NAG) construction sand. Should the tailings be considered potentially acid generating (PAG), this method of construction would be less appropriate.

TESTING PROGRAM

Tailings geochemical prediction often has significant limitations primarily due to the availability of representative tailings samples. During the early stages of permitting and economic assessment, tailings samples are generated as part of metallurgical, laboratory based, pilot plant testing programs to determine which mill flow sheet will provide the best results. These tests are designed

based on expected geological conditions and availability of core samples and may be designed and conducted in a fashion that does not reflect the proposed process. It is the remains from this test work that is then available for predictive testing.

Tailings Geochemistry Tests

Static Tests

Three samples based on ore type were selected for static acid base accounting (ABA) testing during the permitting process. The three samples were based on the three ore types, mesogene, hypogene and supergene with the results being demonstrated in Table 1.

Table 1 Historic Laboratory and Pilot Plant Tailings Samples

	Static Tests Only			Static and HCTs	
	JUN 20-06 LCT Hypogene Tails	**JUN 21-06 LCT M2 Mesogene Tails**	**JUN 22-06 LCT MS1 Mesogene/Supergene Tails**	**Tails Rougher 2092P6**	**Tails Final 2092P6**
Paste pH	8.3	8.2	8.3	8.6	8.5
%S (Total)	0.15	0.18	0.12	0.52	0.42
%S (Sulphide)	0.13 (Calc)	0.14 (Calc)	0.11 (Calc)	0.33	0.27
%S (Sulphate) Carbonate Leach	0.01	<0.01	0.02	0.02	0.05
%S (Sulphate) HCL Leachable	0.02	0.04	0.01	0.02	0.01
Measured NP (kg $CaCO_3$/t)	57	269	193	267	276
SNNP (kg $CaCO_3$/t)	53	264	190	252	264
SNPR	15.2	53.8	61.8	17.6	22.3
As ppm	5.6	37.2	64.7	1090	772
Cu ppm	1055	1650	2210	7890	6380
Se ppm	1	1	1	4	4

As per ore quality at New Afton, the tailings samples have been shown to be heavily neutralizing with the potential for acid generation being very low. Most of the Bulk NP is likely associated with the carbonate-based minerals, based on CaNP levels (Rescan, 2007).

Follow-up Static Tests

The mine permit for New Afton does not contain any geochemical monitoring program requirements for tailings. Since operation of the TSF began only 5 static samples have been taken in order to provide more representative data for the composite tailings. The grab sample program will continue throughout the life of mine to ensure continued understanding of tailings conditions. Samples will be selected based on mill feed characteristics. The ore feed is a blend of the 3 primary

types so the collection of blended samples will provide a better understanding of actual conditions than analyses run on pure ore materials.

Se ppm	1.41	1.46	1.33	1.01	1.15

The ore type is predominately hypogene, however concentrations of each ore type will vary throughout the mine life. Table 3 shows the mill feed by ore type for April to August 2014 to illustrate the current level of variability. BCKGR is partially mineralized ore, and is treated as hypogene for processing requirements.

Table 3 Ore Composite by Type April – August 2014

	Tons	**Supergene**	**Hypogene**	**Mesogene**	**BCKGR**
April 2014	366,941	2.2%	75.9%	8.9%	13.0%
May 2014	392,151	2.5%	74.2%	8.1%	15.3%
June 2014	380,528	2.2%	73.9%	8.1%	15.9%
July 2014	400,030	1.8%	76.5%	8.8%	12.9%
August 2014	413,887	1.4%	75.4%	9.1%	14.1%

Figure 1 shows the expected mill feed as a function of ore type over the life of mine. It can be seen that the relative portion of mesogene and supergene ore increases later in the mine life.

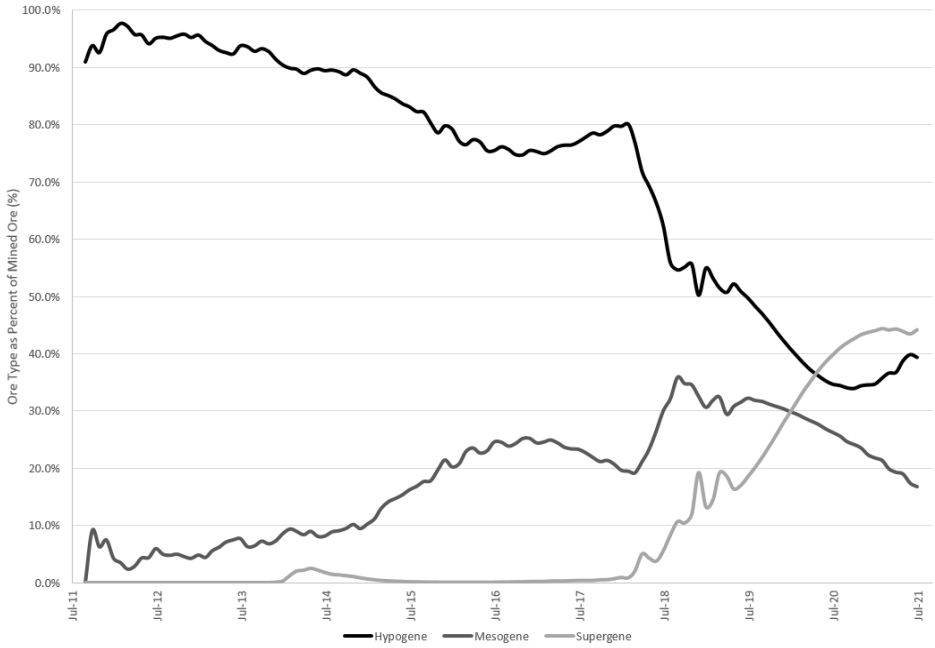

Figure 1 Mill Feed by Ore Type over Life of Mine

Initial Kinetic Tests

New Afton started two humidity cell tests (HCTs) on the 29th May 2008. Initial characterization results are shown above for the two HCTs in Table 1. The two samples were generated during two stages of a pilot plant, rougher and final tails (Rescan, 2012a) and these tests have been running for 329 weeks. The samples for the HCT tests were generated from mesogene ore material. Hypogene ore was also selected for pilot plant testing, however it is believed that there was not enough sufficient tailings produced from this ore type to allow for kinetic testing. Table 4 demonstrates the mineralogy of the tailings samples. No arsenic or antimony bearing mineral phases were identified in these mesogene tailings samples by Rietveld X-Ray Diffraction (XRD), however tennantite and tetrahedrite are considered the main contributing arsenic compound in mesogene ore (Rescan, 2012b).

Table 4 Rietveld X-Ray Diffraction Mineralogy for Tailings Humidity Cell Tests

Mineral	Ideal Formula	2092P6 Final Tls Sands	2092P6 Ro Tls Sands
Dolomite (wt.%)	$CaMg(CO_3)_2$	32.6	32.6
Muscovite, total (wt.%)	$KAl2AlSi_3O_{10}(OH)_2$	21.4	22.3
Plagioclase (wt.%)	$NaAlSi_3O_8$-$CaAl_2Si_2O_8$	18.3	17.2
Quartz (wt.%)	SiO_2	16.9	16.3
K-feldspar (wt.%)	$KAlSi_3O_8$	6.1	6.5
Kaolinite (wt.%)	$Al_2Si_2O_5(OH)_4$	3.4	3.6
Calcite (wt.%)	$CaCO_3$	1	1
Anatase (wt.%)	TiO_2	0.5	0.5

A secondary issue with the samples taken for initial HCT tests is that the feed sample was not representative of witnessed feed grade since operation, even considering mesogene ore feed. The feed grade in the pilot plant test was approximately 2% copper, which is around double what has been seen on average. The tails grade was also disproportionately high, as the pilot plant was targeting a specific concentrate grade not attempting to optimize recovery. This has resulted in elemental content of tailings being higher than average feed grade. For example, the As values for the tails used in the HCTs was 1090 ppm and 772ppm, whereas for 2014 the As values in Final Mill tailings (FTML) ranged between 7.4ppm and 58.5ppm. These are not seen as an error in sample collection, but a challenge when dealing with limited sample availability.

Due to low sulphur content and high neutralization potential, these HCTs were not expected to become acid generating. Metal leaching rates were not predicted for these samples. Figures 2, 3 and 4 demonstrate pH, arsenic and copper results seen for the two original tailings HCTS. While other metal concentrations have been decreasing, arsenic values have been increasing since week 258. It is believed that this increase could be the result of cleaning of fines that had accumulated under the screen which were then placed back on top of the solid sample. A spike in arsenic was also seen at a similar time in some waste rock cells following similar cell maintenance.

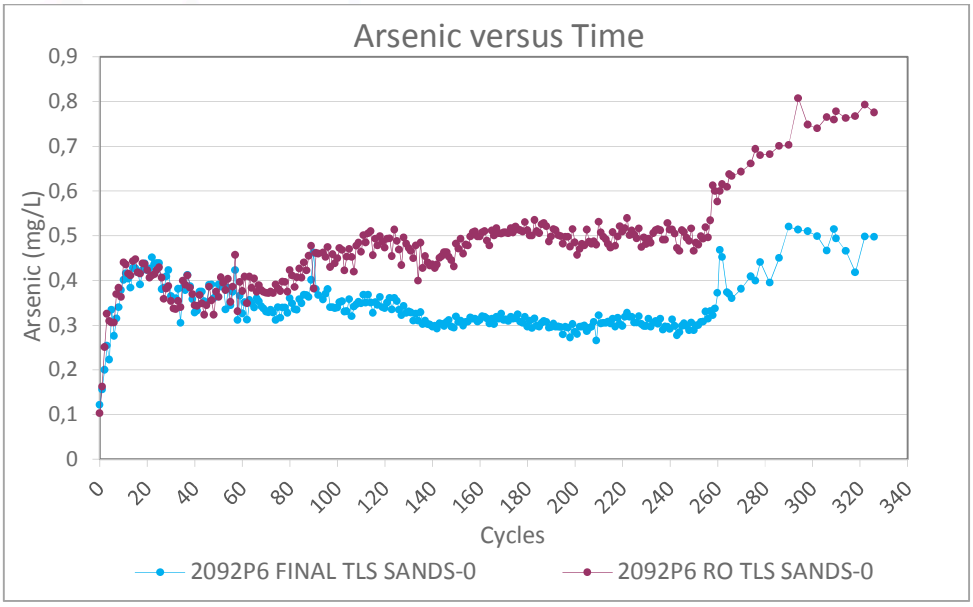

Figure 3 Pre-Operations HCTs Arsenic vs Time

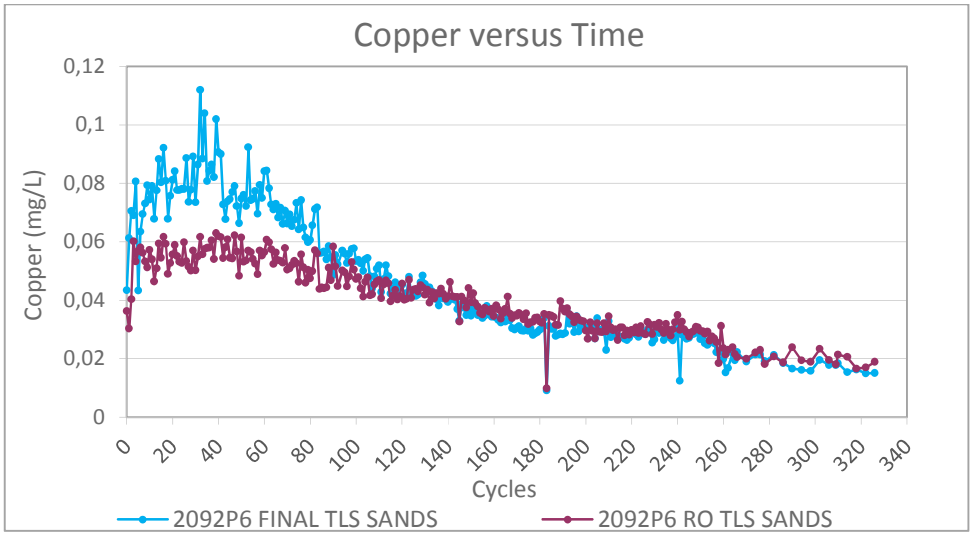

Figure 4 Pre-Operations HCTs Copper vs Time

Secondary Kinetic Tests

In the second quarter of 2014, a weighted composite of tailings was collected for Final Tailings (FTML), Secondary Tailings Underflow (STUF) and Secondary Tailings Overflow (SCOF). FTML is the total tailings that is sent from the mill to the TSF, STUF is the tailings sands that are used for dam construction, and SCOF is the fine slimes that are sent to the center of the TSF. This composite was collected over a 4 month period, in order to obtain required weights of samples for humidity cell testing.

There is currently not sufficient data to estimate time to ARD onset with the new humidity cells, as high loadings of sulphate is being exhibited due to initial flushing. The secondary humidity cells are intended to be continued throughout the life of mine. Additional HCT testing will be initiated later in the mine life when there is a higher portion of mesogene and supergene ore in the mill feed as these will reflect the final tailings produced during the mine.

Tailings Water Quality Tests

TSF water quality is of significant interest to regulators, and local communities of interest. While the water contained in the TSF is reused within the milling process, and the water is understood to be contaminated, monthly monitoring is carried out to ensure a good understanding of this water quality.

Laboratory Supernatant Analysis

Both fresh and 7-day aged supernatant analysis was carried out for the lock cycle test bulk tailings samples for hypogene tails, mesogene tails and a mesogene/supergene blended tails. A sample of these results are shown in Table 5.

Table 5 Lab Tested Tailings Supernatant Results and Actual New Afton TSF Supernatant

Monthly Water Quality Samples

New Afton monitors tailings supernatant monthly as per permit requirements. Table 5 shows monthly averages when compared against the laboratory supernatant tests. pH at the TSF has ranged between 7.83 and 10.4. Higher pH results are likely associated with lime that is added to the mill process, rather than neutralization that is occurring. The major difference between the laboratory and field tests has been conductivity and sulphate. Figure 5 and Figure 6 demonstrate the pH, conductivity, sulphate and alkalinity results seen at the New Afton TSF since operation commenced.

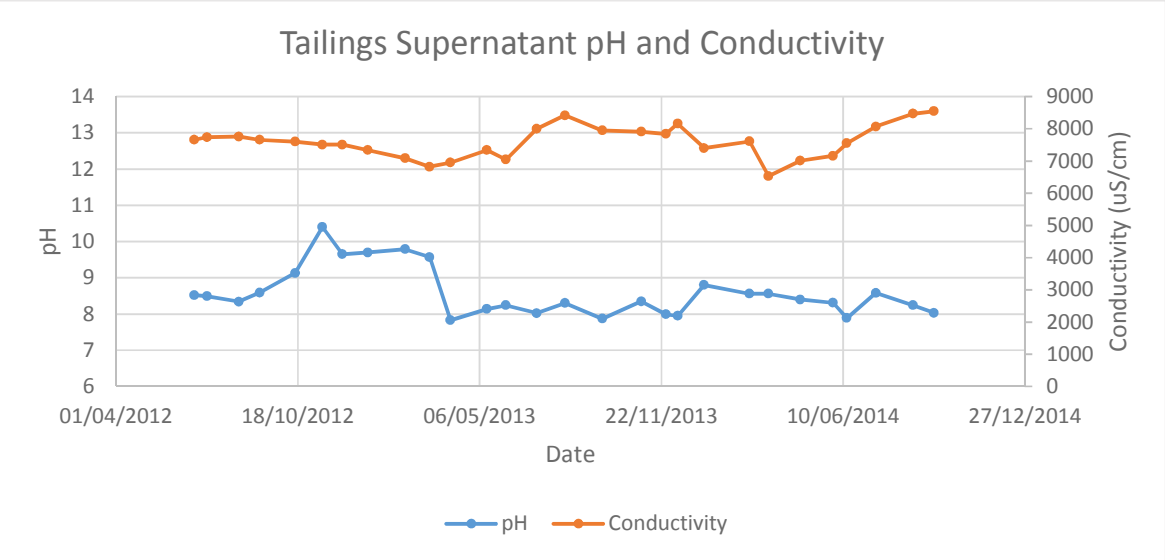

Figure 5 Actual Tailings Supernatant pH and Conductivity

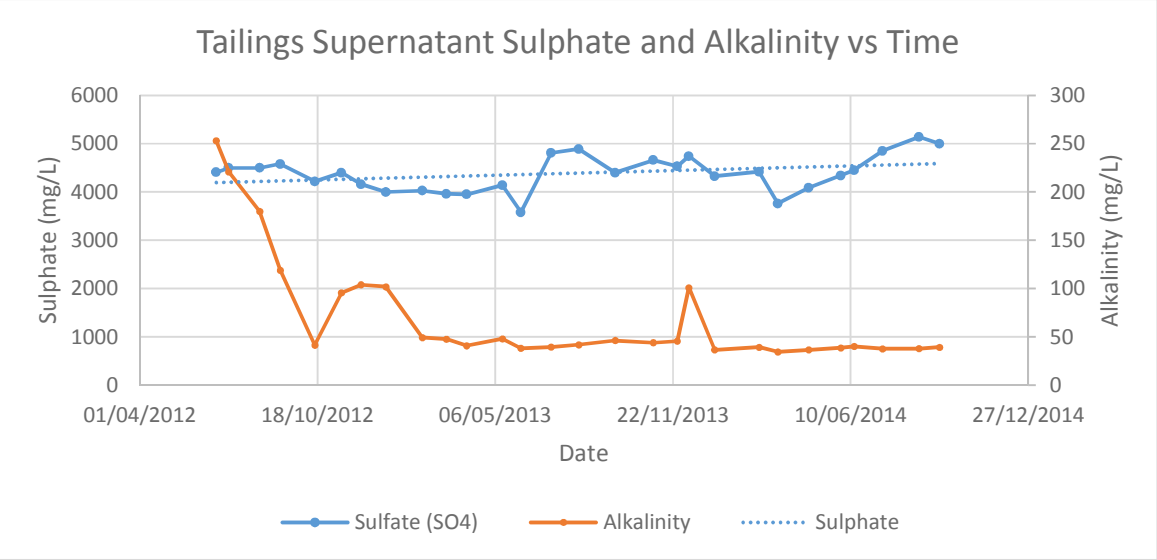

Figure 6 Actual Tailings Supernatant Sulphate vs Time

RESULTS AND DISCUSSION

Overall, kinetic, static and supernatant test results indicate that New Afton should not expect tailings to become acid generating, or have significant issues with ML. Both lab and mill produced tailings demonstrated low acid potential and high neutralizing potential, which was expected based on ore properties. The pre-operation humidity cells are an outlier in comparison to other test results with respect to elemental content.

Operational characterization programs have been developed in order to ensure that there is adequate characterization of the tailings that are being produced over the life of mine. The development of these operational characterization programs is important given with the need to validate or refute the representative nature of the pre-mining characterization samples.

Humidity Cell Results

Humidity cells to date indicate neutral pH and generally low metal loadings. BC Fresh Water Aquatic Life (BCFWAL) concentration guidelines have seen exceedances for antimony, arsenic, copper and selenium. Metal loadings have generally been decreasing throughout testing, however arsenic has seen increasing concentrations since week 250. The samples used in these HCTs, as provided by the pilot plant do not represent actual conditions, with As values in the Final Tails pilot plant sample being greater than 10 times the maximum seen during 2014 operations when the mill feed was primary hypogene ore.

It is expected that these samples were used for HCTs, as no other testing would provide sufficient sample weight to run HCTs. However, there was no documented discussion during permitting or reporting regarding the appropriateness of these samples, so it cannot be determined if these anomalies were picked up prior to initiating the tests.

It is expected that the metal leaching that is occurring under neutral pH is associated with these high metal concentrations and has not been identified as a risk to operation or closure of the New Afton TSF. As results are received for the operating tailings HCTs, it is expected that metal loadings will be lower than those seen in the pre-operations test results.

Tailings Supernatant

It is expected that differences in tailings supernatant results can be explained by the addition of lime in the milling process, processing of the historic Teck Ore Stockpile, and the circulating loads due to the reuse of process water. Lime addition was not included in pre-testing, as it was not expected to be required. This lime addition would contribute to the increased conductivity seen in the supernatant water. The added lime also results in the suppression of pyrite during the flotation circuit resulting in more pyrite reporting to the tailings waste stream. Weathering of the pyrite in the cyclone sands used to construct the impoundment will result in some increases in sulphate concentrations. Early in operation, New Afton processed approximately 129,000 tons of historic ore from the Afton Mine which was operated by Teck and closed around 1995. This ore was significantly weathered and oxidized, which could explain the increase in sulphate loading from the start of the TSF operation. No leachate tests were completed on this ore however. New Afton expects that concentrations will increase throughout life of mine, as metals and nutrients are circulated throughout the process.

It is difficult to make significant comparisons of aging tests versus actual supernatant due to variances in operating conditions, and the recycling of process water. No discussion around scale-up or estimations were completed for the permitting report.

ARD and ML Management

New Afton has the ability to manage ARD through draw control and blending, should a high pyrite or high arsenic zone be identified. To date, this practice has not been necessary and draw control has been based primarily on ore grade requirements and maintaining cave operations. Waste rock was generated primarily through the development of the access declines to construct the underground mine although some waste rock is generated from the base of columns within the block cave. All waste rock produced from the underground mine is disposed of in the historic Afton open pit.

If waste rock is to be used onsite for construction, it must first be tested and meet the requirements of New Afton's M229 permit as NAP waste rock. These conditions include a paste pH of greater than six or NPR greater than two. The open pit is the final location for all PAG waste rock, however, standard practice since operations began has been that all waste rock is disposed of within the historic open pit.

CONCLUSION

Prediction of ARD and ML is an essential part of the permitting process to ensure that environmental effects are planned for and managed correctly however, geochemical characterization programs are often based on small samples that are available at the time of testing. These samples may not always reflect the actual operating conditions, and in the case of New Afton HCTs the samples chosen are statically significantly different to witnessed operating conditions. Scaling up tailings samples is particularly difficult, due to the limited availability of samples produced during the laboratory metallurgical testing process. These challenges do not indicate that these tests should not be completed, but that ongoing checks and verification of the results is important. Lessons learned from the permitting aspect of New Afton, is that documentation for reasons behind sample selection is essential and verification of appropriateness of sample should be carried out. A review of As levels was completed in 2012, however no reasoning for why As levels were significantly higher in the samples was provided. It was recommended that additional tailings HCTs be set up based on actual tailings samples to provide a comparison.

In New Afton's case, it is expected that metal leaching will demonstrate lower concentrations than those predicted through the initial humidity cells. While pre-operation research is valuable, it is important for companies to continue to improve and increase their knowledge of ARD and ML based on actual operating conditions in order to confirm or refute the initial predictions. This ensures that adequate resources are available as needed to control ARD/ML after the mine has closed.

While New Afton does not expect to see any detrimental effects from changes in predictions, there has been significant benefit in repeating ARD/ML tests based on mill produced tailings. This allows New Afton to have greater confidence when communicating to regulators and communities of interest that potential effects are well understood and managed.

ACKNOWLEDGEMENTS

The authors appreciate the work that Rescan Environmental (ERM) completed as part of the permitting process and in setting up the HCTs. There was also ongoing reporting associated with these HCTs which has provided significant information to the New Afton site.

It is appreciated that New Gold Inc has allowed the time to prepare this paper and provide significant management review.

ABSTRACT

Accurate prediction of acid rock drainage (ARD) during early life-of-mine stages is critical for the development of effective waste management strategies. However, tests and methodologies used by industry focus on the extensive use of geochemical tests i.e., those associated with acid base accounting. Due to the high costs and turn-around time of such tests, only a limited number of samples are selected for predictive testwork. Consequently, detailed ARD characteristics of a deposit cannot be understood, resulting in the development of inadequate waste management plans and rehabilitation strategies. Instead, industry requires effective tools and protocols which allow for a greater number of samples to be evaluated, and are simple enough to perform in a field-laboratory, thus keeping costs to a minimum and turn-around time short. To satisfy such requirements, simple field-based pH tests should be utilised. In addition, methods to improve mineralogical characterisation in drill core materials should be employed including an ARD focused logging code, chemical staining and the use of portable instruments (i.e., portable XRF, Equotip). Finally, methods for evaluating geometallurgical data for ARD prediction should be used, and have real potential to add-value to existing datasets.

These new tools and protocols were developed and tested using drill core and waste rock materials obtained from several Australian mines with differing geology, mineralogy and mineralisation style. Our research shows that by adopting these improved tests and methods, the industry will be able to: i) perform effective predictive ARD testwork; ii) achieve detailed deposit-wide characterisation, iii) develop the best possible waste management plan; and iv) evaluate only the most suitable rehabilitation options.

Keywords: management, geochemical, prediction, waste rock, test

INTRODUCTION

Oxidative dissolution of sulphidic minerals present in mine waste materials (e.g., waste rock, tailings) has the potential to release acidic leachate (acid rock drainage, ARD), sulphate and potentially deleterious elements e.g., As, Ag, Cd, Cr, Cu, Hg, Ni, Pb, Sb, U and Zn. Therefore, in order for mining operations to adequately control and manage ARD during the entire life-of-mine, a comprehensive approach to ARD prediction must be adopted, benefits of which will be minimisation of environmental impacts, and reduction of financial liabilities associated with closure. Such an approach requires: i) analysis of an adequate number of samples, and ii) a short turnaround time frame in which to collect pertinent ARD data to allow for basic waste classification. The current industry approach to ARD prediction relies upon using geochemical tests (e.g., static, kinetic). However, limitations of static testing have long-since been established (i.e., the use of sulphide-sulphur vs. total sulphur in calculation of maximum potential acidity (MPA), variations in reaction times and chemicals in acid neutralising capacity (ANC) experiments). Furthermore, kinetic tests run for a minimum of 30 weeks i.e., data returned too slowly to guide development of an adequate waste management strategy. Most significantly, neither static nor kinetic testwork are suitable to perform on regulator recommended number of samples for ARD testwork during early life-of-mine stages (e.g., several hundred; Australian Government, 2007) due to the costs involved. For example, a basic net acid producing potential (NAPP) and net acid generating (NAG) package costs A$50 (Australian Laboratory Services, 2014) and can take at least 5 days (on sample receipt) for data to be reported. Performing such screening tests on best practice number of samples (e.g. 500 samples) would cost at least A$25,000, excluding sample preparation and handling costs. Additional mineralogical testwork would likely be required (average cost per sample: A$50-150), and any further geochemical testing (i.e., sulphide-sulphur determination, pH testing, advanced NAG tests) would result in significant financial expenditures.

Ideally, industry needs to have a field-appropriate ARD prediction toolbox that allows useful data to be collected more time-efficiently and cost-effectively. If such tests can be readily performed at mine sites, then samples for more detailed ARD testwork (i.e., using the established methods) can be better chosen. Considering this, we have evaluated several test methods (both geochemical and mineralogical) for rapid field-based ARD prediction. These included: i) chemical staining to identify neutralising potential, ii) field-based pH testing, iii) field portable instruments and iv) ARD focused logging. All results were validated against established methods e.g., X-ray diffractometry (XRD), X-ray fluorescence (XRF), and static tests (total-sulphur, multi-addition NAG and Sobek methods). These methods were tested using drill core and waste materials collected from several Australian mine sites, including two operational volcanogenic massive sulphide deposits located in Western Tasmania, and one abandoned lode gold deposit located in Queensland. Examples from these studies are presented in this paper.

METHODOLOGY

Both drill core and waste rock samples were collected from three sites (1, 2 and 3) between 2007 and 2013. Site 1 is an operational polymetallic volcanic-hosted massive sulphide deposit located on the western coast of Tasmania. Site 2 is an abandoned lode-Au mine operations in Queensland where the dominant waste rock lithologies comprise hydrothermally altered rhyolite/ rhyolite tuffs which host sulphide bearing quartz lodes. Site 3 is a deposit part of the large Cambrian hybrid volcanogenic-magmatic Cu-Au-Ag system at Mount Lyell, Western Tasmania.

Sample preparation

Each sample from site 1 and 2 was sawn in two to allow for photography and logging of a fresh surface. One portion was subjected to crushing and milling to <63 μm for geochemical and mineralogical testwork. The other portion was kept intact for mineralogical and chemical analyses using stains and field-appropriate equipment. Drill core from site 3 were first subjected to chemical staining and geometallurgical testwork, followed by the selection of representative samples every 1 m for validation geochemical and mineralogical analyses. These samples were also crushed and milled to <63 μm.

Chemical staining

Chemical staining techniques are under-utilised in the mining industry despite being simple and inexpensive tools to distinguish mineralogy and texture in a range of sample types (i.e., drill core, grain mount and thin section). Various carbonate staining techniques exist as published by Freidman (1959), Warne (1962) and Reid (1969). The methods presented in Freidman (1959) were used in this study as these are the most commonly used (Hitzman, 1999). The advantage of using chemical stains on drill core is that carbonate materials (particularly effective neutralisers such as calcite and dolomite) can be confidently identified, thus allowing for improved estimations of their modal abundance during logging or initial ARD assessments.

All drill core samples (n= 51- site 1; 70 m - site 3) were subjected to staining. Prior to staining, drill core materials were etched with dilute hydrochloric acid (HCl) for 2 to 3 minutes, and subsequently washed with water. Samples were then left to dry for approximately 30 minutes. Site 1 samples were placed directly in a plastic container containing the stain and left to soak for approximately 15 minutes in a dual stain comprising the organic dye Alizarin red-S (ARS) and potassium ferricyanide (PF) dissolved in HCl. For site 3, samples were stained directly with the same stain using a paintbrush. The ARS produces a pink to red stain on any carbonate that will react with dilute acid. The more reactive carbonates such as calcite and aragonite stain red, but the less reactive such as dolomite and siderite, remain unstained (Friedman, 1959; Hitzman, 1999). Whilst pure dolomite does not stain, if iron is substituted into the dolomite lattice, it becomes more reactive thus; ferroan dolomite and ankerite stain with ARS (Hitzman, 1999). The PF stain is more effective at identifying ferrous carbonates, as it reacts with ferrous iron causing a precipitate of Turnbull's blue to form (Dickinson, 1966). Siderite does not react with this stain. Therefore where zones of high acid neutralising capacity (ANC) are reported, but no staining colour is observed, the effective ANC can be considered low as siderite is not an effective carbonate neutraliser. After staining, samples were imaged to allow for comparison against unstained images.

Environmental logging

Textural analysis is largely absent from predictive acid rock drainage (ARD) assessments despite the direct control of texture on acid formation as discussed in Parbhakar-Fox et al. (2011). Motivated by this, these authors developed the 'ARD Index' (or ARDI) which allows for simple textural evaluations to be performed. The generated ARDI values are recommended for use in conjunction with sulphur assay or paste pH data to domain ARD forming potential. The ARDI proposed by Parbhakar-Fox et al. (2011) required assessments to be performed on both a mesoscale and microscale. However, a modified ARDI has since been developed for site 1 to allow for the performance of simpler, more time efficient assessments. An assessment was performed on all

samples, over an 8.5 cm x 5.5 cm size area, with the area most dominated by sulphide chosen for assessment, as the most conservative ARDI value was sought.

Field pH testing

Paste pH testing represents the most efficient manner by which to assess a sample's immediate acid forming characteristics. Considering this, it was performed on all samples at the University of Tasmania (UTas, School of Physical Sciences, CRC ORE laboratory), with the ASTM D4972-01(2007) method used on drill core materials (i.e., site 1 and 3) following recommendations given in Noble et al. (2012). For weathered materials from site 2, the AMIRA P387A Handbook method (Smart et al., 2002) was used. The pH value of each tested sample was measured in triplicate, with the standard deviation calculated as <0.5.

A method to accelerate the paste pH test by using a hot electrolyte solution to encourage faster reaction kinetics was trialed. Select pulverised (< 63 μm) materials from sites 1 and 3 (n=20) were paste pH tested using three different electrolyte solutions: i) tap-water; ii) deionised water (DI); and iii) 0.01M $CaCl_2$. Certified reference materials KZK-1 and NBM-1 (purchased from CANMET; Natural Resources, Ottawa) were also tested. These solutions were heated to 100°C and poured onto 10 g of sample weighed out in 50 ml glass beakers, with a 1:2 solid: solution ratio used. Once poured, beakers were stirred for 30 seconds and allowed to cool to room temperature. Measurements of pH and EC were taken after 1 hour in triplicate, with standard deviation calculated as <0.01.

Field instrumentation

Short-wave infrared

The application of short-wave infrared (SWIR) spectroscopy in determining pale, fine-grained alteration minerals has been demonstrated in ore-deposit characterisation studies (e.g., Thompson et al., 1999; White et al., 2010). Mineral identification is based on absorption spectra collected from clean, dry, flat, rock surfaces (Gifkins et al., 2005). SWIR therefore has potential to improve mineral identification of altered drill core samples for ARD characterisation. Two instruments were selected for testing in this research on samples from site 2; a portable infrared mineral analyser (PIMA; manufactured by Integrated Spectronics, Australia) and a TerraSpec spectroradiometer (manufactured by analytical spectral device (ASD) Inc.). Materials from site 3 were tested using the TerraSpec only, however in this study, both intact pieces and homogenised powders from each 1 m interval were analysed to assess which is a more appropriate sample type.

Portable XRF

Accurately measuring chemistry and comparing these data to ARD parameters (e.g., paste pH, total-sulphur) allows for a first-pass indication of potential leachate quality issues which may arise towards the life-of-mine end (i.e., mine closure). This in turn allows the development of appropriate waste management plans. Field-portable XRF (pXRF) instruments have in recent years been used in mine site characterisation studies for determining element concentrations (e.g., Haffert and Craw, 2010; Higueras et al., 2012). Most recently, Parbhakar-Fox et al. (2014) discussed its application in mesotextural classification at abandoned mine-sites. In this study, a hand-held Olympus-InnovX instrument was used (UTas, School of Earth Sciences) on intact drill core (three

areas selected) and homogenised powders at site 1, and powders taken at 1 m intervals at site 3, with reference standards NIST 2781, GXR3-538 and GXR4-2843 used throughout the analyses. A benchtop Innov-X X50 XRF instrument was used to analyse waste materials collected from site 2. Both homogenised powders and intact portions (three areas analysed) were tested in this particular study. The instrument was routinely calibrated by the material supplied by the manufacturer during the analyses (i.e., after ever 10th measurement).

Equotip

Measuring the susceptibility of a lithology to weathering is required to understand how rapidly acid forming minerals will become exposed in a waste rock pile. Therefore, the application of Equotip (a non-destructive, core-based measurement technique) which measures hardness was explored. The Leeb (Ls) hardness value (0 to 1000) is automatically calculated, and is the quotient of the rebound velocity over the impelled velocity multiplied by 1000 (Keeney, 2008). The impact body rebounds faster from harder test samples than it does from softer ones, resulting in a greater value. Approximately 3000 Equotip measurements were collected on site 3 material only, using an Equotip 3 (Proceq) instrument, across the whole 70 m interval. Average values were calculated for each 1 m interval based on measurements taken at 2.5 cm intervals. These values were used alongside total-sulphur values for comparison with NAG pH vs. paste pH data. This has the potential to allow for a low-cost first-pass understanding of lag-time to ARD on a deposit-scale.

Geochemical and mineralogical validation testing

Rapid and accurate measurement of total sulphur (wt.%) for comparison against Equotip and calculation of maximum potential acidity (MPA) was performed on samples from sites 1 and 3 using an Eltra C-S 2000 instrument at UTas (School of Physical Sciences). For site 2 samples, total sulphur was measured using a Thermo Finnigan 1112 Series Flash Elemental Analyser instrument (Central Science Laboratory (CSL), UTas). Appropriate standard materials were analysed on both instruments during all analyses. In addition, the total element chemistry of samples from site 2 was measured for comparison against pXRF data using a Philips PW1480 X-ray Spectrometer (UTas, School of Physical Sciences). Acid neutralising capacity (ANC) was measured by the Sobek method at ALS Brisbane for samples from all three sites. The multi-addition net acid generation (mNAG) test was performed on materials from all sites at UTas (School of Physical Sciences) following the AMIRA P387A method (Smart et al., 2002).

Mineralogical determination of material from sites 1 and 3 was performed using a benchtop Bruker D2 Phaser X-ray diffractometer at UTas (School of Physical Sciences). Mineralogical analyses for samples from site 2 were performed at the University of Ballarat, Australia, using a traditional Siemens D501 diffractometer.

RESULTS AND DISCUSSION

Domaining neutralising potential: staining

The dominant carbonate textures observed in drill core material from site 3 comprised of clasts (in limestone conglomerates) and veins. The Alizarin red S-potassium ferricyanide (ARS-PF) stain appropriately reacted with calcitic material in both textural forms; with the pink stain appropriately uptaken, with corresponding XRD data confirming this as calcite. Comparison of samples analysed

by the stain painted directly on, and those soaked directly in the stain, confirmed that stains were better uptaken by the latter method (Figure 1).

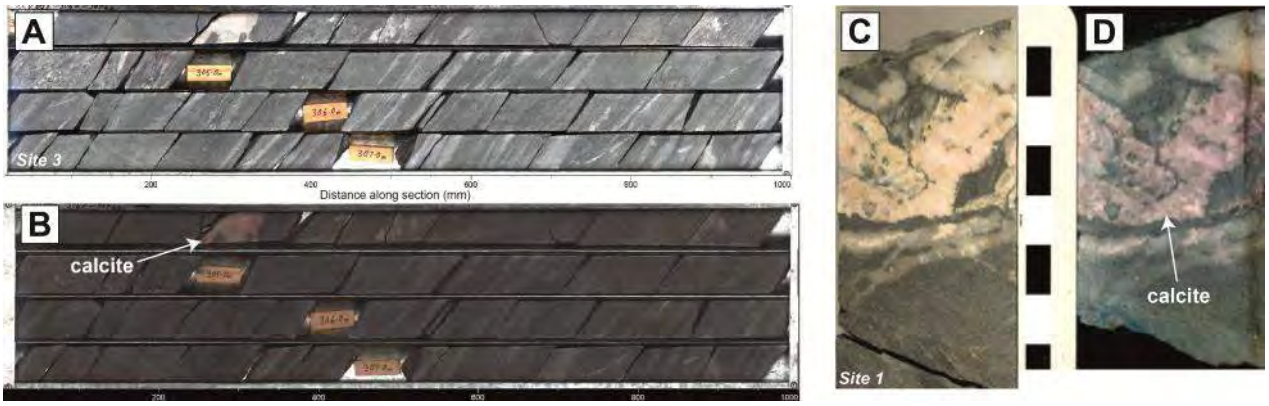

Figure 1 Photograph images of drill core from site 3 (massive sulphide deposit, western Tasmania, Australia); A) unstained and B) after several coatings of stain were painted directly on; C) unstained drill core sample from site 1 (operational polymetallic mine, western Tasmania, Australia); C) stained drill core sample from site 1 after soaking in stain bath for 30 minutes. The pink colour seen in both examples indicates the presence of calcite thus identifying effective acid neutralising capacity

Domaining neutralising potential: SWIR

Whilst major rock forming minerals can be easily recognised in hand-specimen based on their different rock properties (i.e., hardness, lustre, habit), hydrothermally altered minerals are much harder to identify. Typically, they can appear as pale and fine-grained, and with such a grain size, potential for participating in neutralising reactions (cf. Plumlee, 1999) is much greater. As stated, homogenised powder samples from site 2 were used in a study to compare two commonly used SWIR instruments, namely the PIMA and TerraSpec. Muscovite was confirmed by XRD as the dominant alteration mineral in these hydrothermally altered rhyolite samples. Two examples of typical PIMA and TerraSpec results are shown in Figure 2. Spectra collected by TerraSpec (Figure 2b and d) were better defined (i.e., less noise), and show better agreement with the reference spectra. Results from PIMA showed greater deviation from the reference spectra for sample 1 (Figure 2a), and were aspectral from sample 2 (Figure 2b). Based on these results, the TerraSpec is given preference for use. Furthermore, the TerraSpec is not restricted to analysis of pale-coloured minerals like PIMA and can detect a greater range of minerals including iron-oxyhydroxides.

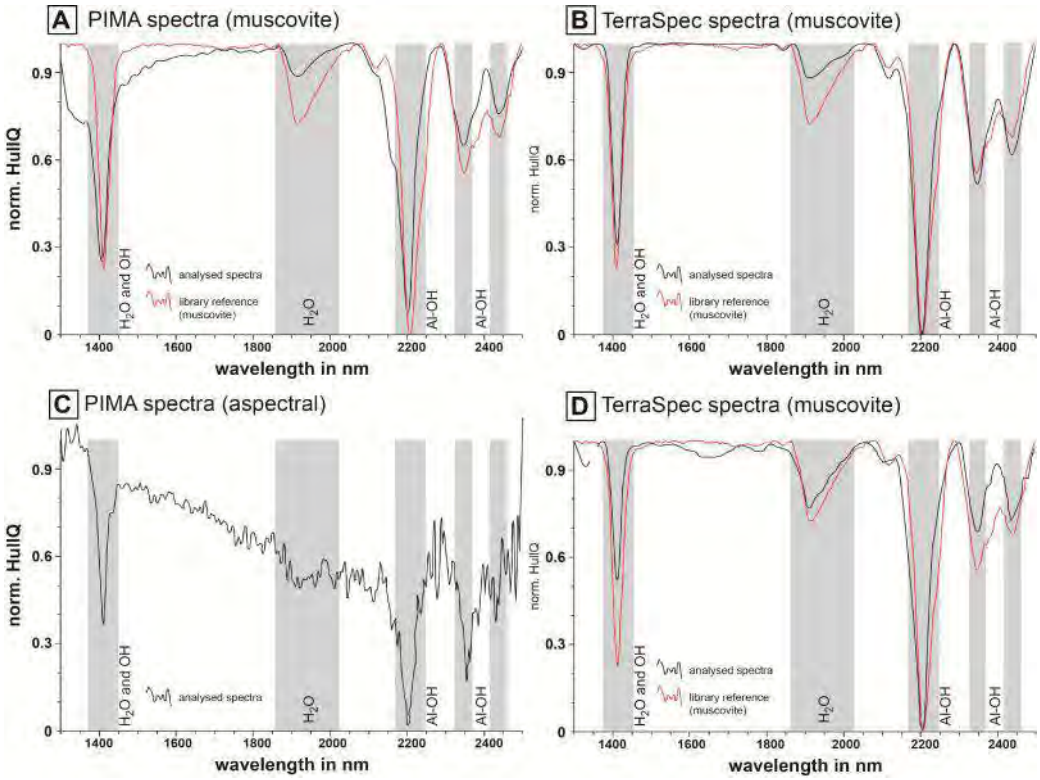

Figure 2 Example of alteration mineral identification in Site 2 (abandoned lode-Au mine, Queensland) waste rock materials; A) Sample A analysed on a PIMA with muscovite identified; B) Sample A analysed on a TerraSpec with muscovite confidently identified; C) Sample B analysed on a PIMA with an aspectral result; and D) Sample B analysed on a TerraSpec with muscovite confidently identified

In order to identify the best sample type for TerraSpec analysis, both powdered and intact drill core materials from site 1 were tested. For powdered samples, noisy spectra were collected, which were classified as aspectral, therefore, preference is given to using intact drill core. However, in validation testwork, the TerraSpec was less accurate than XRD. Whilst the TerraSpec was able to confidently identify the presence of calcite, muscovite and chlorite in 52% of the samples, it occasionally misidentified minerals such as tourmaline and epidote, which were neither logged, nor detected by XRD. Furthermore, whilst the TerraSpec instrument correct detected the presence of carbonate minerals in 52% (i.e., identified as calcite) of these samples, the exact carbonate mineral type was only correctly identified in 10% of samples when compared to XRD. This is likely explained by having performed these analyses on intact drill core (i.e., non-homogenised, randomly selected areas for analysis); therefore there is a high likelihood of conflicts when compared to XRD data. Based on these results, it is evident that applications of TerraSpec for ANC domaining are limited.

Assessing acid forming characteristics

Paste pH measurements are shown in Figure 3 with data compared against NAG pH and total sulphur measurements as recommended in Parbhakar-Fox et al. (2011). A spread of data was seen for all sites. Site 1 samples were mostly classified as potentially acid forming to non-acid forming;

site 2 samples showed a range of classifications with both extremely acid forming and non-acid forming materials identified; and site 3 samples were potentially acid forming to acid forming.

Accelerated paste pH data (DI water, tap water and ASTM D4921-01) were compared against standard ASTM D4921-01 results for drill core materials from site 1 (Figure 4a) and site 3 (Figure 4b). In general, for site 1 the accelerated ASTM D4921-01 returned the lowest pH values by up to 2.3 units. Results from both accelerated water electrolyte experiments were in close approximation (R^2= 0.995). However, when values were compared against standard ASTM D4921-01 method data, they were neither consistently higher, nor lower (pH unit difference range of +1.2 to -2.2). A similar trend was seen for site 3, with the accelerated ASTM D4921-01 test returning the lowest pH values for the accelerated tests. When these were compared against the standard ASTM D4921-01 method, an inconsistent trend was once against observed with a pH unit different range of +1 to -2.25. These results confirm that the accelerated test is encouraging reaction kinetics to proceed quicker as all accelerated values differ to the standard ASTM method. In order to understand the changes occurring during these tests, the supernatant chemistry will be assessed and a detailed XRD study of the residual powder will be undertaken. In addition, a re-evaluation of field-NAG tests is to be undertaken. The aim of this will be to produce a simple pH testing methodology (which can be performed at mine sites), the results from which can be used in more informative paste pH vs. NAG pH classifications.

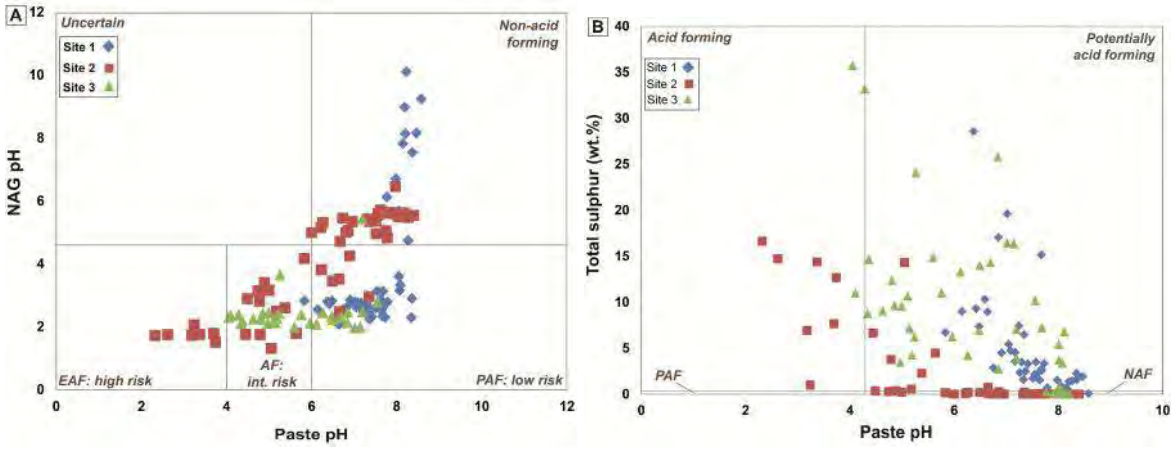

Figure 3 Paste pH measurements performed on drill core and waste materials from sites 1, 2 and 3; A) NAG pH compared against paste pH (after Weber et al., 2006); B) Total sulphur compared against paste pH (after Parbhakar-Fox et al., 2011). Abbreviations: AF, acid forming; EAF, extremely acid forming; PAF, potentially acid forming; NAF, non-acid forming)

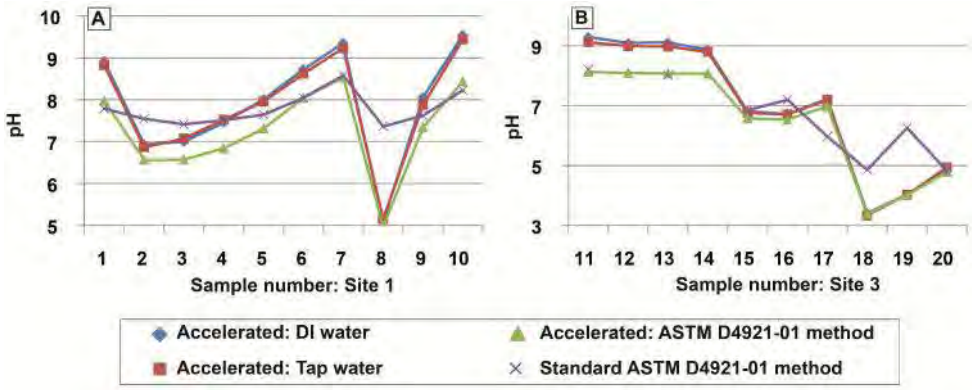

Figure 4 Paste pH test results for 10 samples from site 1 (operational polymetallic mine, western Tasmania, Australia; 1 to 10) and site 3 (massive sulphide deposit, western Tasmania, Australia; 11 to 21). Data from four experiments (3 accelerated, and one standard) are shown

Determination of bulk chemistry

Measurements of sulphur are essential for the calculation of MPA. However, the turnaround time for assay data may be significant (i.e., >48 hours). Alternatively, sulphur can be measured using a portable XRF or a benchtop element analyser. To test the accuracy of the various sulphur measurement techniques, materials from site 2 were subjected to measurements using an: i) element analyser; ii) traditional XRF; and iii) pXRF with results shown in Figure 5. Data from the element analyser and XRF were in close approximation (R^2= 0.9979), however, data from the pXRF was in less agreement when compared with both methods (R^2= 0.886 against EA; R^2= 0.8197 against XRF). Based on these results, the use of pXRF to directly calculate MPA should be avoided. Instead, this can be accurately determined using an element analyser (e.g., Eltra CS 2000 instrument), whereby reliable sulphur data can be collected efficiently. Instead, data from a pXRF instrument could be used to aid the identification of samples requiring such testwork, i.e., those with relatively high sulphur (i.e., above the specified total-sulphur cut-off).

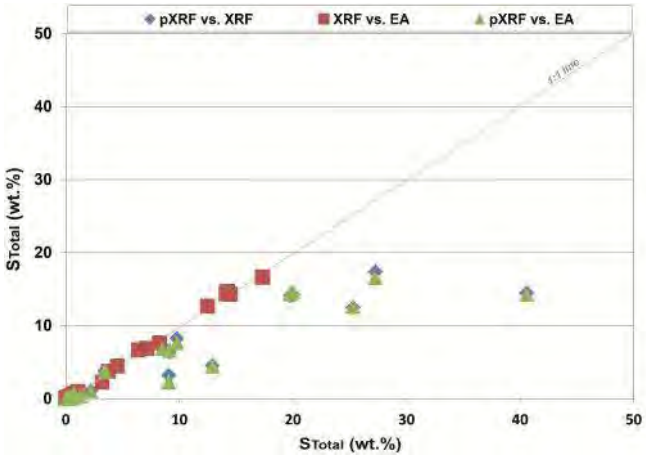

Figure 5 Total sulphur measurements made by three different analytical instruments (portable XRF, pXRF; XRF and an element analyser, EA) on samples from site 2 (abandoned lode Au-operations, Queensland, Australia)

The bulk chemistry was measured by XRF and pXRF for samples from site 2. Results for six elements commonly of environmental concern which were measured above detection limit are shown in Figure 6. Both techniques returned results in very close agreement (range of $R^2 = 0.9413$ for Sb, to $R^2 = 0.998$ for Pb). This indicates that element data collected from pXRF is relatively accurate, and therefore can be confidently used in classification schemes such as Ficklin plots (Plumlee, 1999). A similar conclusion as to the accuracy of pXRF instruments for waste classification purposes at the MacArthur River Mine, Australia was made by Landers et al. (2014).

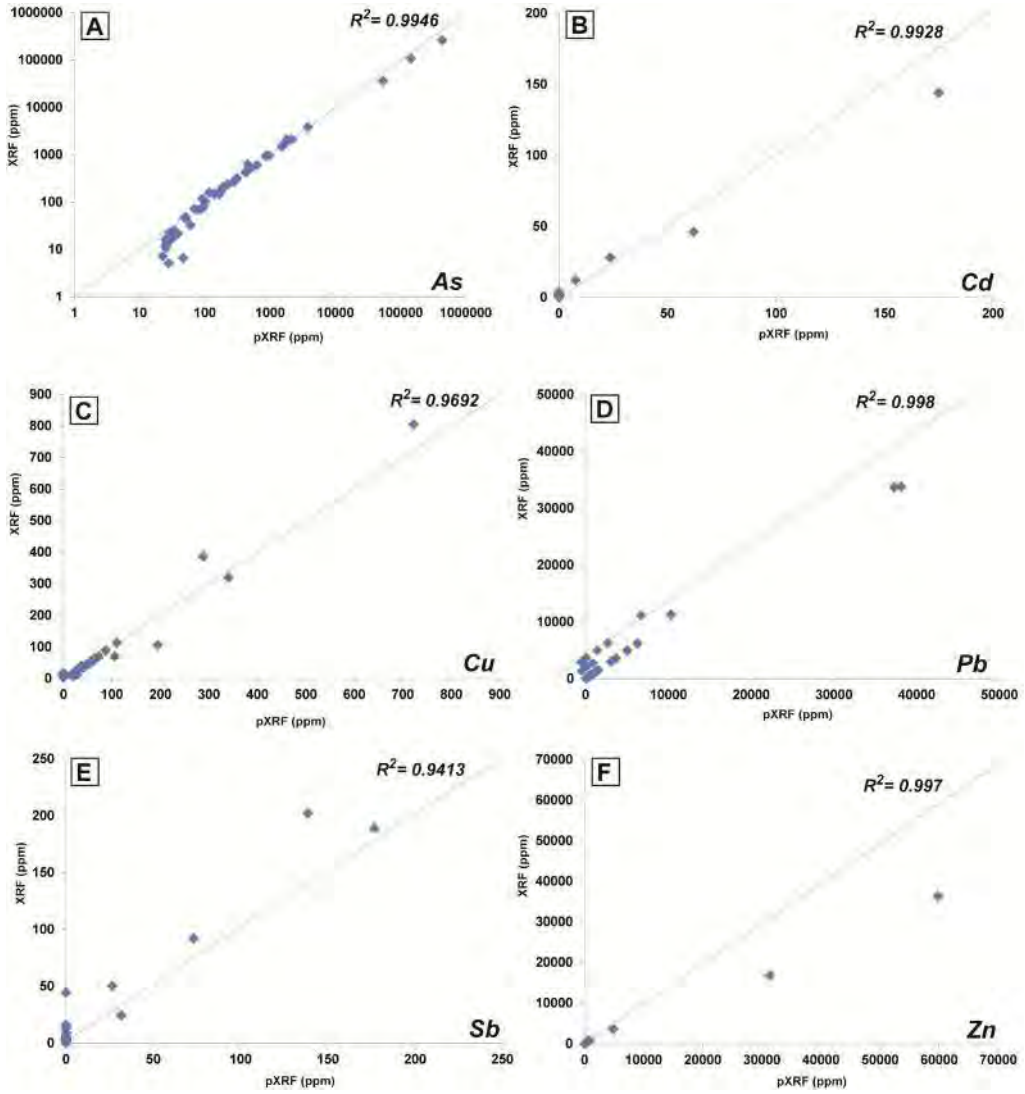

Figure 6 Concentrations (ppm) of selected elements: As (A); Cd (B); Cu (C); Pb (D); Sb (E); and Zn (F) measured in waste rock materials from site 2 (abandoned lode-Au, Queensland, Australia) by portable XRF (pXRF) and XRF techniques.

The type of sample to use in pXRF tests was evaluated using material from site 1. Both were homogenous powders and intact drill core were examined with results for the sum of metals (as considered in Ficklin plots) is shown in Figure 7. In general, there is positive correlation between both datasets (R^2= 0.81), with powdered samples generally returning higher values. From an efficiency perspective, collection of data on intact drill core is preferred; however, subjective (bias) sampling is introduced through identifying a particular interval for analysis. Furthermore, over a given interval (i.e., 1 m or 5 m), if one final value is to be utilised, how many analysis should be performed, and should an average value calculated and used? If analysis on drill core is to be pursued, a standard operating procedure must be enforced. To reduce such sampling issues, pXRF should be performed on powdered materials (again, it would be advantageous to use the same powdered materials as in total-sulphur and paste pH testing). In doing so, appropriate certified reference materials (CRMs) used here and described in Hall et al. (2014) and Piercey and Devine (2014) should also be analysed. Additionally, samples should be systematically selected for validation (using routine whole-rock analysis techniques) and if necessary, specific correction factors developed.

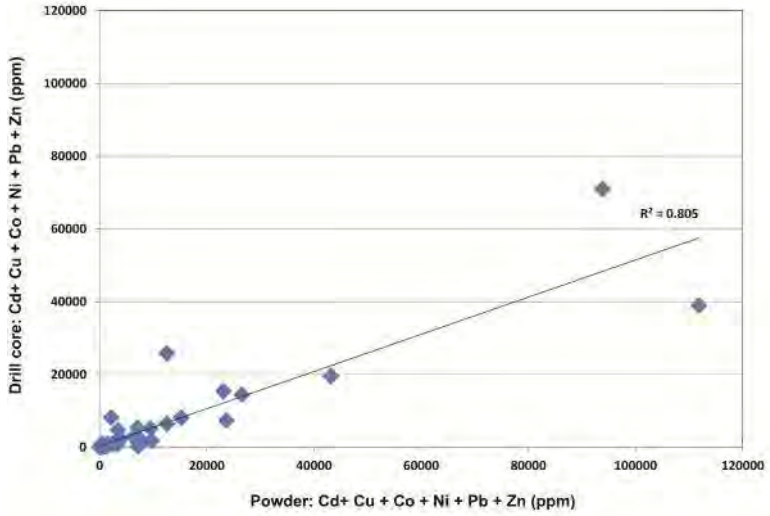

Figure 7 Total metal concentrations (Cd, Cu, Co, Ni, Pb, Zn in ppm) measured by portable XRF (pXRF) in drill core and homogenised powdered sample material collected from site 1 (operational polymetallic mine, western Tasmania, Australia, n= 51)

Using hardness for waste classification

Mineral hardness data was measured by Equotip for all drill core material collected from site 1 (304 m to 375 m). Whilst the objective was to domain ARD risk for the sulphidic schist material (345 m to 375 m), the Equotip data also allowed for ANC assessment for the carbonate-breccia material (304 m to 344 m). Comparisons of Equotip data against total sulphur and paste pH values are shown in Figure 8. If a mineral hardness value was <648 Ls, it was classified as soft in accordance with Keeney (2008). The schist material was classified as 'PAF-rapid ARD likely' by the criteria: paste pH <5.5, total-sulphur >0.3 wt. %, and < 648 Ls. Such a classification indicates that the material is susceptible to weathering as it is friable, which was observed in the field and during handling. Therefore, there is a greater likelihood of acid generation at a rapid rate, as sulphides in this material (i.e., pyrite and chalcopyrite) will be quickly liberated. These findings are in agreement

with the NAG pH vs. paste pH classification (Figure 3a). Materials were classified as having ANC by the criteria: paste pH ≥8, total-sulphur values < 0.3 wt. % and <648 Ls (e.g., 309 m to 315 m; Figure 8d).These were taken to represent the most effective neutralisers. This study indicates the potential assistance of Equotip data when performing field-based ARD studies. It is noteworthy that in the absence of paste pH data, mineral hardness and total sulphur data would have been sufficient to conservatively classify the behaviour of these materials.

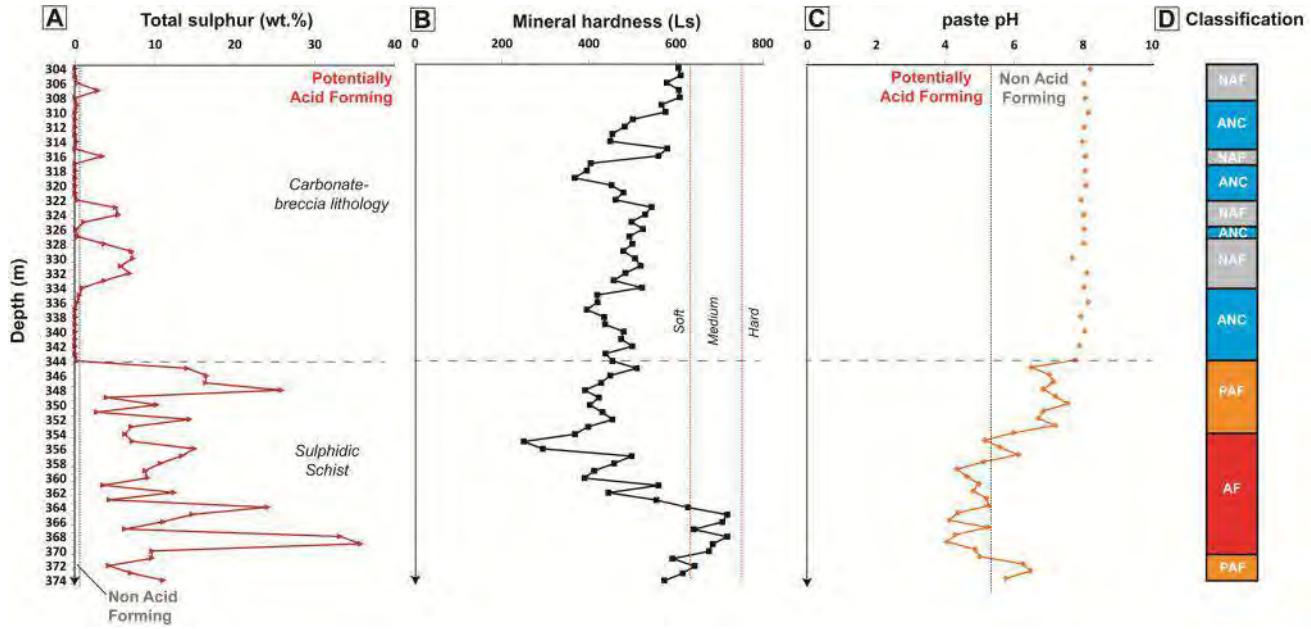

Figure 8 Downhole geochemical and geometallurgical data from site 3 (massive sulphide deposit, western Tasmania, Australia) drill core material (304 m to 375 m, change of lithology indicated by the horizontal dashed line at 345 m; A) Total sulphur values (wt. %; n=70) with 0.3 wt. % used as the classification cut-off criterion (Parbhakar-Fox et al., 2011); B) Mineral hardness values as measured by Equotip and reported in Leeb (Ls), with criteria for defining hard, medium and soft samples shown (Keeney, 2008); C) Paste pH values (n=55) with pH 5.5 used as the classification cut-off criterion; D) ARD classifications based on total sulphur, mineral hardness and paste pH values. Abbreviations: AF, acid forming, high risk with rapid ARD formation, ANC, acid neutralising capacity, highly effective; NAF, non-acid forming; PAF, potentially acid forming, medium risk with lag-time to ARD formation.

Geoenvironmental logging

A validation study of the acid rock drainage index (ARDI) was performed on drill core materials from site 1, whereby ARDI values collected in mesotextural scale drill core material only were compared against geochemical data (Figure 9). The ARDI was able to correctly identify samples with acid forming capacity (PAF, AF and EAF) when compared against total sulphur (Figure 9a), NAPP values (Figure 9b) and NAG pH (Figure 9c). The ARDI was more conservative in its classification of samples with neutralising capacity with several identified as NAF by the ARDI, but were identified as having an ANC by Sobek testing (Figure 9d). In this instance, the ARDI was

considered more accurate, as it evaluated the content of sulphides in proximity to, and the mineral associations of carbonate minerals. This study demonstrates the application of the ARDI, consequently, more mine sites should adopt such an ARD focused logging code in order to populate their mine database with this environmental attribute. Additionally, this method can be performed at mining operations in various stages of the life-of mine; for example: during exploration on hand specimen samples, during mine operations to check the correct placement of waste materials, and post-closure at historic or abandoned sites.

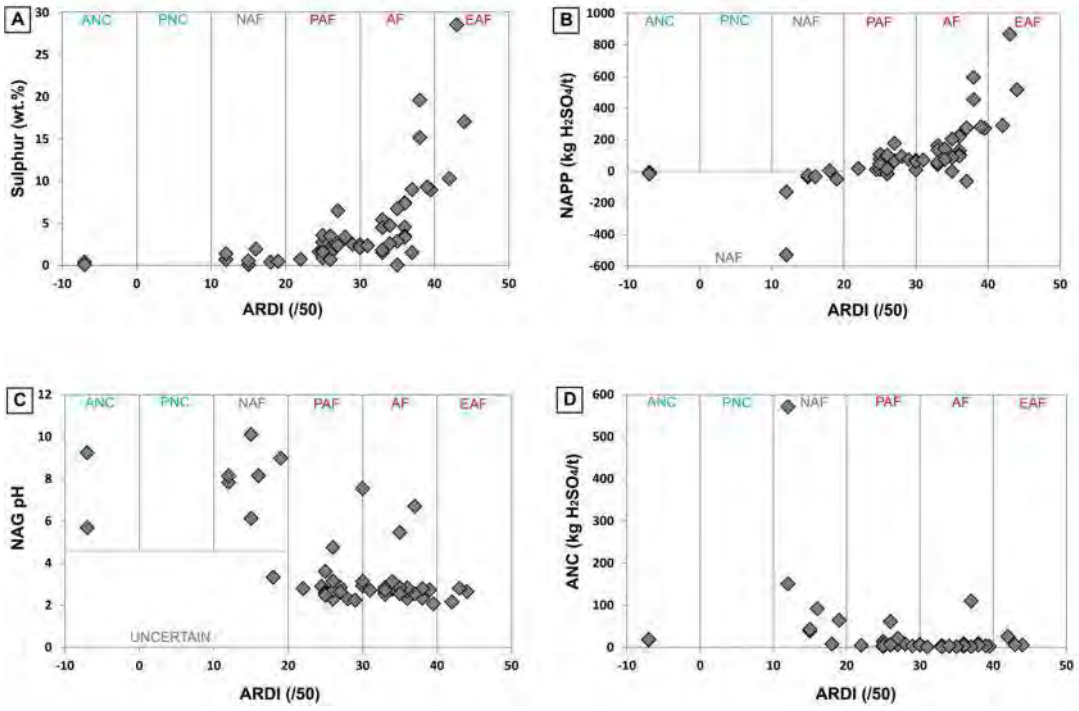

Figure 9 Comparison of acid rock drainage index (ARDI) scores given to site 1 (operational polymetallic mine, western Tasmania, Australia) drill core materials (n=51) against: A. Total sulphur (wt. %); B.net acid producing potential values (NAPP; kg H_2SO_4/t); C. net acid generation (NAG) pH; and D. acid neutralising capacity (ANC; kg H_2SO_4/t).

CONCLUSION

To effectively select the most appropriate samples for detailed geochemical and mineralogical test work, which allows for ARD prediction and waste classification during early life-of-mine operations, a pre-screening testing stage is required as described in Parbhakar-Fox et al. (2011). Such a stage must allow for a deposit-appropriate number of samples to be evaluated in order to build a database of ARD information allowing for the construction of a deposit-wide ARD model. Such a pre-screening stage must utilise efficient and cost-effective field-based tools. This permits site-based staff to characterise their own materials, thus reducing turnaround time for obtaining ARD relevant data, and improving the quality of decision making with regards to waste management (e.g., scheduling, handling and placement). A range of both existing and newly developed tools were examined in this study using materials collected from three Australian mine sites.

Our study indicates that chemical staining is an appropriate technique by which to identify the presence of carbonates if traditional mineral identification methods fail (e.g., if it is very fine grained and present in the rock matrix). Whilst the best stain responses are returned from soaking drill core directly in chemical stains, it may not be practical to perform in a field laboratory. Therefore, painting stains directly onto core gives sufficient results. Carbonate staining responses should be used to assist with environmental logging using a modified ARDI (i.e., mesoscale analysis evaluation only). The use of automated hyperspectral loggers (e.g., HyLogger) as used for geometallurgical testwork should be considered, as was demonstrated in Parbhakar-Fox and Lottermoser (2014). Short-wave infrared data collected by a TerraSpec instrument can be used to confirm the presence of carbonate but will only provide an indication of the exact carbonate mineral. Such analysis should only be performed on intact drill core materials and not on homogenised powders. In order to classify the geochemical behaviour of the materials, paste pH tests should be performed and used against portable XRF data (collected from homogenised powders) on Ficklin plots. However, paste pH testing must be standardised industry-wide, and methods in which to turn this simple method into a predictive test must be developed. The accelerated paste pH test represents one option; however, alternatives exist such as using a field NAG pH test. In addition, sulphur data should be collected on a bench-top instrument (if no assay data exist), and used with mineral hardness values (as collected by Equotip) and paste pH to domain lag-time to ARD.

The benefit of utilising these field-based techniques is that it enables a database of ARD data to be collected and held on site thus allowing for in-house expertise to be built up. Ultimately, this will lead to an improved quality of waste management strategies, and better forecasting of appropriate of rehabilitation options. Additionally, as demonstrated by using materials from site 2 (abandoned lode-Au operations, Queensland, Australia) these simple field-techniques can be used at mines in the final life-of-mine stage i.e., post-closure.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the support of CRC ORE, established and supported by the Australian Government's Cooperative Research Centres Programme. The two western Tasmanian mines (sites 1 and 3) are thanked for access to drill core materials. Additionally, the Queensland Department of Natural Resources and Mines are thanked for granting access to the abandoned lode-Au mine operations (site 2). Peter Harding and Dr. David Green of Minerals Resources Tasmania (MRT) are thanked for allowing drill core testing on materials from site 3 to be performed at MRT. Finally from the University of Tasmania, Dr. Nathan Fox, Craig Winter and Angela Escolme are acknowledged for analytical assistance.

The Effects of Preferential and Matrix Flow and Water Residence Time on Seasonal Fluctuations in Mine Waste Rock Effluent Water Quality

Holly Esther Peterson[1], K. Ulrich Mayer[2] and Roger Beckie[2]

1. *Department of Geology, Guilford College, USA*
2. *Department of Earth, Ocean and Atmospheric Sciences, University of British Columbia, Canada*

ABSTRACT

Unsaturated flow regimes in mine waste rock control the volume, timing and quality of dump effluent water. The objectives of this research are to determine the role of particle size distribution on water residence times and to assess how unsaturated flow regimes affect water quality in a two-season (wet/dry) climate. Effluent flow and water quality data are presented for three 36 m x 36 m x 10 m experimental waste rock piles composed of distinct waste rock types at the Antamina Mine in Peru. In boulder- and cobble-dominated carbonate waste rock (Pile 1), matrix flow velocities are 3-12 cm/day and preferential flow velocities are up to 20 m/day. Most dissolved solute concentrations are lowest during the wet season in Pile 1 effluent due to shorter residence times, activation of preferential flow paths, and dilution at the base of the pile. In gravel- and sand-dominated intrusive waste rock (Pile 2), matrix flow velocities are 2-3 cm/day and evidence of fast preferential flow is limited. Pile 2 effluent solute concentrations are highest during the wet season, partly due to solute accumulation in the finer-grained matrix material during dry season and displacement during the wet season. In gravel- and sand-dominated skarn waste rock that contains a significant proportion of boulders in the outer slope (Pile 3), matrix flow velocities are <2-4 cm/day and there is strong evidence of fast preferential flow (up to 2.5 m/day). Most dissolved solute concentrations are lowest during the wet season in Pile 3 due to activation of preferential flow paths and dilution at the base of the pile. Results highlight the effect of particle size on flow distribution and water residence times, which in turn affect seasonal solute concentrations. The results are relevant for predicting seasonal fluctuations in drainage quantity and composition in a variety of waste rock materials.

Keywords: Unsaturated flow; Aqueous geochemistry; Solute accumulation; Dilution; Antamina

INTRODUCTION

The factors controlling mine waste rock effluent water quality are numerous and complex. Simplified, they include waste rock elemental and mineralogical composition, particle size, hydrological properties, microbiology, and meteorology, many of which are strongly linked. Many of the geochemical processes of acid mine drainage in waste rock and tailings, such as sulfide oxidation and acid neutralization, have become relatively well understood through numerous, comprehensive geochemical studies (e.g., Blowes et al., 2003; Moncur et al., 2005), and the amount of research conducted concerning waste rock hydrology is also increasing (e.g., Smith et al., 1995; Eriksson et al., 1997; Smith and Beckie, 2003; Nichol et al., 2005; Neuner et al., 2013). As our understanding of the geochemical and hydrological processes controlling waste rock water quality increases, so does the need to provide the links between the two disciplines, both at the mechanistic level (e.g., Sracek et al, 2004; Stockwell et al., 2006; Wagner et al., 2006; Bay et al., 2014) and through reactive transport modelling (e.g., Lefebvre et al., 2001; Linklater et al., 2005; Molson et al., 2005; Fala et al., 2013). As the research body concerning interactions between hydrology, material type, reaction rates, and metal release and attenuation grows, reactive transport models will become more accurate and uncertainty associated with water quality predictions will be reduced.

The primary purpose of this study is to experimentally investigate quantitative links between waste rock hydrology and geochemistry. Specifically, the study focusses on variability of solute concentrations due to high water residence times and solute accumulation, solute flushing during periods of high precipitation and increased matrix velocities, and dilution of higher-concentration water by lower-concentration water travelling through preferential flow paths. While the study focusses on a limited number of processes, it is recognized that other processes simultaneously affect seasonal fluctuations in water quality, such as variable sulfide oxidation rates, changes in pH, and secondary mineral precipitation and dissolution, and those processes are discussed separately (Nordstrom 2011; Peterson, 2014).

The conclusions of this study are based on observations of seasonal solute concentration fluctuations in the effluent water of three experimental waste rock piles composed of physically and mineralogically distinct materials. The experimental piles are located at the Antamina Mine in Peru and are exposed to almost identical meteorological conditions, isolating the effect of material type – and specifically that of particle size -- on unsaturated flow regimes and effluent water quality.

PROJECT DESCRIPTION

The open-pit Cu-Zn-Mo Antamina Mine in Ancash, Peru consists of a skarn deposit formed during an upper Miocene quartz-monzonite porphyry intrusion (Love et al., 2004). The mine is expected to produce 2.2 billion tonnes of waste rock by proposed mine closure in 2029 (Harrison et al., 2012). Antamina's multi-scale waste rock research program focuses on the characterization, linkage, and scaling of flow, evaporation, and biological and geochemical processes in waste rock. This study focuses specifically on the hydrology and geochemistry of three of the project's five 36 m x 36 m x 10 m experimental waste-rock piles (Figures 1 and 2), which are located at the mine and are exposed to the distinct wet (September-April; approximately 1100 mm to 1300 mm of rain annually) and dry (May-September; approximately 100 mm to 200 mm of rain annually) seasons of the high Peruvian Andes (elevation ~ 4500 m).

The experimental piles were constructed with run-of mine waste rock using the end-dump/push-dump technique, mimicking the construction of the full-scale dumps. Waste rock was placed/dumped on the piles in four phases: a protective layer at the base of the pile and three end-dumped 'tipping phases' building progressively outward. The piles are each composed of a single rock type (i.e., carbonate, intrusive, or skarn), but rocks from each phase originate from different locations in the open pit. Pile 1 consists of marble/hornfels rock with estimated high neutralization potential and low acid production potential. Pile 2 consists of intrusive rocks with estimated low neutralization potential and moderate acid production potential. Pile 3 consists of skarn rocks that have estimated moderate neutralization potential and moderate acid production potential.

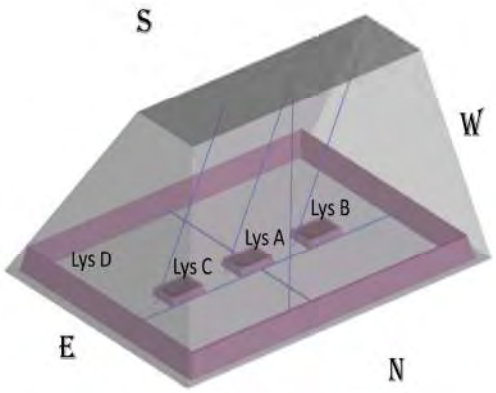

Figure 2. Schematic of the experimental piles, including three internal Sub-Lysimeters A, B, and C (4 m x 4 m) and outer Lysimeter D (36 m x 36 m).

FLOW AND TRANSPORT CHARACTERIZATION

Matrix flow and preferential flow are two hydrological components that directly affect solute concentrations by way of water residence time and dilution. In this study, matrix flow is defined as capillary flow through the granular matrix that adheres to the Richards (1931) equation and has pore water velocities on the order of millimeters to centimeters per day. The term preferential flow has different definitions in different disciplines, and for this study is considered to be 'the observation of water or solute movement faster than expected by an experimental observer or the concentration of flow into spatially localized areas' (Nichol et al., 2005). 'Fast' preferential flow is considered for this study to be water velocities on the order of meters per day.

A few tests were performed to evaluate hydrological and geochemical factors controlling seasonal concentration fluctuations, including particle size distributions (PSD), observations of effluent flow rates and patterns, a tracer study, and analysis of aqueous geochemistry. The details of these tests are described below.

Particle size distribution (PSD) analyses were performed for samples from each of the tipping phases and protective layers for all three experimental piles. Analyses were conducted by Golder Associates during the construction process according to method ASTM D 5519, and are described in Aranda (2009).

Recharge volumes and flow rates were measured continuously using acrylic tipping bucket flow meters. There is no runoff leaving the piles, so all precipitation that falls on the piles evaporates, is stored within the pile, or infiltrates to the collection lysimeters at the bases of the piles (internal Lysimeters A, B, and C = 4 m x 4 m; outer Lysimeter D = 36 m x 36 m; Figure 2) Most of the results presented here are from the D lysimeters, which account for ~97% of the lysimeter area and which collect ~97% of recharge.

The conservative tracer bromide was applied as individual, artificial rain events on the crowns (but not the slopes) of each of the three experimental waste-rock piles in January 2010 according to the methods in Blackmore et al. (2012) and Peterson (2014). The tracers were applied at rates of 6.0-8.5 mm/hr and corresponded to approximately to 7 to 8-year, 5-year, and 6 to 7-year rain events for Piles 1, 2, and 3, respectively. Reported preferential and matrix flow velocities were calculated using peak concentration arrival times as opposed to mean tracer mass arrival times because not all of the applied tracer mass had been recovered by the end of the study period. Sharp spikes in lysimeter bromide concentrations shortly after tracer application represent faster preferential flow, and more gradual increases and decreases in bromide concentrations represent slower matrix flow.

Effluent water was analysed on a weekly to monthly basis for anions, cations, dissolved and total metals, and alkalinity by external laboratories (2007-2009: Envirolab S.A, Lima Peru; 2010-2013: SGS Del Per, S.A.C.).

RESULTS AND DISCUSSION

Particle size distributions

From the PSD analysis we observed that Pile 1 is composed of coarser-grained, boulder- and cobble-dominated marble and hornfels waste rock (Figure 3). Pile 2 is finer-grained, sand- and gravel-dominated intrusive waste rock that is relatively homogeneous with a narrow range of PSD curves among material sub-types. Pile 3 skarn waste rock is similarly finer-grained as Pile 2 and is also sand-and gravel-dominated, but is more heterogeneous with a broader range of PSDs among tipping phases, including a significant amount of large (>1m) boulders in the outer tipping phase of the pile.

The discussions that follow highlight the effect of the boulder size fractions in Piles 1 and 3 on the development of preferential flow paths through waste rock in those piles, and the effect of the relatively finer-grained, homogeneous nature of the Pile 2 waste rock on solute accumulation within slower matrix flow paths in that pile.

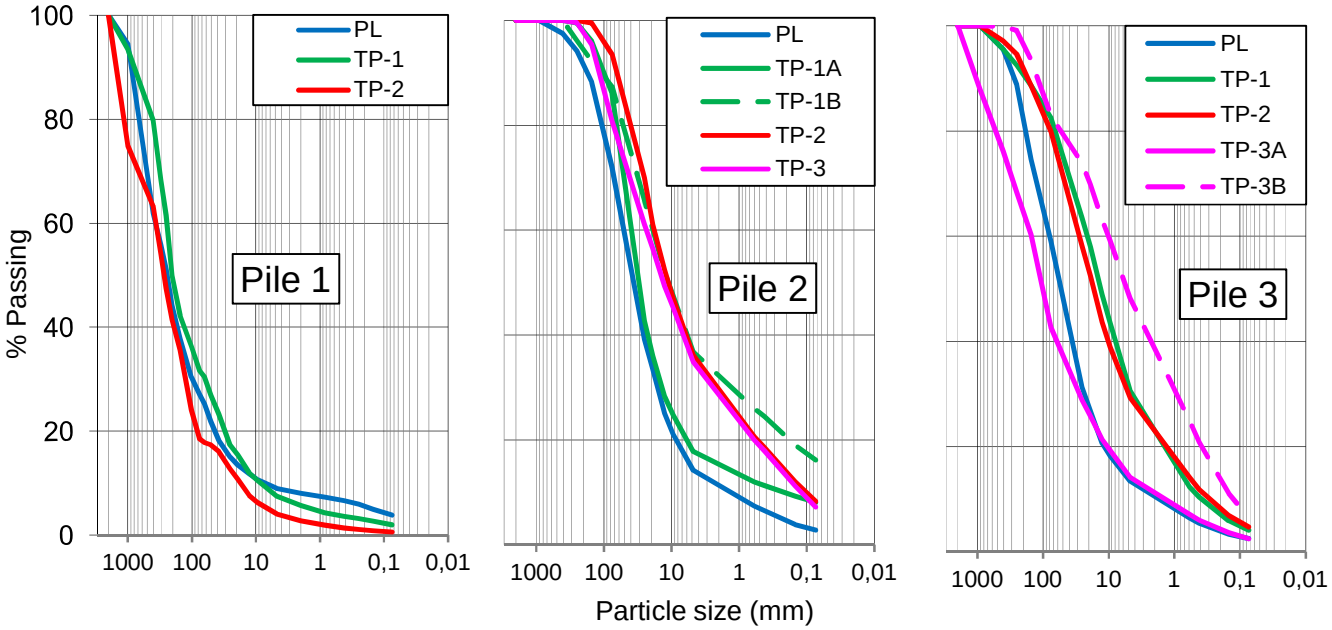

Figure 3 Waste rock particle size distributions for the protective layer (PL) and each tipping phase (TP)

Tracer study and effluent flow

All three piles are matrix-flow dominated, as shown by tracer mass release that is consistent with matrix flow conditions for the corresponding pile material (Peterson, 2014). Matrix flow velocities (v_m) as calculated with bromide breakthrough curves from the coarser-grained Pile 1 are much higher with a broader range (v_m range 3-12 cm/day; Figure 4). Matrix velocities are low in the relatively homogeneous, finer-grained Pile 2 (v_m range 2-3 cm/day), and velocities are spatially uniform throughout that pile as evidenced by relatively smooth, delayed bromide breakthrough curves (Figure 5) and closely matching lysimeter hydrographs for all four Pile 2 lysimeters). Compared to Pile 2, matrix flow velocities are similar in value but broader-ranged in the similarly finer-grained but comparatively heterogeneous Pile 3 (v_m range <2-4 cm/day). Velocities of wetting fronts are approximately five to ten times higher in the wet season than in the dry season for all three materials, as evidenced by internal moisture content probes (Peterson, 2014).

Spikes in waste rock drainage flow rates are often observed following large precipitation events in Piles 1 and 3, as evidenced by outflow hydrographs (Figure 5). The spikes – for example those observed at the beginning of the peak of the wet season in January 2010 for the slope-dominated C and D lysimeters of the carbonate (Pile 1) and skarn (Pile 3) waste rock – may indicate fast preferential flow in those materials, especially underneath the slopes.

Rapid effluent response in response to rain events does not always indicate the presence of preferential flow (Nichol et al., 2005), but bromide breakthrough curves from the tracer study confirm that there is indeed a greater proportion of faster preferential flow in Piles 1 and 3 than in Pile 2 (Figure 4). Specifically,

spikes in bromide concentrations soon after tracer application correspond to preferential flow velocities up to 20 m/day (Pile 1) and up to 2.5 m/day (Pile 3). It is hypothesized that preferential flow in Pile 3 primarily occurs as fast flow over the surfaces of boulders present in the outermost tipping phase of that otherwise finer-grained waste rock pile.

When assessing these flow patterns in light of the waste rock PSDs for each pile, it is reasonable to conclude that the boulder (Piles 1 and 3) and cobble (Pile 1) size fractions most strongly influence the development of preferential flow paths in those piles, likely as fast flow over the surfaces of the larger clasts. Dominant sand and gravel size fractions result in relatively low, narrow ranges in matrix flow velocities in Piles 2 and 3. This is especially the case for the more homogeneous Pile 2, which additionally has relatively spatially uniform matrix flow velocities. The PSDs and flow patterns, in turn, play important roles in solute accumulation in finer-grained waste rock, and solute displacement and dilution during periods of high precipitation, as discussed below.

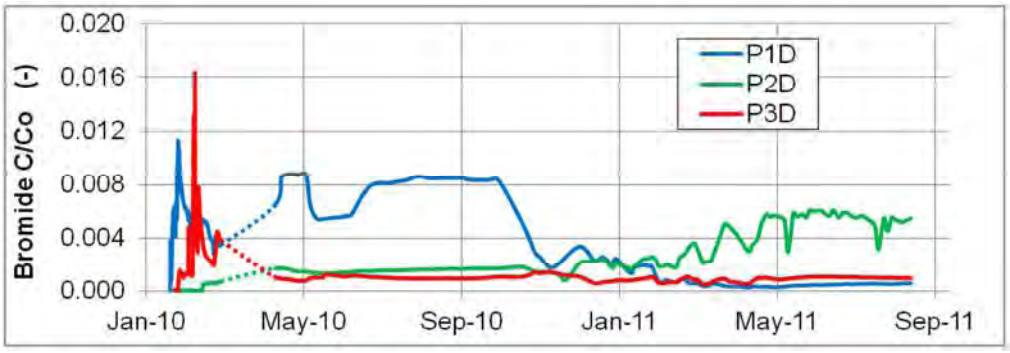

Figure 4 Bromide tracer breakthrough curves from Piles 1, 2, and 3 Lysimeter D

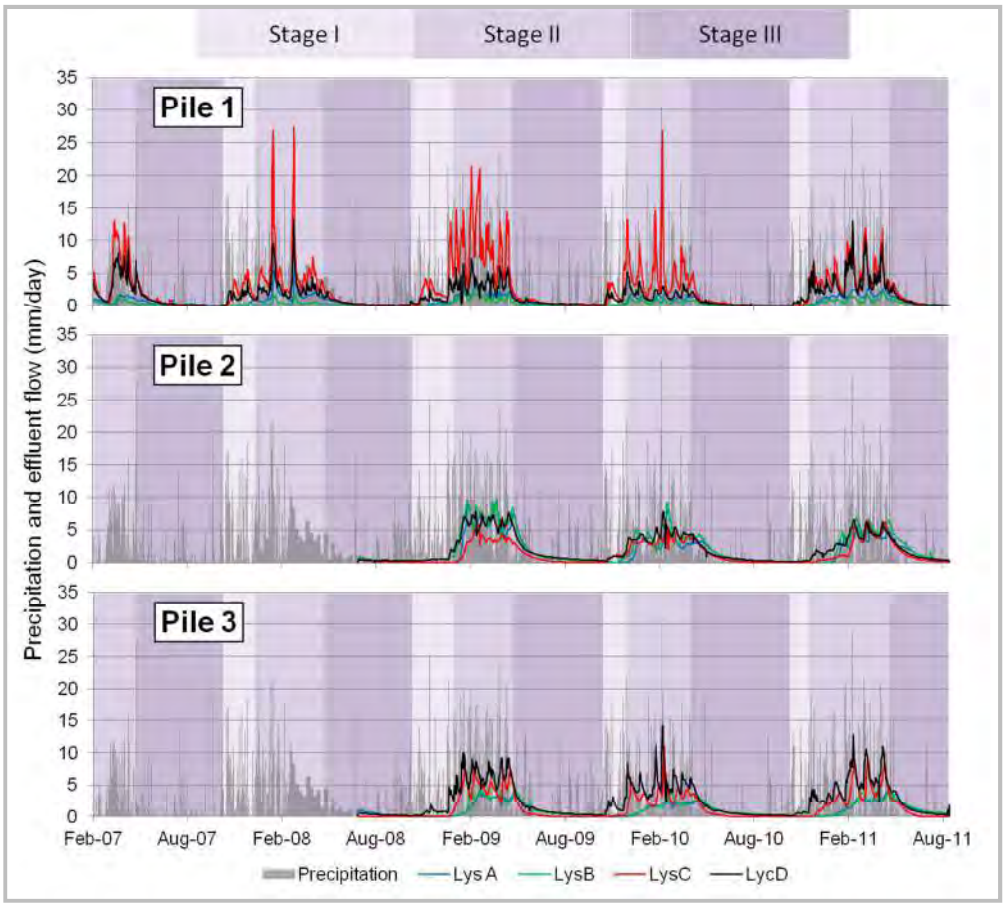

Figure 5 Precipitation and area-normalized effluent flow from Lysimeters A, B, C, and D during Stage I (beginning of the wet season), Stage II (peak of the wet season), and Stage III (draindown and dry season)

Water Quality

Dissolved solute concentrations in experimental waste rock pile drainage fluctuate significantly between the wet and dry seasons for most solutes in all three piles. Peak concentration patterns (i.e., the seasons during which solute concentrations are highest) depend on the solute and waste rock material type. There are several hydrological and geochemical controls on seasonal solute concentration fluctuations (e.g., changes in pH, secondary precipitation and dissolution, changes in internal moisture content), including solute accumulation during periods of low precipitation, displacement during periods of high precipitation, and dilution at the base of a waste rock pile, as discussed below.

An illustrative example is the behaviour of dissolved Zn concentrations, which fluctuate significantly between the wet and dry seasons for all three piles (Figure 6). Specifically, concentrations are highest for Pile 2 during the wet season (e.g., October 2008-April 2009), which can be associated with the flushing out of solutes that accumulate during the dry season when velocities are lower and residence times are longer. The pattern is the opposite for Zn concentrations in Piles 1 and 3, however, where concentrations are

highest during the dry season and decrease during the wet season, which can be associated lower residence times and dilution of higher-concentration water at the base of the pile.

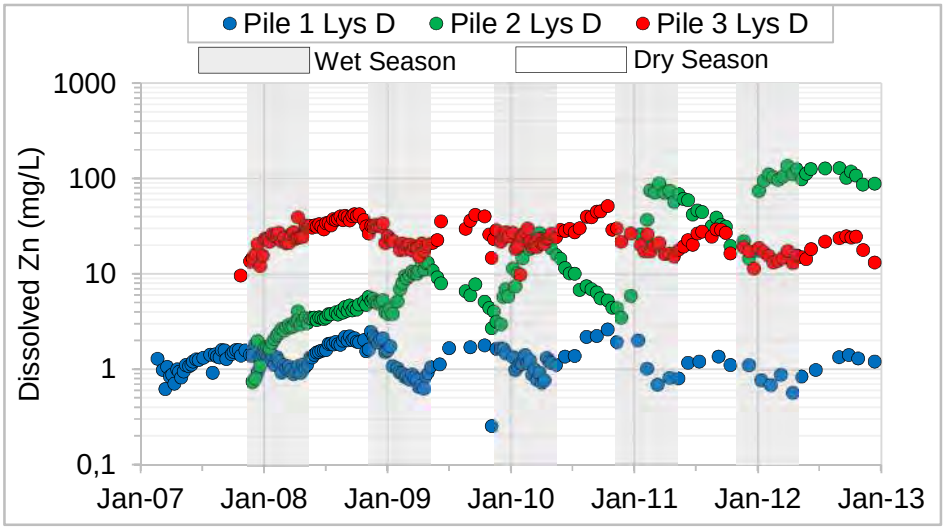

Figure 6 Dissolved zinc concentrations for Piles 1, 2, and 3

Linking particle size distributions, flow patterns, and seasonal fluctuations in solute concentrations

The coarser-grained nature of boulder- and cobble-dominated Pile 1 causes fast flow and low residence times during the wet season, which in turn contribute to solute dilution of the base of the pile and lower effluent concentrations. The more homogeneous, finer-grained nature and lack of boulders in sand- and gravel- dominated Pile 2 leads to higher, spatially even matrix velocities without the activation of fast preferential flow paths in the wet season, resulting in the flushing out of high-concentration water that accumulates during the dry season, without strong dilution at the base of the pile. Similar flow and solute flushing patterns (and hence, higher concentrations during the wet season) should also be expected from the finer-grained, sand- and gravel-dominated Pile 3 skarn, but instead the opposite is true. Solute concentrations tend to decrease in the wet season, indicating dilution from low-residence time preferential flow water, most likely resulting from fast flow over the surfaces of boulders in the outer tipping phase.

CONCLUSIONS

In finer-grained, sand- and gravel- dominated waste rock materials that have spatially uniform unsaturated matrix flow velocities with little preferential flow, higher solute concentrations can be expected during wet seasons as they are flushed from the pile after periods of low precipitation. Solute concentrations from similarly finer-grained materials that do have a significant component of preferential flow, however, can be expected to decrease during high precipitation months as a result of dilution at the base of the pile by high-velocity fresh water travelling through fast flow paths with shorter residence times. Solute concentrations in effluent from coarser-grained, boulder- and cobble- dominated waste rock

can also be expected to decrease during periods of high precipitation as a result of dilution from water traveling through faster flow paths with lower residence times.

Physical flow mechanisms effects on drainage water quality are often not considered over the recognized controls imposed by the biogeochemistry of the waste. While factors such as pH, the precipitation and dissolution of secondary minerals, and changes in seasonal sulfide oxidation rates due to temperature variations are significant and widely recognized controls on drainage chemistry, it is also important to consider physical hydrological controls when assessing or prediction waste rock effluent water quality in light of site, climate, and waste rock characteristics. As our knowledge of the links between waste rock unsaturated hydrology and geochemistry increases, the uncertainty in water quality predictions will decrease.

ACKNOWLODGEMENTS

Funding for this project was provided mine by Teck-ART, Compañia Minera Antamina S.A., and the National Sciences and Engineering Research Council of Canada (NSERC). Special thanks to Daniele Pedretti for his scientific and editorial contributions.

ABSTRACT

Lignite mining in central Germany has played an important role for more than 100 years. Former and present mining activities, as well as remediation processes, affect the aquifers. The investigation area, south of the city Leipzig, occupies 205 km². For this area, the environmental objectives of the European Union (EU)'s Water Framework Directive are currently not achieved. A prediction of ground and surface water qualities has been established focussing on pyritic sulfuroxidation and the generation of sulfate .

To predict the sulfate migration out of overburden dumps into unaffected aquifers, as well as the influence on surface waters, several steps were necessary. The first step involved characterization of the un-disturbed overburden material to predict the geochemical behaviour of the dumps. Therefore, a geological model, generated from several thousand drillings, was formed. Furthermore the concentrations of sulfur and carbonate, within the different geological layers, were examined in the geochemical model. The average dump compositions were based on a blending of the geochemical parameters with the thickness of the different geological layers.

The prediction of dump water quality was carried out using PhreeqC (Parkhust & Apello, 1999) modelling. Predicted amounts of weathering products were used to calculate the equilibrium between groundwater, secondary minerals (gypsum, siderite) and CO_2 concentration of the gas phase by consideration of redox reactions, mineral dissolution, precipitation and cationic exchange. The flow and one component transport modelling for the investigation area was carried out by the existing large scale model (HGMS) of the company IBGW Leipzig and was based on the flow and transport code PCGEOFIM®. Selected "Hotspot zones" were subsequently modelled using a reactive hydro-geochemical transport model, based on the program code PHT3D.

The results describe an expansion of dump water plumes into unaffected aquifers within the stratigraphic sequence from the upper to the lower layers.

Keywords: lignite mining, groundwater quality, pyrite oxidation, hydro-geochemical modelling, prediction

INTRODUCTION

The Central German Mining District has been influenced by lignite mining for more than 100 years. Due to former and present mining activities, aquifers in this area are significantly affected and the environmental objectives of the EU's Water Framework Directive are currently not achieved for the area south of Leipzig. This region is a main part of the Central German Mining District, which occupies a working area of 205 km^2. The University of Freiberg has been commissioned by operators of remediation (LMBV) and active mining (MIBRAG) to predict the future mass fluxes of sulfate in the groundwater bodies and the impact on surface waters. Overburden of tertiary and quaternary age contains distinct proportions of pyrite. During the mining process, the aeration of reduced sulfur compounds in overburden material causes high concentrations of sulfate, iron and trace metals in pore water, which can subsequently be mobilised.

After the mining process has been completed, groundwater levels rise, natural flow systems are re-established and Acid and Metalliferous Drainage (AMD) may occur. In order to predict the potential impact of overburden dump pore waters on unaffected aquifers a geological model, which includes the regular sequences of geological layers, was generated. Concentrations of total sulfur, sulfide-sulfur and carbonate were balanced from existing drilling data in the geochemical model. Simultaneously, the actual groundwater compositions in the investigation area were recorded, to assess the groundwater quality for the mining districts. Migration processes in groundwater were simulated using the existing large scale model (HGMS) of IBGW Leipzig, based on the transport code PCGEOFIM® and sulfate distribution in 2100 main pollution plumes out of overburden dump bodies were assessed. Furthermore, the trend of sulfate concentration was presented on several virtual water gauges. To estimate the overburden dump water impact on surface water bodies, the sulfate mass flow in selected rivers and lakes was calculated. Selected "Hotspot zones" were modelled subsequently, by means of a reactive hydro-geochemical transport model, based on the program code PHT3D.

METHODOLOGY

Determination of the dump groundwater chemistry

Initial concentrations of the main dissolved constituents in overburden dump pore water are a key input into transport modelling and the prediction of future groundwater pollution. Predictions are based on the geological structure of the investigation area (geological model) and the chemical behaviour of the groundwater observed in the field (geochemical model).

Geological model

To verify the distribution of geological layers in the investigation area, petrographic data were collected. Afterwards, several thousand drillings were used to generate a geological model, which describes the deposits and sequences of the overburden layers. Different vertical layers of silt, clay, sand or gravel were detected. According to their chemical properties, these layers are combined to stratigraphic units. Table 1 shows the stratigraphic units with high acidity potential or buffering potential.

Table 1 chart of geological layers in the investigation area

Unit-nr.	Stratigraphy		Lithology	Acidity potential	Buffering effect
1	Quaternary	Quaternary, cohesionless	gravel, sand	0	0
2		Quaternary, cohesive	alluvial clay glacial till banded clay	0	++++
3		Late pleistocene	rubble	0	0
4	Tertiary (Paleogene)	"Thierbach" layers, cohesionless	gravel, sand	(+)	0
5		"Thierbach" layers, cohesive	silt	(+)	0
6		Aquifers 2.2, 2.4	sand	+	0 – (+)
7		Aquifer 2.5	shell sand, shell silt	+	(+) - +
8		Aquifers 2.6, 2.7	silty sand, glauconite silt	+++	0
9		Aquifer 3	fine and coarse sand	+++	+
10		Aquifer 4	Sand, silty sand	++	0
11		Aquifer 5	sand	+	0
12+13+14		Cohesive intermediate material	clay, silt	(+) - +	0

Occurrence of the characteristic:	
0	not
(+)	very low
+	low
++	high
+++/ ++++	very high

Geochemical model and balancing

In order to characterize overburden materials related to their chemical and physical properties, results of geochemical investigations of about 200 drilling locations were used. During the investigation, parameters such as total sulfur content, sulfate-sulfur content, total carbon content (Ct), carbonate content ($CaCO_3$) and exchange capacity (CEC) were determined for sediments in each geological layer. The analyzed parameters were then integrated using a laminar interpolation, to determine the geochemical potentials of several areas. A weighting of geochemical parameters, according to their thickness inside the geological layer, was found to be necessary (Hoth et al., 2000). The interpolation is based on a kriging method, realized with the modeling and visualization software SURFER®. Fig. 1 illustrates the results of interpolation for Unit 4. Total-sulfur contents in sediments of this unit are shown in Fig. 1(a). In summary, 58 drillings with 160 soil samples located into aquifer 2.6 or 2.7 were analyzed. The red parts of this map illustrate very high total sulfur contents up to 3 wt%. The calculated buffering potential in materials of this unit is shown in Fig.1(b). Beside some northern parts, Unit 4 is nearly free of carbonate. This causes a very high potential for acidification.

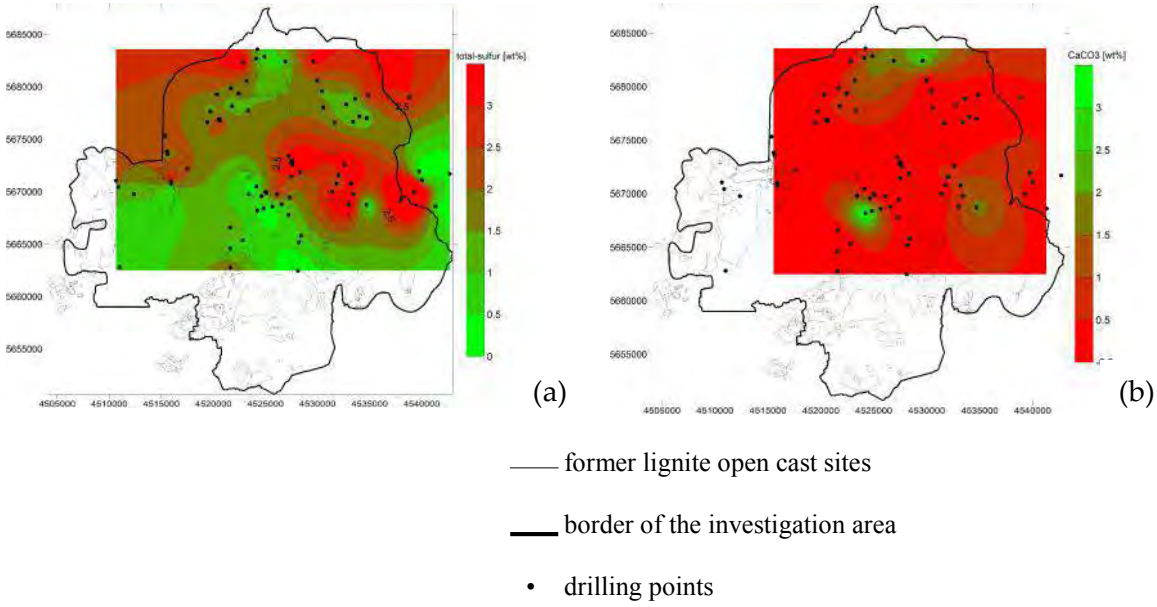

Figure 1 Predicted total-sulfur (a) and $CaCO_3$ (b) contents (wt%) in unit 4

Predicted dump pore water quality

Determination of average dump compositions is based on a "blending" of geochemical parameters with the thickness of the stratigraphic units. The investigation area is rasterized with a spacing of 125 x 125 meter. Geochemical parameters, derived from analyses, are converted into predicted parameters for overburden dumps (Hoth et al., 2000).

The prediction of overburden dump pore water quality is carried out using the hydro-geochemical equilibrium model PHREEQC (Parkhust & Appelo, 1999) and the important initial amounts of minerals including pyrite, calcite, dolomite, siderite and gypsum are used. The potential of precipitation of ($Fe(OH)_3$ and kaolinite) is respected as modelling minerals. Furthermore, the CO_2 content of the pore waters and in the gas phase is also considered and is related to the equilibrium of carbonic minerals. To calculate the equilibrium of groundwaters, an initial CO_2 concentration in the gas phase was defined. Also, the equilibrium between water solution and predicted CEC was included in the model, based on standard exchange coefficients of the PHREEQC database.

Analysis of current groundwater conditions

Characterization of the groundwater conditions of the whole investigation area is based on an intensive data analysis for generating a fundamental database. Data total of 1300 groundwater observation wells were used. To describe the actual sulfate pollution of groundwater, a series of measurements from 2009 to 2014 were considered and medians determined.

The saturation state of the groundwaters, related to relevant mineral phases (gypsum, calcite, siderite) was also determined using PHREEQC. At sulfate concentrations around 1600 mg/l a reduction of calcium is observed, because of precipitation of gypsum.

Saturation indexes of calcite and siderite depend mainly on pH values. Groundwater samples of dumps with pH values according to buffer range of calcite and siderite are often characterized as saturated groundwaters.

Overburden dump aquifers show the highest sulfate concentrations (on average 1650 mg/l) in the investigation area. The reason for elevated sulfate concentrations, greater than 3000 mg/l, appears to be the combination of overburden material behavior (high content of pyrite) and very low carbonate contents (no buffering) together with low clay contents (allowing oxidizing conditions via air access). Furthermore, slopes and edges of active mining and overburden dumps have high sulfate concentrations, due to exposure to oxygen in air. In some parts of the investigation area, groundwater of unaffected aquifers also shows high sulfate concentrations related to aeration during the artificial lowering of the groundwater level. The interaction with outflowing of dump pore waters also plays an important role. For modelling sulfate transport in groundwater, initial concentrations of sulfate were defined for every stratigraphic unit.

Mass flow and one-component transport modelling

Groundwater flow model

Results of overburden characterization and groundwater analysis were combined into an existing large scale model for mass flow modelling (called HGMS) (IBGW Leipzig). The program code PCGEOFIM® was used to calculate groundwater flow and migration processes. The model was based on the expected geological structure. Natural geological layers, overburden dumps and parameters of active mining were included in HGMS (see IBGW GmbH, 2010). The geological series of layers included all aquifers of the investigation area and zones between aquifers were regarded as aquitards. The model was adjusted for hydraulic parameters such as flooding concepts or lake-water levels using water levels from 11.000 observation wells within the calculations.

Concept and parameterization of sulfate transport

The rise of groundwater level influences the solute migration process of overburden dumps. For the simulation of the migration process, including advection, dispersion and relevant chemical reactions, PCGEOFIM® was used. Intended operations in active open cast mines were also considered alongside the mass flow inside unsaturated dump material. The sulfate concentration in groundwater was impacted by chemical reactions. Accordingly, a concept for consideration of minerals in solid matter was developed. The formation of gypsum, during the genesis of dumps and the rise of groundwater level, was found to be important. Therefore, the additional storage of gypsum was described with isotherms, including the thermodynamic equilibrium between formation and dissolving. In summary, nine classes of isotherms were defined (Figure 2).

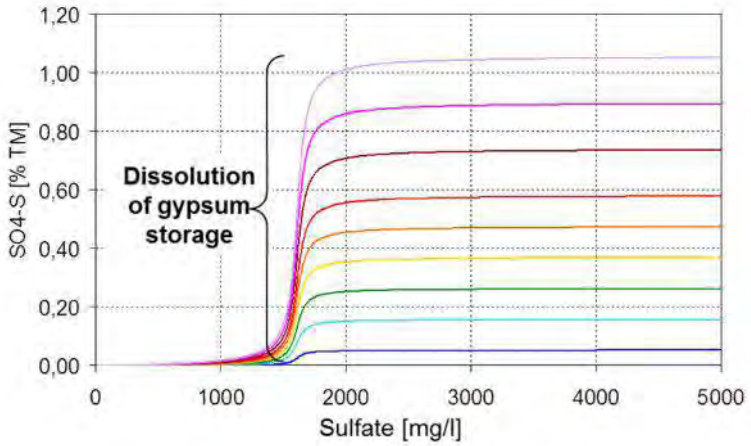

Figure 2 Dissolution of gypsum, considered as isotherms

The consideration of mass flux by using HGMS was possible in lateral and vertical direction. The first step was to investigate zones likely to have considerable plumes in future. Thereafter, current groundwater conditions were included and the mass flow out of overburden dumps was considered and future groundwater compositions simulated up to the year 2100.

Reactive transport model

A reactive transport model was used to investigate the three-dimensional reactive processes of mass flow, for two small scale parts of the whole investigation area. Using this approach, a model which describes sulfate formation and sulfate release, according to other substances in aqueous solution or in solid phases, was generated. The large scale model HGMS, including hydraulic parameters and storages of substances, was used as a background for reactive transport modelling. Calculations of reactive transport and the regional distribution of sulfate were based on the computer code PHT3D, it combines geochemical modeling (PHREEQC) with three-dimensional groundwater flow.

RESULTS AND DISCUSSION

Predicted dump compositions and hazard potentials

After the blending of geological structures and geochemical conditions, predicted dump compositions were derived. Figure 3 presents the predicted total-sulfur (a) and carbonate (b) contents for two selected overburden dumps. Red coloured areas in figures (a) and (b), depict high total-sulfur contents and very low carbonate contents and are described as hazard areas, because of high acidity potential and low buffering effect.

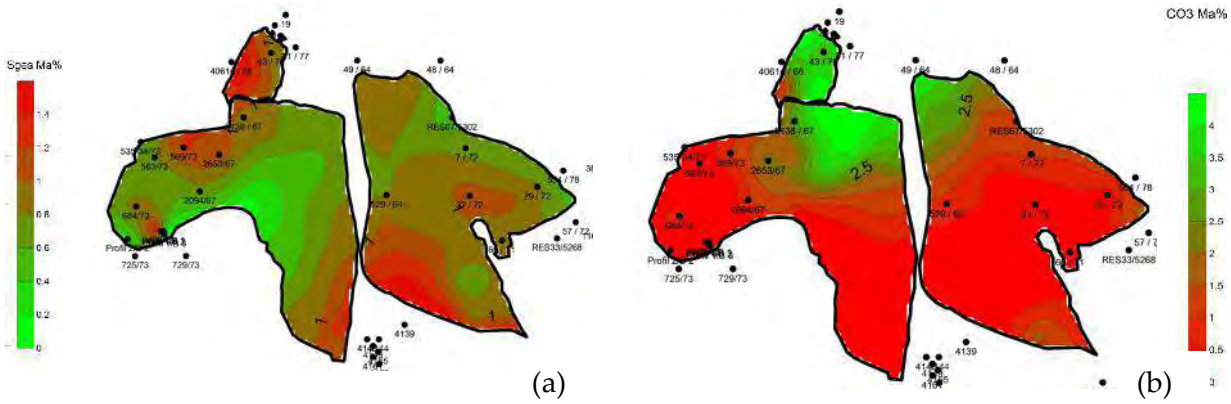

Figure 3 Predicted dump pore water composition (a) total-sulfur and (b)carbonate content in two overburden dumps

Predicted overburden dump pore water qualities

The predicted sulfate concentrations for one part of the investigation area are presented in Figure 4, along with monitoring measurements from the observation wells (coloured points). In the northern dump (called dump Witznitz), very high sulfate concentrations (up to 6000 mg/l) were calculated. Overall, not every measuring point could be reproduced by hydro-geochemical modelling. In these overburden dumps (especially Witznitz) the displacement of overburden because of the mining technology was not considered in the modelling, therefore the red area could be shifted. Furthermore, the measurements represents the part of the filter (around 2 m) and therefore weathering zones were not considered. In summary, the main groundwater condition could be simulated by the model.

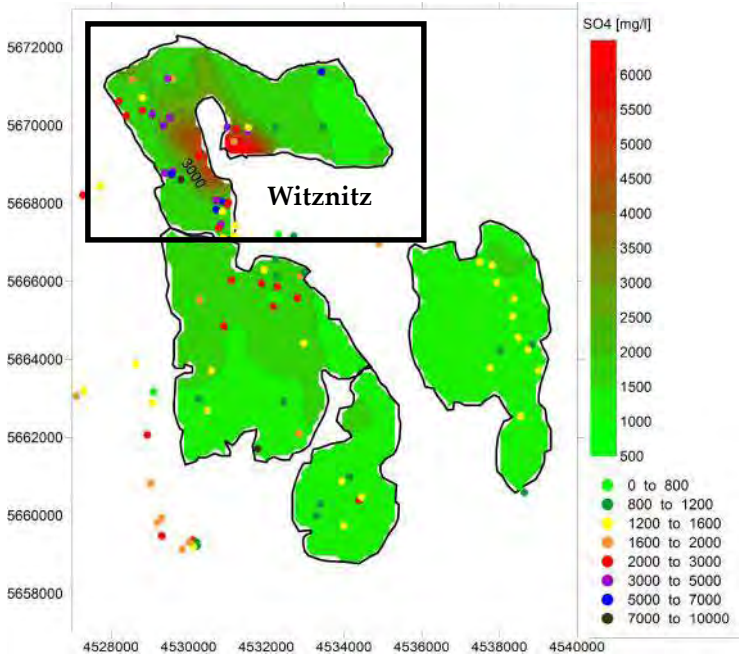

Figure 4 Predicted sulfate concentrations compared with measurements in observation wells

Results of sulfate transport modelling

Figures 5 and 6 present the sulfate concentrations in the outflow of the overburden dumps for selected stratigraphic units in the year 2100. Yellow, orange and red coloured areas suggest groundwater pollution because of dump pore water migration. In unaffected areas the sulfate concentration is around 300 mg/l. According to hydro-dynamical circumstances, stationary conditions are expected in the year 2100.

Overall, the pollution plumes with sulfate concentrations higher than 600 mg/l widen out within the stratigraphy. Local plumes around the dump boarders appeared in the upper layers, because of dilution effects (groundwater recharge) and groundwater seepage into watercourses.

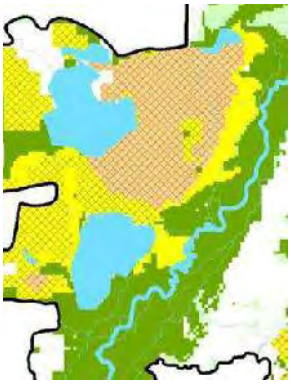

Figure 5 sulfate concentrations in 2100 after transport modelling, aquifers 1.1-1.7

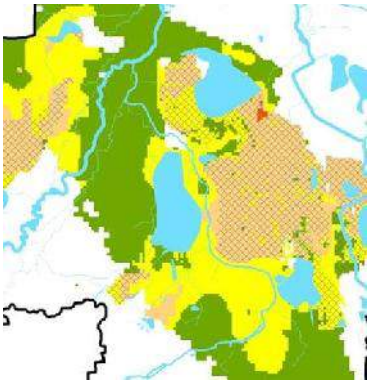

Figure 6 sulfate concentrations in 2100 after transport modelling, aquifer 4

The development of the sulfate mass flow from groundwater to lakes is shown in Figure 7, and is illustrated for one selected lake (Kahnsdorfer See) in the investigation area. This relic lake is next to Witznitz, one of the overburden dumps with the highest sulfate concentrations in pore water. According to Figure 7, the sulfate mass flow into the lake will be reduced from 4210 m^3/d in 2013 to 762 m^3/d in 2100, by nearly constant groundwater influxes.

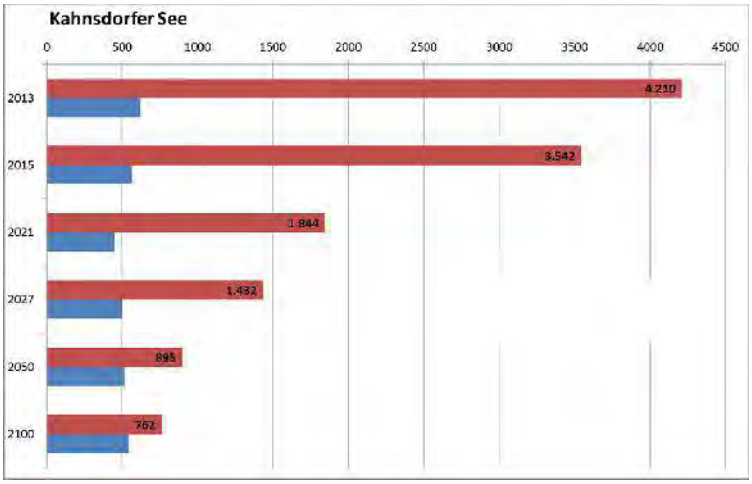

Figure 7 sulfate balance till 2100 for one lake in investigation area

CONCLUSION

Calculated geochemical parameters from overburden dump sediments, especially sulfate, carbonate and total carbon, have been used to describe conditions for every stratigraphic unit and depict hazard potentials. In these zones, high sulfate concentrations, as a result of pyrite oxidation, were generated. Sulfate migration into groundwater and flow to unaffected areas has resulted in AMD effects, as buffering geological materials are generally not available. The main AMD problems were related to two stratigraphic units - unit 8 (aquifers 2.6, 2.7) and unit 6 (aquifers 2.2, 2.4), with high sulfur and low carbonate contents, combined with the high permeability. The results were integrated into a sulfate transport model and the current groundwater conditions determined by analysing numerous data of observations wells and dump gauges. The highest sulfate concentrations, of more than 6000 mg/L, were detected in dump aquifers. An average sulfate concentration of 1650 mg/L was shown for dump pore waters. For stratigraphic units 6 and 8, high sulfate concentrations in unaffected aquifers were also detected. The evaluation of saturation states in aquifers, and respective gypsum, calcite and siderite contents indicate that pore water in overburden dumps and the zones discussed are predominantly saturated or oversaturated. Based on the current groundwater conditions and calculated geochemical potentials of the overburden dumps, initial parameters were defined and implemented in the sulfate transport model. The first results of sulfate transport modelling indicate mainly local pollution plumes in areas adjacent to the overburden dumps.

In summary, the investigations show, that the downstream area of the polluted aquifers will be impacted by the inflow of dump groundwater for several decades. Whilst there are identified pollution plumes; areas between these plumes will not be affected.

Distinctive Estimation of Stored Acidity Forms in Acid Mine Wastes

Andrea Gerson[1], Jun Li[1], Rong Fan[1], Nobuyuki Kawashima[1], Roger Smart[1] and Russell Schumann[2]

1. *Minerals and Materials Science and Technology, Mawson Institute, University of South Australia*
2. *Levay & Co Environmental Services, University of South Australia*

ABSTRACT

It is well known that weathering and sulfide mineral oxidation in sulfide-containing waste rock dumps and tailings dams can result in release of acidity and potentially biotoxic metal species as acid mine drainage. In addition to the acid generated by the dissolution of the sulfide minerals, 'stored' acidity can also be released with changing pH by hydrolysis and dissolution of several non-sulfide oxidation products formed during weathering particularly in the unsaturated zones of the mine wastes. The matching of acid and neutralization release rates in kinetically controlled processes is, in principle, the only sustainable option for long-term mine closure but, to date, there is little predictive capacity regarding secondary mineral behavior in tailings. Due to this, secondary mineralization is rarely effectively analyzed and usually not considered in site environmental risk assessments or by regulatory authorities.

Secondary mineralization is generally ultra-fine grained with high surface area and mobility. Secondary minerals formed within mining wastes can act as a both a sink and source of latent acidity and biotoxic metal species *e.g*. As, Se, Cu, Zn, Pb, Ni and several other metals of direct environmental impact. Acid sulfate salts including iron sulfates (e.g. melanterite), jarosites, and schwertmannite can be formed in the unsaturated oxidation zone of these wastes together with ferrihydrite and goethite. These secondary mineral products have widely different acid release rates at different pH and strongly affect drainage water acidity dynamics. Some of the crystalline secondary products (*e.g*. Na, K-jarosites, goethite) dissolve very slowly and can mitigate release rates of toxic species to acceptable concentrations in effluent from tailings. Others, *e.g.* H-jarosite, schwertmannite and amorphous mineralloids, form initially with similar uptake of biotoxic metals but subsequently recrystallize to more stable minerals. Whether they release or transfer these metals during recrystallization is not known but is clearly important in acid and metalliferous drainage control. A four -step extraction procedure to quantify jarosite and schwertmannite separately with various soluble sulfate salts has been validated with synthetic and real sulfide waste materials with XRD and SEM verification. Correction to acid potential and estimation of acid and some toxic metal release rates can be based on this method.

Humidity Cell Test with Pyrite Concentrate from Tailings Flotation

Refugio González[1], Antonio Barrera[2], Liliana Lizárraga[1] and Carmen Durán[2]

1. *Universidad Autónoma del Estado de Hidalgo, Mexico*
2. *Universidad Nacional Autónoma de México*

ABSTRACT

A humidity cell test was performed with tailings from a massive sulfide mine, located in the State of Mexico, Mexico. These wastes have a high acid generation potential and null net neutralization potential. The aim of this work was to compare the leachate characteristics from the tailings and the sulfide concentrate obtained by tailings flotation, in order to show how trace neutralizing minerals affect pH evolution. The samples were analyzed by XRD: pyrite, sphalerite, quartz, clinochlore, calcite and muscovite were identified in the tailings, whereas dolomite, sphalerite with cobalt, hydroxisilicate of potassium, magnesium and aluminum and moscovite with vanadium and barium were identified in the flotation gangue and only pyrite was detected in the sulfide concentrate. The tailings and pyrite concentrate were submitted to a modified humidity cell test from ASTM D 5744-96 method, by circulating 3 $Lmin^{-1}$ of air on the surface and dropping 50 mL of water during the wet period. The cycle duration was 14 days with a one-day wet period, the test was performed for 4 cycles. The starting leachates pH were 4.60 and 4.63 and electrical conductivity (EC) were 3673 and 235.5 μScm^{-1} respectively, for the tailings and the concentrate. The lowest leachate pH for the pyrite concentrate was 4.15, and 4.48 in the original sample. EC increased 5 times in the concentrate (1246 μScm^{-1}) and decreased to 2785 μScm^{-1} in the tailings. These results suggest that traces of neutralizing minerals can partially buffer the acidity generated in the first oxidation stages and flotation can improve tailings characterization.

Mine Water Quality Prediction over the Long Term: A 15-Year Column Test for a Flooded Uranium Mine

Ulf Jenk, Jürgen Meyer, Marcus Frenzel and Michael Paul
Wismut GmbH Chemnitz, Engineering and Radiation Protection Division, Germany

ABSTRACT

Within the Wismut Remediation Project the Uranium mine at Schlema-Alberoda, where about 80,000 tonnes of uranium had been mined conventionally between 1946 and 1990, have been flooded since 1991. The mine water is contaminated with uranium, radium, iron, manganese, and arsenic and has to be treated for discharge into the Mulde River over the long term.

In order to understand the basic hydrogeochemical processes and to predict the future trend of mine water composition, column tests have been set to work in 1999 on a pilot scale (volume 1 m^3, filled with mine typical ores and materials). Two scenarios are being simulated with 9 columns over a time period of about 15 years: a) saturated conditions with oxygen limitation (simulating flooded mine areas) and b) unsaturated conditions (simulating surface near mine areas which are flooded temporarily)

The most important finding is that most of the concentration trends have been developed stable not before 2 to 4 years, and a number of parameters are still in movement. In general, under unsaturated conditions weathering processes and pollutant mobilization (As, U, Ra) keeps on whereas in the saturated columns reductive immobilisation, particularly of uranium, is ongoing. First geomicrobiological investigations show sulphate reducing bacteria in the saturated columns. The results confirm the long term nature of pollutant behaviour in flooded mines. Short term experiments are not able to describe these time depending processes in an adequate way.

Leachability of Metals from Gold Tailings: A Modeling and Experimental Approach

Bronwyn Camden-Smith[1], Raymond Johnson[2] and Hlanganani Tutu[1]

1. *Molecular Sciences Institute, School of Chemistry, University of the Witwatersrand, South Africa*
2. *SM Stoller Corporation, USA*

ABSTRACT

Mine leachates emanating from gold tailings in the Witwatersrand Basin, South Africa, usually contain elevated concentrations of metals and sulphates that tend to impact negatively on water and soil quality in the vicinity. This study aimed at assessing the leachability of metals from oxidised by rainwater. Leaching of tailings was conducted experimentally using artificial rainwater and simulated using the PHREEQC geochemical modelling code to further understand the dominant processes. The formation of evaporite secondary minerals was also simulated to understand processes leading to their formation from tailings leachates and surface water.

The results indicated that the predominant metals in tailings were aluminium, copper, cobalt, iron, lead, manganese, nickel, uranium and zinc. These were found to be held in secondary mineral phases, mainly sulphates that constituted the readily soluble fraction. Results from modelling showed that the secondary minerals were chemically similar to leachates from oxidised tailings while leachates from oxidised tailings and unoxidised tailings would likely mix to form the immediate groundwater. The secondary minerals consisted of simple sulphate salts and complex multi-element sulphates that formed along a flow path between tailings and receiving surface water systems. Dissolution of these salts would likely cause episodic pollutant input to receiving water.

Development of Technical Criteria for the Chemical Stability in Mining Facilities

María Carolina Soto[1], Raquel Charte[1], Angela Oblasser[1], Lilian Valdebenito[2] and Jorge Campos[2]

1. Fundación Chile

2. SERNAGEOMIN, Chile

ABSTRACT

In 2011, a new Mine Closure and Mining Facilities Law was promulgated in Chile, requiring that all mining companies submit a Closure Plan of all their facilities for approval by the National Geological and Mining Survey (SERNAGEOMIN) prior to implementation of the exploitation.

Prior to the introduction of this law, regulations regarding mine closure considered only the physical stability of mining facilities. The new law and its regulations include a new requirement related to ensure chemical stability of the mine waste; however, it does not give details or technical criteria on how this should be assessed and guaranteed. This new requirement constitutes a major challenge towards more sustainable mining operations, which involves the integrated management of massive mine waste and mine facilities during the life cycle of a mining project.

Since mid 2013, Fundación Chile and SERNAGEOMIN are working on a project that considers the development of a methodology and technical criteria to evaluate and ensure chemical stability at mining facilities in order to guide the actions necessary during the lifetime and closure of a mining project. One of the results of this project is the development of a technical guide, that is expected to be published in December of 2014, that will gather information from national and international documents and guides related to chemical stability, mining-influenced water, acid and neutral mine drainage, mobility of contaminants and risk assessment, among others, and will be applied to the geological, mining and climatic conditions in Chile. Also, the project includes validation of the methodology and technical criteria in public-private workshops, in which all related stakeholders, participate. This work is co-funded by the Government Production Development Corporation (CORFO).

CHAPTER 5

MINE WATER DRAINAGE COLLECTION AND TREATMENT – PHYSICAL CHEMICAL ACTIVE TREATMENT

Commercial Case Studies of Life Cycle Cost Reduction of ARD Treatment with Sulfide Precipitation

David Kratochvil[1], Songlin Ye[1], and Oscar Lopez[2]

1. *BioteQ Environmental Technologies, Canada*
2. *BioteQ Water Chile SpA, Chile*

ABSTRACT

Sulphide-based precipitation of divalent metals has been shown to greatly reduce life cycle costs and waste generation for the treatment of acid rock drainage (ARD) at mine sites. BioteQ's ChemSulphide® process has been applied in multiple countries and continents and has proven to be a more cost effective solution than HDS or LDS lime plants on their own. Two case studies are presented in which the ChemSulphide® process has been applied to reduce the life cycle cost of water treatment at sites facing active ARD treatment in perpetuity. The case study examines the lessons learned and causes of plant downtime at the Wellington Oro water treatment plant. The plant, which has been operating for over five years, has continually been able to meet strict discharge requirements for cadmium and zinc while entirely eliminating the production of waste sludge, however mechanical and secondary process issues had reduced plant availability. Lessons learned and mitigation methods that are currently being implemented are presented and discussed. The second case study looks at the ChemSulphide® plant installed upstream of a HDS lime neutralization plant treating ARD at the Yinshan Mine in China. The plant selectively recovers copper as a commercial grade concentrate with the net revenues largely offsetting treatment costs to achieve both economic and environmental benefits. The net present value of the savings generated by the ChemSulphide® plants at Wellington Oro and Yinshan are also analysed and discussed.

Keywords: acid rock drainage, metal recovery, life cycle costs, sulphide precipitation, environmental compliance

INTRODUCTION

Preventing acid rock drainage (ARD) has become a key component of mine development planning and operations. Unfortunately, there are many legacy sites and/or active mines where despite the adoption of best management practices, the generation of ARD cannot be avoided, leading to the need for active treatment in perpetuity. The life cycle cost of active treatment over several decades can be very high and the amount of solid waste generated in the treatment process and the composition of this waste may not only significantly contribute towards the overall life cycle costs (LCC) but also impart long-term liabilities.

This paper presents two commercial case studies of active ARD treatment using BioteQ's ChemSulphide® process at sites with prolonged time horizons of water treatment. One is at an abandoned mine where the ChemSulphide® plant has been in operation since 2009 and where BioteQ recently performed a plant review as part of the customer follow-up process. The other is at an operating mine currently undergoing expansion and where a new ARD treatment system that combines HDS lime neutralization with ChemSulphide® was commissioned in 2014. The long-term benefits of the ChemSulphide® process including the reduction in LCC, process robustness to meet stringent discharge limits, and the reduction or elimination of waste sludge are discussed.

Traditionally, ARD has been treated with lime neutralization in a typical flow sheet shown below in Figure 1. In this process, lime is added to the metal laden water to neutralize the dissolved metals.

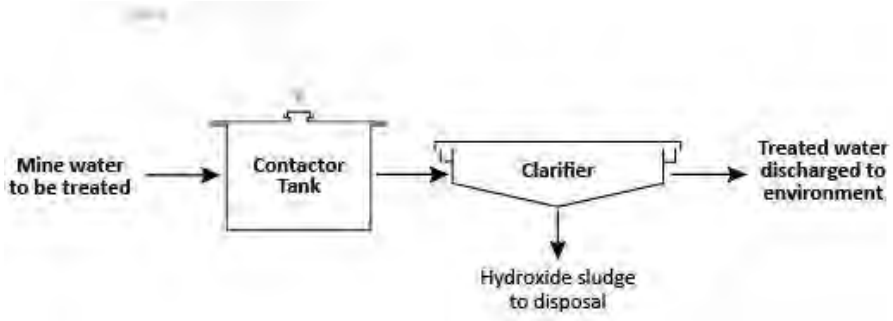

Figure 1 Traditional ARD Treatment Flow Diagram

As shown above, all metals in the ARD are precipitated in a voluminous hydroxide sludge that will bring significant disposal costs and associated liabilities. Adding to the complexity of sludge management is that storage and disposal is controlled by site-specific licenses or permits in some jurisdictions.

Sulphide precipitation technology, depending on the ARD composition, can recover all the metals as salable metal sulphide products and completely eliminate the sludge generation and disposal, or partially recover the valuable metals to reduce the overall sludge management cost.

CASE STUDY: WELLINGTON ORO MINE

The Wellington Oro (WO) treatment plant is located approximately five kilometres east of the Town of Breckenridge, Colorado. A former United States Environmental Protection Agency (EPA) superfund site, the WO mine was seeping ARD with zinc and cadmium from its historic underground workings to waterways and a downstream fishery (US EPA, 2014). An international call for proposals resulted in ChemSulphide® being selected as the best available technology to meet site-specific effluent discharge regulations and minimize the quantity of solid waste generated and stored on-site. Since it is impossible to prevent water ingress into the mine, ARD treatment will be required for many decades and possibly in perpetuity at the site. The flow diagram of the ChemSulphide® treatment process designed by BioteQ and installed at WO is shown in Figure 2.

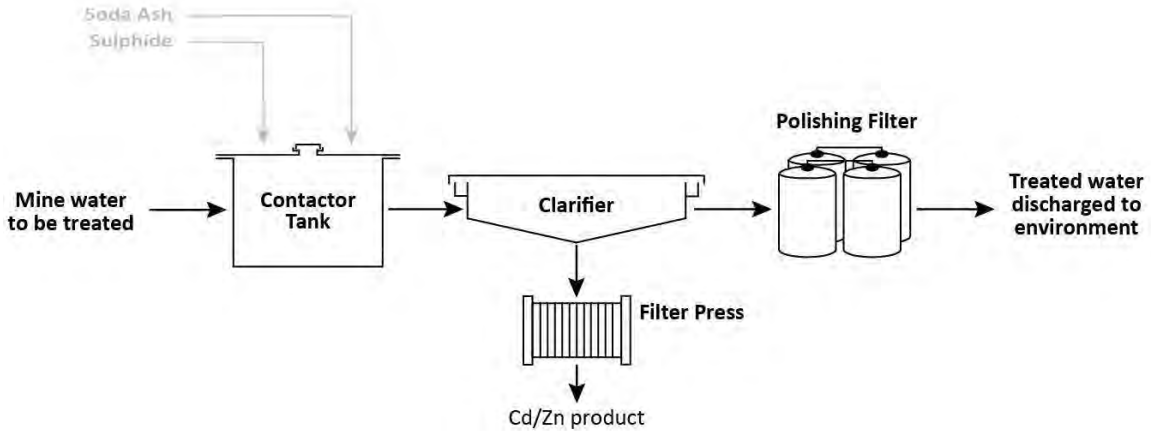

Figure 2 WO ChemSulphide® Process Flow Diagram

The ARD treatment at the site works by selectively precipitating the dissolved Cd/Zn in the mine water as metal sulphide solids using chemical sulphide as the primary reagent. The water is then separated from the Cd/Zn solid and sent to polishing filters before being discharged to the environment. The Cd/Zn solids are filtered to remove excess water, producing a high-grade metal product suitable for refining.

The plant was constructed and commissioned in 2008. Within approximately three months following the plant start-up, the treatment plant was meeting all project objectives summarized in Table 1.

Table 1 Wellington Oro Treatment Objectives and Results

Parameter	Feed	Objective	Result
Zn	132 mg/L	< 225 ppb	< 67 ppb
Cd	122 ppb	< 4 ppb	< 0.5 ppb
pH	6.15	6.5 to 9.0	7.5 to 8.5
Waste sludge generation	-	Zero waste	Zero waste
Hydraulic flow	-	9 to 27 m^3/hr	16 m^3/hr

Following the successful commissioning of the plant and training of local operators, the Town of Breckenridge took over responsibility for plant operations. In Q1 2014, the city made the decision to take advantage of the available follow-up services and invited BioteQ to perform an on-site review and optimization of the plant, five years after start-up.

BioteQ's review revealed that while the ChemSulphide® plant has continuously met regulatory discharge limits and successfully eliminated waste sludge, which were the primary benefits of the process, the overall plant availability was impacted due to several issues as summarized in Table 2.

Table 2 Wellington Oro Plant Availability Impacts

Operational Issue	Impact on Operability
Frequent soda ash pump seal failure	Increased downtime, higher maintenance costs
Hard scale deposit build-up in polishing filters	Higher operating cost to include media filter replacement every 6 months
Significant % of time spent in recycle	Reduced plant availability

Further review of the plant operating data and discussions with plant operators revealed that over the course of the past five years, plant operating conditions changed substantially from the original design. The key parameters that have changed are noted in Table 3.

Table 3 Wellington Oro Plant Changes in Operating Conditions

Parameter	Unit	Design	Actual Results
Feed flow	m^3/hr	9 to 34	< 9 m^3/hr
Feed alkalinity	mg/L as $CaCO_3$	0	120 to 150
Metal acidity	mg/L as H_2SO_4	410	150 to 175

The changes in the operating conditions needed to be taken account during the on-site review and plant optimization to determine the extent to which they contributed to the operational issues identified in Table 2 and the recommendations to address the plant availability impacts.

Elucidating Pump Seal Failure

The soda ash pumps installed at WO are centrifugal pumps with a single mechanical seal. Originally, the seal flush plan was based on using the pump discharge (6% soda ash solution) as the source of gland water. This was recognized by the operators as the main cause of seal failure due to the build-up of soda ash crystals in the seal. The new flush plan involved using local groundwater as the gland water source. By switching the flush plan to groundwater, the frequency of seal failure was reduced but not enough to have a positive impact on the overall plant availability.

BioteQ's review of the groundwater quality data revealed the water contained very high levels of calcium hardness (~ 1,200 mg/L). Although this type of water may be suitable as gland water for many pumping applications, its use as gland water for pumping concentrated soda ash solution at WO is problematic. The reaction between calcium hardness and sodium carbonate results in the precipitation of calcium carbonate inside the pump seal which is the most likely cause of pre-mature seal failures.

Therefore, BioteQ provided the city with two options to remedy the current situation including: 1) install a small house size water softener for reducing calcium hardness upstream of pump glands, and 2) replace soda ash with caustic soda as the alkali used for pH adjustment in the ChemSulphide® process.

Elucidating the Formation of Hard Scale Deposit in Polishing Filters

Samples of the scale that built up in the multimedia filters were analyzed and revealed that the solids contained calcium and iron carbonate. As part of the on-site review, BioteQ reviewed the current plant feed water quality data and completed acid titrations of the feed water to confirm the alkalinity present in the mine drainage. Water quality data showed the feed to contain approximately 400 mg/L Ca with the titration results indicating a feed pH of 6.3 and alkalinity of approximately 130 mg/L. This data points to the fact that the plant feed is saturated with respect to $CaCO_3$.

Based on the original design criteria it was expected the feed would contain zero alkalinity and high metal acidity which would result in the generation of free acid and a drop in solution pH in the metal precipitation stage via reaction (1). Therefore, the original design included the addition of soda ash into the metal sulphide precipitation contactor in order to buffer the pH in the reactor.

$$Zn^{2+} + NaHS = ZnS + Na^{+} + H^{+} \quad (1)$$

Due to the fact the feed already contains 130 mg/L alkalinity and metal acidity is only 175 mg/L, the addition of soda ash to the treatment process results in a significant increase in the alkalinity of the treated water. This was confirmed by an acid titration performed on the reactor discharge solution indicating that the alkalinity increased by 260 mg/L to 390 mg/L as $CaCO_3$.

The increase in alkalinity produces solution supersaturation and significantly increases the scaling potential of the treated water where both $FeCO_3$ and $CaCO_3$ can precipitate out of solution. Scale formation in the multimedia filters can be explained by the filter media having a high solid surface to liquid volume ratio inside the filter housing. This acts as seed for relieving at least a portion of the solution supersaturation.

It is also likely that the gradual build-up of scale inside the filters was exacerbated by a less than optimal back-flush regime where it is imperative that the best possible conditions are created to

remove solids trapped inside the filters. The current back-flush conditions are far from optimal due to the following:

- The plant flow rate is below the minimum back-flush flow required (multimedia filters use filter discharge to back-flush); and
- Limited volume of water in the backwash feed tank.

Based on this process analysis, BioteQ recommended the following three remedies: 1) automate the filter backwash based on the level in the filter feed and backwash collation tanks to ensure adequate backwash volume and time is allocated to cleaning the filters; 2) move the soda ash addition downstream of the polishing filters; and/or 3) replace soda ash with caustic as the alkali of choice to control the pH in the process and for discharge. While moving the soda ash addition is a more versatile solution that is applicable over a wide range of feed water quality, it may still result in scaling in the effluent piping. The replacement of soda ash with caustic completely eliminates carbonate formation and scaling but is applicable only when the plant feed contains sufficient alkalinity to buffer the pH in the metal sulphide precipitation stage.

Elucidating the Cause of Poor Plant Availability Due to Recycle

The ChemSulphide® process is designed for continuous operation; as such, any time there is a plant upset that causes the process to shut down, there will be a certain amount of operating time before on spec water can be produced again. Typically, the longer the process is shut down, the longer it takes to get the process back up to steady state.

The current plant configuration does not allow for an automatic recycle of off spec water back to the mine if a minor upset occurs. If an off-spec issue occurs, the plant automatically shuts down and requires operator intervention to start back up. As the plant was designed for operation with limited supervision, there are times when the process will be idle for 10-12 hours depending on operator availability. This can turn a small process upset, which with a recycle loop would result in a minor upset, into the plant being shut down for an extended period and then taking 3-5 days for the process to restart.

In order to keep the process running following an upset, BioteQ recommends that automated valves and a recycle line should be added to the discharge line to ensure the plant can continue to circulate water when producing off-spec water. This should reduce the 3-5 day timeframe for plant restart to a matter of hours. The existing manual valves can be modified to accept a pneumatic or electric actuator and, along with a few modifications to the PLC program, the plant will be able to recycle automatically.

Plant Review Summary

The review of the ChemSulphide® plant operation five years after plant start-up revealed the following:

- The ChemSulphide® process is robust and has been successful in meeting project objectives that include compliance with stringent discharge limits and the elimination of waste sludge;
- To ensure high plant availability and low maintenance costs, it is important to use only soft water as gland water for centrifugal pumps used for conveying soda ash solutions for pH control;
- Where mine drainage may contain significant alkalinity, the plant design should allow for the use of caustic in addition to soda ash to avoid the risk of scaling in polishing filters; and
- When sizing the filter feed and backwash tanks, it is important to consider not only the maximum design flow but also the minimum design flow.

Positive Impact of Metal Recovery on Life Cycle Costs

On average, the WO ChemSulphide® plant treats and discharges over 45,000 m^3 of water annually while recovering over 99% of the zinc and cadmium in the ARD. The recovered metals equate to roughly 23,000 lbs of Zn/Cd which are formed into a filter cake concentrate and shipped to a smelter. By recovering these metals, the WO treatment plant avoids the production of HDS lime sludge which would necessitate the construction of dedicated sludge ponds and/or significant costs of ultimate sludge disposal in a final resting place such as an industrial waste landfill.

CASE STUDY: YINSHAN MINE

In Q2 2014, BioteQ along with its joint venture partner Jiangxi Copper Corporation (JCC), completed the construction and commissioning of a new water treatment plant at JCC's Yinshan mine. The treatment plant combines conventional high density sludge (HDS) lime neutralization with the ChemSulphide® process to treat ARD and recover copper. The plant is the second such plant built by the partners. The first was constructed at the nearby Dexing Mine in 2007 and has been operating continuously and successfully since start-up.

At Yinshan, there are two main sources of ARD including surface run-off collected from the open pit and toes of the waste rock dumps, and water collected and pumped from underground mine workings. The initial objective for the site was ARD treatment to meet regulatory requirements with a properly designed HDS plant. However, during the project definition stage, it became evident that the copper and zinc concentrations in the ARD have sufficient economic value to warrant potential metal recovery. A subsequent engineering feasibility study confirmed this and the decision was made to expand treatment to include the ChemSulphide® process to recover copper with a further allowance made for a possible future expansion to include zinc recovery. The flow sheet of the ARD treatment system installed at Yinshan is schematically depicted in Figure 3.

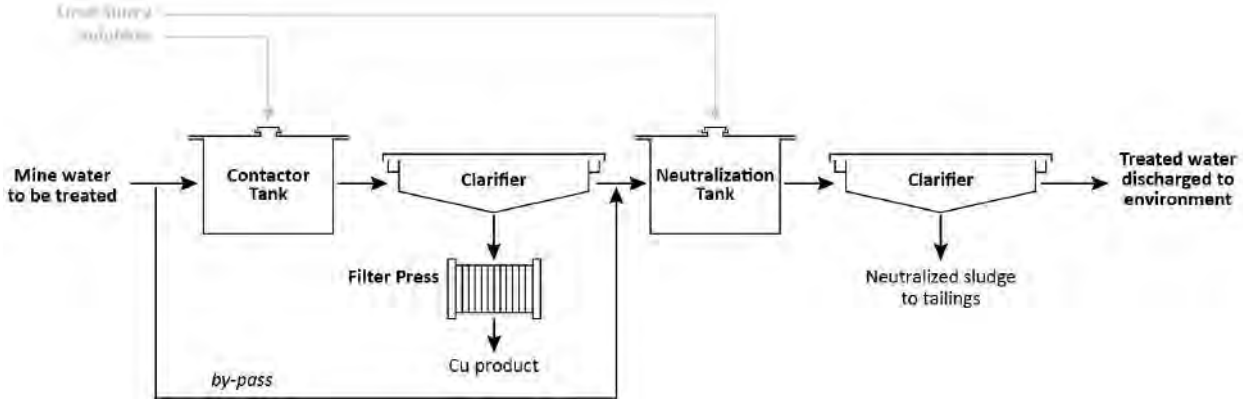

Figure 3 Yinshan ChemSulphide® Process Flow Diagram

As can be seen from Figure 3, a portion of the mine water is designed to by-pass the copper recovery stage. This is due to the fact that not all sources of mine impacted water at Yinshan contain sufficient amounts of copper to warrant recovery and the need to reduce the capital cost of the overall treatment. A chemical sulphide reagent is used to precipitate the dissolved copper in the ARD into a copper sulphide slurry. The slurry is dewatered to produce a high-grade copper concentrate that is sold to a local smelter.

Although the ChemSulphide® circuit of the overall treatment currently recovers only copper, the operating conditions of the plant also removes arsenic and cadmium from the ARD to ultra-low levels which is deported to the copper concentrate hence preventing them from being discharged to the environment. A downstream HDS lime plant is currently used to remove zinc (before the Zn recovery is put into place) along with aluminum and iron, prior to final discharge. The plant effluent is discharged into a local river that is part of the watershed of the largest fresh water lake in China – the Poyang Lake. The HDS lime sludge with reduced metal content is disposed of in the tailings pond.

Due to permitting and construction delays of the ARD collection and storage facilities, the plant has yet to reach and operate at the maximum design capacity for an extended period of time. Average copper concentrations in the plant feed are also lower than designed for the same reasons. The plant has been fully tested during the May to July 2014 storm season peak flow days and has met all design expectations. Table 4 summarizes the key design objectives against the actual averages since the start of operation.

Table 4 Yinshan Treatment Objectives and Results

Parameter	Feed	Objective	Result
Cu	80 mg/L	1 mg/L	< 1 mg/L
Cu concentrate grade	-	35%	31-33%
Cu recovery	-	90%	90%
pH	2.6	2.2	2.2
Hydraulic flow – Cu recovery	-	700 m^3/hr	400 m^3/hr
Hydraulic flow – HDS	-	1,000 m^3/hr	600 m^3/hr

BioteQ continues to provide technical support for ongoing plant operations.

Positive Impact of Metal Recovery on Life Cycle Costs

Using the actual capital cost of the fully installed plant and the operating cost figures from the first three months of operation, the projected LCC of ARD treatment with a 20 year net present cost (NPC) was estimated for three treatment scenarios: HDS alone, HDS with the current copper recovery, and the future possible scenario of HDS with copper and zinc recovery.

The LCC were calculated using a 5% discount rate with no adjustment for future cost escalation for inflation, and assumes a fixed copper price of $3.30/lb and zinc price of $1.13/lb over the life of the project. It should be noted that base metals in China trade at a price premium of approximately 10 to 15% over the London Metal Exchange prices.

The calculated LCC are also based on zero sludge disposal costs. This is true for the Yinshan mine operation where HDS lime sludge is pumped to an existing tailings facility nearby. However, in many cases of active ARD treatment, this option for sludge disposal is not available and the sludge handling and disposal costs can be quite significant.

From this perspective, the LCC presented in Table 5 represent the worst case scenario for the positive impact of metal recovery by the ChemSulphide® process on the overall economics of ARD treatment. For illustration of the additional potential benefit of the ChemSulphide® process for other sites, the sludge reduction associated with metal recovery are also provided.

Table 5 Yinshan Plant Life Cycle Cost Comparison (US$)

	HDS	HDS + Cu	HDS + Cu/Zn
CAPEX			
ChemSulphide®	-	$ 3,400,000	$ 3,900,000
HDS Lime	$ 5,300,000*	$ 4,300,000	$ 4,300,000
OPEX			
ChemSulphide®	-	$ 1,100,000	$ 2,117,000
HDS Lime	$ 875,000	$ 827,000	$ 807,000
Value of Metal Recovery			
Cu	-	$ 1,768,000	$ 1,768,000
Zn	-	-	$ 1,224,000
Net OPEX (incl Metal Value)	($ 875,000)	($ 159,000)	$ 68,000
LCC (20 yr NPC @ 5%)	$ 16,200,000	$ 9,681,000	$ 7,353,000
Cost per m^3 ARD treated	$ 1.17	$ 0.70	$ 0.53
Sludge Reduction (tons/year)	0	1,440	5,160
Sludge Reduction (m^3/year)	0	1,030	3,690

*** Construction of a HDS plant alone would cost $1 M more due to cost efficiencies from shared infrastructure and mechanical/electrical installation when a HDS plant is built in conjunction with a ChemSulphide plant.**

As indicated by the LCC comparisons, copper recovery can offset the HDS treatment cost and reduce the long-term liability associated with treating ARD by more than $ 6 M. On an initial capital cost of $7.7 M for the HDS + Cu recovery option, the LCC is $9.7 M to treat ARD for 20 years.

When zinc is also recovered in combination with copper recovery, the liability of treating ARD can be turned into a profit centre. The capital cost for HDS + Cu/Zn is $ 8.2 M. The LCC is $ 7.4 M. Over a 20 year treatment period, the project will have generated a profit of $ 800,000.

CONCLUSION

ChemSulphide® is a robust and efficient process technology for the treatment of mine impacted waters to meet regulatory compliance while contributing positively to the LCC of the project. The technology has been applied at multiple sites with different site conditions and requirements.

At Wellington Oro, the ChemSulphide® plant has operated for five years, successfully meeting stringent discharge requirements and generating no waste for disposal. By eliminating waste and its associated liabilities, operational costs are reduced. And as operating conditions change over time from the initial design, the process can be modified to maximize plant operability.

The newly installed Yinshan plant illustrates how a metal recovery component when treating ARD can reduce project LCC. Depending on the value of metals in the ARD, the flow rate and metal prices, the revenues generated can range from offsetting treatment costs to becoming a profit centre.

The two cases presented in this paper can be applicable to many mine sites that have similar ARD issues. Sulphide precipitation, due to its high process efficiency and metal selectivity, can also be combined with other mine water treatment applications such as ion exchange and membranes to address complex ARD issues, or meet ultra-low effluent discharge limits.

Mine water treatment is a necessity but can be costly. The two cases in this paper demonstrates that options now exist to treat ARD to comply with environmental regulations and reduce LCC, thereby improving overall project economics.

The Feasibility of Treatment of Acid Mine Drainage with Seawater

Devin Sapsford, Lawrence de Leeuw, James Phillips and Peter Brabham
Cardiff University, United Kingdom

ABSTRACT

This paper presents results from an experimental study on the interaction of acid mine drainage from the abandoned Parys Mountain mine site (UK) and seawater with a focus on its potential use as a reagent in mine water treatment. Parys Mountain is a former copper mine, the acid mine drainage discharge measured during the study was pH 2.1 – 2.4 with elevated iron concentrations (up to 490 mg/L) and a range of other elevated metal concentrations including copper (34 mg/L), zinc (11 mg/L), lead (109 μg/L) aluminium (57 mg/L), and cadmium (135 μg/L). Currently the discharge (circa 10 L/s) flows via the Afon Goch for approximately 2 km to discharge to the Irish Sea. Remediation options have been considered for the site and include active and hybrid active-passive treatments with active treatment being favoured given the challenging AMD chemistry. Because active treatment is costly, alternative remediation strategies would be favourable. Considering that seawater has alkalinity due to the presence principally of dissolved carbonates and borates, this study looks at the feasibility of using seawater as a reagent to treat the mine drainage. Field titrations were performed using seawater to titrate the acidic mine drainage whilst pH was monitored and samples withdrawn for analyses of dissolved species. It was determined that mixing of mine water with seawater in ratio 1:1 was found to give the following removals (quoted as load removal with residual metal concentration in parentheses): Cd 77% (16 μg/L); Zn 77% (1.3 mg/L); Cu 74% (4.5 mg/L); Al 68% (9.2 mg/L) and Fe 36% (58 mg/L), thought to be due to precipitation of K-jarosite. The load removal is reasonably good at simple mixing ratio of 1:1 but the residual concentrations are relatively high. Clearly if stringent concentration-based discharge consents were imposed then mixing (1:1) with seawater would not satisfy these consents (mixing at higher ratios might), however, if the aim is to reduce metals loading to the coastal water for as low a cost as possible, then seawater mixing and removal of precipitated metals may be a promising avenue to explore further.

Keywords: Neutralization; metals removal; remediation

INTRODUCTION

Acid mine drainage is a widespread problem for mining operations around the world, both for active sites and former mine sites. One such legacy site is Parys Mountain, Anglesey, UK where AMD currently pollutes local water courses and the near-shore environment. This study focusses on AMD from the Dyffryn Adda adit discharge which enters the Afon Goch Amlwch watercourse, which then flows through the town of Amlwch and into the Irish Sea. Parys Mountain is an Ordovician/Silurian volcanogenic massive sulphide ore deposit (Barrett et al. 2001). The "mountain" lies approximately three kilometres from the north Anglesey coast in North Wales, and reaches a peak height of < 150 m above ordnance datum. The ore bodies' occurrences comprise both massive and banded polymetallic sulphide lenses, hosting copper, zinc, lead, silver, and gold. Despite the range of metals in the ore, the mountain has been predominantly mined for copper. Archaeological evidence suggests that mining activity has been present on the site for approximately 4000 years, and around the time of the industrial revolution, circa 1750, it was Britain's and one of the World's primary sources of copper. A range of treatment technologies for the principal Parys Mountain discharge have been reviewed including active treatment using standard chemical precipitation of metals and long sea outfall without treatment. The regulatory framework to achieve compliance is detailed by the requirements of the European Water Framework Directive. The CAPEX and OPEX associated with conventional lime treatment and uncertainty about the success of passive treatment drives the research and development of novel approaches to treating problematic discharges without excessive cost.

Aims

The key aims of the present study were to (i) examine the interaction of mine water with seawater (ii) to determine whether this presents a viable potential treatment method for removing dissolved metals. There is a paucity of studies that examine the interaction of mine water with seawater, exceptions include Braungardt et al. (2003) and Achterberg et al. (2003) who studied AMD / seawater interactions in estuary systems. There is also no mention of seawater as a reagent in water treatment with the exception of the study by Muraviev et al. (1997) which examined the use of seawater as a reagent to regenerate ion exchange resins used in mine water treatment.

Figure 1 Parys Mountain mine site, Anglesy, UK

METHODOLOGY

Field experiments were undertaken to determine the ratio of sea water to mine water required to raise the pH to 7 and determine any concurrent removal of dissolved metals. Mine water neutralization experiments were carried out using water directly from the Dyffryn Adda Adit. Each ratio of mine water to seawater mixing (1:1 to 1:90) was conducted as a separate experiment rather than sequentially adding seawater. pH, DO, Redox potential (presented corrected to v. SHE) were measured in the field using a Hanna HI 9828 Multiparameter probe throughout the process and water samples for dissolved metals analyses were taken at the different stages. Acidity/Alkalinity and anion determination ion (using IC) were carried out in the laboratory. In a second round and third round of neutralization experiments, air was bubbled through each mine water/seawater mixture (using a 12V air compressor) for 10 minutes. In addition to aeration, in the 3rd round of neutralization experiments the seawater was reacted with limestone chippings (4 – 10 mm) for 24 hours prior to the mixing experiments. All water samples for metals analyses were filtered (0.45 μm) and acidified with 1ml of 10% nitric acid, diluted x 10 and analysed by ICP-MS.

RESULTS AND DISCUSSION

Mine water neutralization

The water quality parameters of the Parys Mountain mine water were as follows on the two sampling occasions: pH 2.37, Eh 419 mV, pH 2.10, Eh 402 mV and acidity 1786 mg/L. Corresponding data for the seawater used was as follows, pH 8.14, Eh 300 mV. The seawater used in the aeration experiment was pH 7.50, Eh 290mV and a third batch of seawater attained a pH of 8.26 and Eh of 215 mV on 24 hour contact with limestone chips. Fig 2 shows the results of mixing 1 part mine water with increasing amounts of seawater. It can be seen that neutralization to pH 7 requires 90 parts seawater to 1 part Parys Mountain mine water when simply mixed. If the mixture is aerated for 10 minutes after the seawater addition a reduction can be seen in the volume of seawater required to bring the pH to 7 (MW:SW of 1:40). This is probably due to stripping of dissolved CO_2 from the mixture as it is formed during the reaction of HCO_3^- in the seawater with H^+ in the mine water. The increase in alkalinity (116 to 182 mg/L as $CaCO_3$) imparted to the seawater by soaking it in limestone for 24 hours explains the reduction in the volume of this pretreated seawater required to reach pH 7 (MW:SW of 1:25). The mine water flow at Parys Mountain is cicra 10 L/s. An upper estimate of a viable seawater mixing ratio for use in treatment is 1:10 (MW:SW) which would result in a combined flow of 110L/s (comparable to some of the larger coal mine drainage treatment flows in the UK). It can be seen that at 1:10 ratio that the pH values are 4.9, 5.33 and 5.79 respectively.

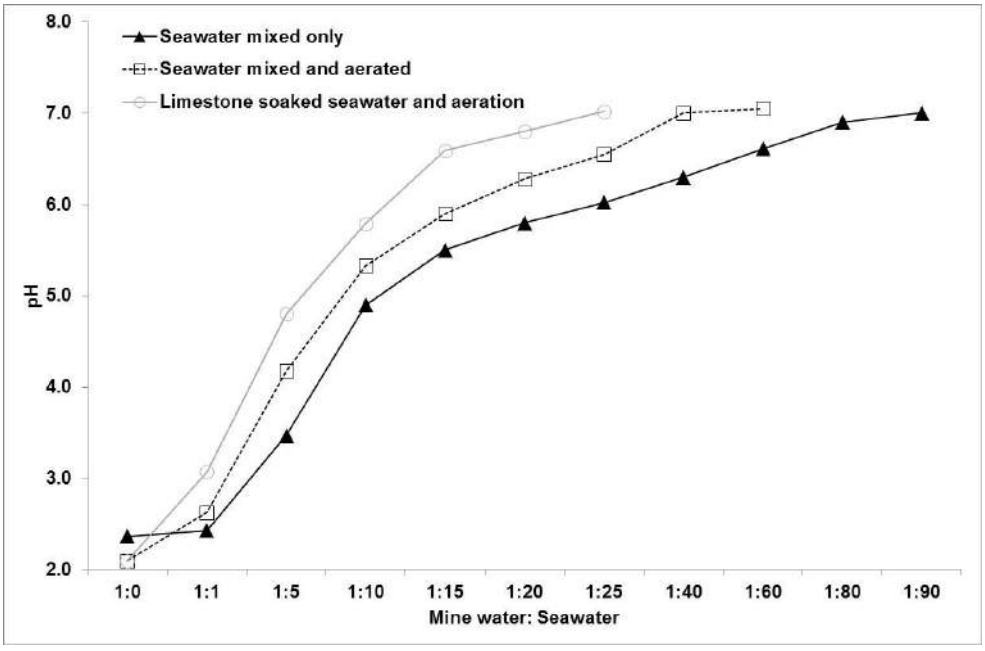

Figure 2 pH of mine water and seawater mixtures

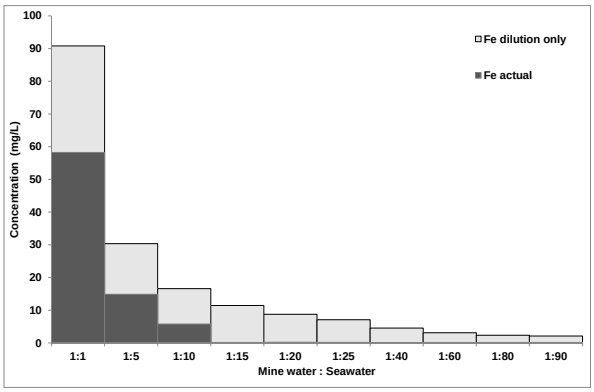
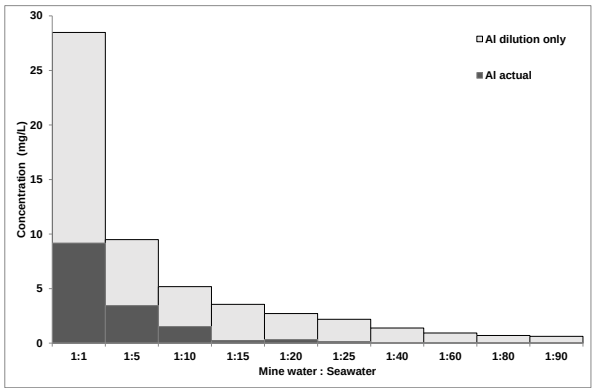
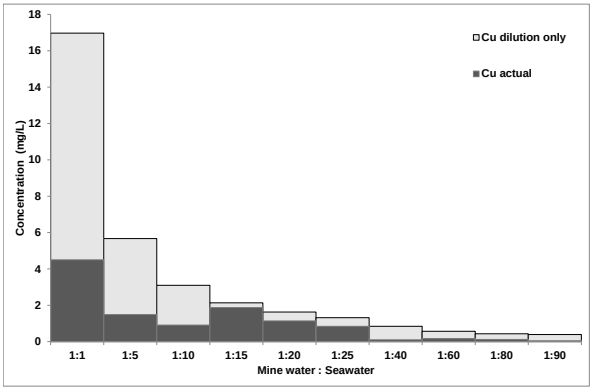


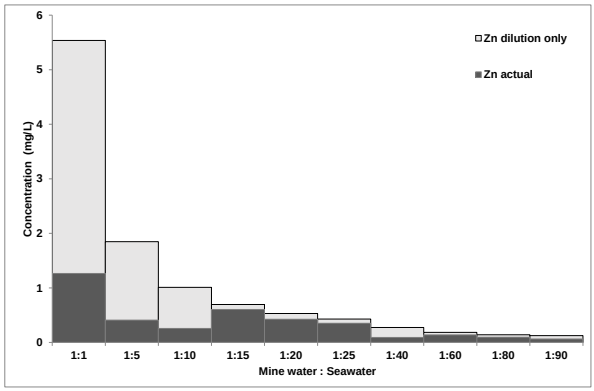
(a) Fe



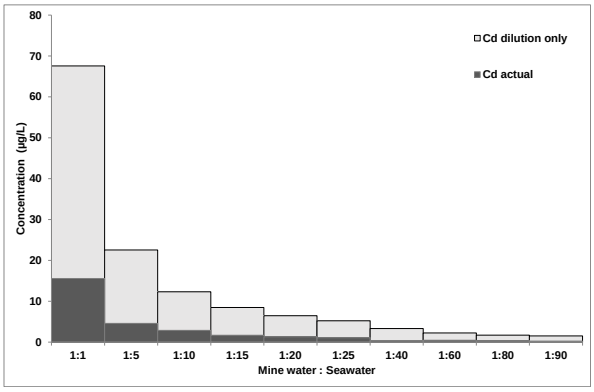
(b) Al



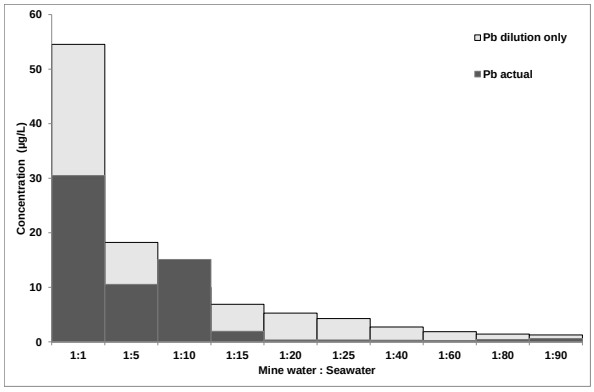
(c) Cu



(d) Zn



(e) Cd



(f) Pb

Figure 3 Residual dissolved metals after mixing with seawater at different ratios. Shown are concentrations predicted from dilution of mine water and actual measured concentrations.

Metals removal

Mixing of the mine water with equal parts seawater led to an instantaneous colour change from colourless to orange indicative of precipitation of iron, with higher proportions of seawater the orange colour was less detectable due to the high volume of seawater. As the pH increased, metals began to precipitate out and form a layer on the bottom of the mixing container. The resultant settled sludge can be seen in Fig 4 at the base of the reaction vessel. Fig 3 shows the concentrations of residual dissolved Fe, Al, Cu, Zn, Pb and Cd in solution after mixing with various amounts of seawater. Since when creating mine water and seawater mixtures the high concentrations of metals in the mine water are diluted, each graph also shows the decrease in concentration expected by dilution alone. It can be seen that in all cases (except for Pb at a ratio of 1:10) at all dilution ratios, the residual dissolved metals concentrations are considerably lower than by simple dilution indicating that metals have been removed from solution during mixing with seawater. For Fe (Fig 5) it can be seen that 36% of the dissolved Fe is removed by simple mixing 1:1 with seawater, this indicates (also suggested by the observed colour change) that an Fe(III)-bearing precipitate formed, which also buffered the pH (only a small change in pH observed (see Fig 2). 92 – 99% of Fe is removed at ratio of 1:15 and above. 68 % of the Al is removed by mixing 1:1 with seawater, with 88 – 99 % of the Al removed above 1:15 (where the pH < 5.5) as expected from the solubility of Al. The removal of Fe and Al at1:1 ratio whilst the pH is low suggests the precipitation of an Fe-Al mineral, possibly jarosite-alunite. PHREEQC modelling with the mine and seawater compositions demonstrates that precipitation of K-jarosite can account for the observed decrease in Fe concentration.

Figure 4 Precipitate formed from mixture of mine water with seawater can clearly be seen at the bottom of the reaction vessel.

74% of Cu (Fig 4 (c) and Fig 5) was removed from solution by mixing 1:1 with seawater. Of note is the variable Cu removal; a high removal at 1:1 through to 1:10, very low removal of 12% at 1:15 though to a maximum Cu removal observed for MW:SW ratio of 1:40. This behaviour is also observed with Zn, with 77% being removed at 1:1, and the highest removal between mixing values of 1:1 and 1:10, whilst lows of 13% removal occurred at 1:15, and removals did not recovering above this ratio. This behaviour is indicative of complex adsorption behaviour, whilst there is an abundance of Fe/Al precipitates to sorb to, it is likely that at the pH reached 5 and above that

competitive sorption by the swamping excess of ions in the seawater outcompete Cu and Zn for sorption sites on these precipitates. Achterberg et al (2003) found that AMD source metals remain in the dissolved phase in an estuary (albeit at much lower concentrations). 77% of the dissolved Cd is removed by mixing 1:1 with seawater and removal thereafter remains reasonably constant with a high of 88% removal at ratio of 1:40. Why Cd behaviour is different to Zn and Cu is unknown but note the difference in magnitude of the starting concentrations. The removal of Cu, Zn and Cd at low pH at low mixing ratios may be due to the suspected jarosite-alunite precipitation. Cu, Zn, and Cd are known to be able to substitute into the jarosite-alunite structure.

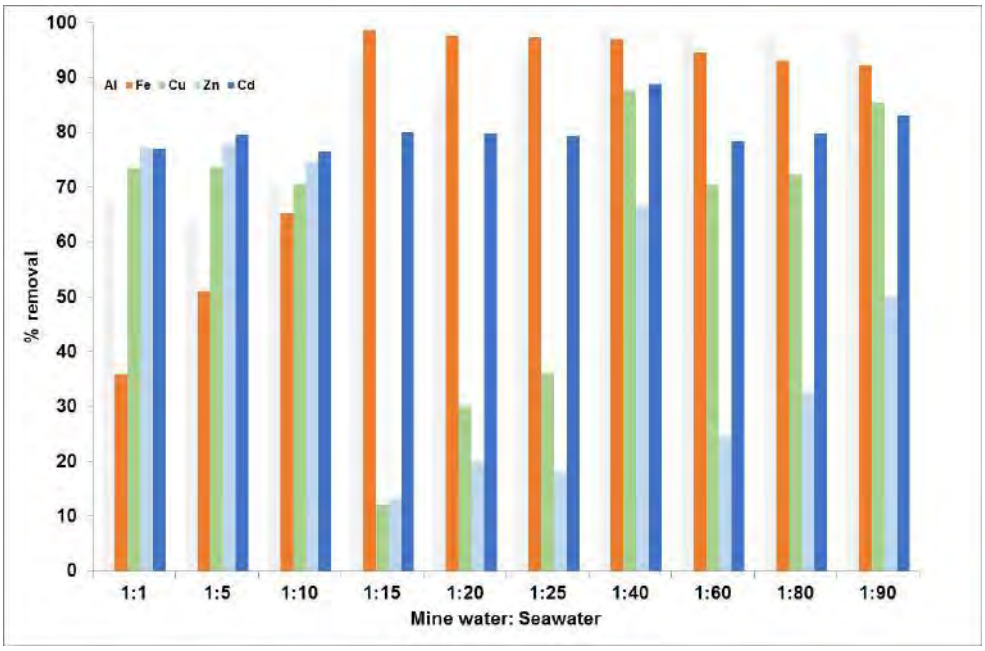


Figure 5 % removal of metals from solution upon mixing with different ratio of seawater

CONCLUSION

Mixing seawater with Parys Mountain AMD at ratios between 1:1 to 1:90 results in the removal of dissolved metals Fe, Al, Cu, Pb, Zn and Cd from solution. Cu and Zn showed decreased removal at certain ratios thought to be due to competitive sorption between Cu and Zn and seawater cations such as Mg^{2+}. This may have significant implications for the fate and transport modelling for AMD releases to sea. Neutralization of the AMD occurs as the mixing ratio is increased. Incorporating aeration, and contacting the seawater with limestone chips decreases the amount of seawater required to raise the pH of the mine water/seawater mixtures. Mixing of mine water with seawater in ratio 1:1 was found to give the following quoted as load removal with residual metal concentration in parentheses: Cd 77% (16 µg/L); Zn 77% (1.3 mg/L); Cu 74% (4.5 mg/L); Al 68% (9.2 mg/L) and Fe 36% (58 mg/L). Clearly the load removal is reasonably good at simple mixing ratio of 1:1 but the residual concentrations are relatively high.

Feasibity of use for AMD treatment at Parys Mountain

Treatment of Parys Mountain mine water (or other similar discharges close to the sea) is likely to comprise mine water capture, treatment and final discharge to the sea. The feasibility of using seawater as a reagent in mine water treatment would depend upon the regulatory framework for the discharge. Clearly if stringent concentration-based discharge consents were imposed then mixing (1:1) with seawater will not satisfy these consents (mixing at higher ratios might), however if the aim is to reduce metals loading to the coastal water for as low a cost as possible then seawater mixing and removal of precipitated metals may be a promising avenue to explore further. It should be noted that the mixing with seawater removes metals from solution, for full treatment a suitable liquid/solid separation would be required in the treatment train. For example settling ponds, VFRs (Sapsford et al., these Proceedings; Sapsford et al., 2007) or reedbeds. Thus a full system would comprise a pump and piping for seawater abstraction, a mixing chamber for seawater (perhaps contacted with limestone in a limestone drain to boost alkalinity) and mine water followed by the selected settling/filtration system. If pumping of seawater was not an option, there might be scope for a tidally driven mixing system which would further reduce costs.

ACKNOWLEDGEMENTS

The authors wish to thank Natural Resources Wales for the financial support and supporting data for this study.

Acid Drainage Treatment Using Phyllite Rock in an Underground Mine

José Santos, Alejandrina Castro, Angélica Cervantes, Ángeles Neri, Juan Goslinga and Guadalupe Isidro
Universidad Nacional Autónoma de México

ABSTRACT

Tizapa mine is located in the State of Mexico, Mexico, the ore deposit is volcanogenic and its mineralization consists of Fe, Zn, Pb, Cu and As sulfides and Ag sulfosalts. Pyrite is the most abundant sulfide mineral and is found in massive and disseminated form. The host rock is schist and graphitic phyllite, their composition is mainly quartz, plagioclase, chlorite and muscovite; but the phyllite also has abundant calcite as filling fissures. Presence of water in the underground mine generates acid mine drainage (AMD) in old working areas. Water source was evaluated by testing soil infiltration, permeability and fracturing of the rock. AMD pH varies from 2.4 to 3.4; it has high conductivity and soluble concentrations of Fe, Al, Cu, Cd, Mn, Zn and sulfates. The flow varies from 0.7 L/s to 1.7 L/s and the presence of water is mainly associated to an upper aquifer. AMD drains down a ramp and it is directed to an active treatment plant inside the mine. Treatment involves raising the pH using sodium carbonate to a 5.5 value. Phyllite associated with calcite allows proposing a passive treatment system alternative to control the AMD. The objective of this work is to develop a passive system using phyllite rock to neutralize the AMD within the mine to replace the current active treatment plant. Stirring batch tests were conducted to raise the pH to values between 6.2 and 6.6. Removal of 100% (Fe, Al, and Cu), 19-40% (Cd), 0-32% (Mn) and 4-36% (Zn) was achieved. Currently, the research is focused on the design of an open canal system with phyllite to install it in different parts of the mine and force the AD to flow through it.

Keywords: Acid mine drainage, passive treatment, phyllite rock, underground mine

INTRODUCTION

Acid mine drainage (AMD) is a natural phenomenon that occurs in mining working areas or waste deposits where sulphide minerals have been exposed to environmental conditions of weathering (Lottermoser, 2007). There has been much research on the development of treatment methods for the control of AMD, mainly into so-called passive treatments (López et al., 2002; Johnson et al., 2005). Some of the main passive treatment methods have been applied to AMD such as limestone canal systems (Alcolea et al., 2012) or permeable reactive barriers (Macías et al., 2012). These applications have been made to treat acid drainage generated in waste deposits, or acid drainage which comes from mining works and receives treatment outside of the mine. However, little research has been done on controlling acid drainage inside mines which are still in operation and where this may have further effects on the aquifers. The poor quality water in abandoned mining areas is partly associated with the generation of acid drainage from mining works (Younger et al., 2002; Wolkersdorfer, 2008). Tizapa mine is located in the State of Mexico, Mexico (Figure 1). The ore is a volcano-sedimentary deposit of massive Zn-Pb-Cu with Ag and Au values sulphide mineral (Coremi, 1996; Alfonso et al., 2011). Mineralization consists mainly of pyrite, sphalerite, chalcopyrite, arsenopyrite, pyrrhotite and freibergita. In old working areas located nearest to the surface, AMD is being generated by the presence of water, coming primarily from shallow aquifers and surface infiltration from rainwater. Inside the mine AMD is drained by canals leading to a treatment plant where it is then neutralized by a solution of sodium carbonate. The neutralized water is used for mineral processing.

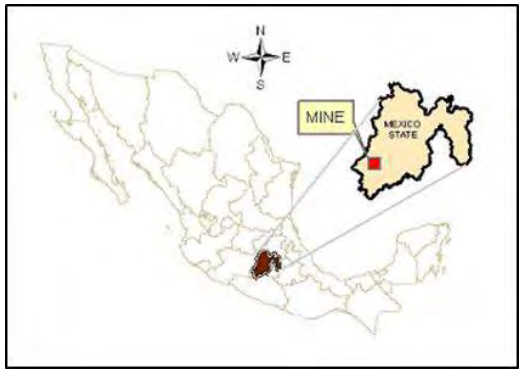

Figure 1 Mine location

Stratigraphy of the area consists of metamorphic rocks from the Triassic-Jurassic: phyllites and gneisses; above these, it is a set of metavolcanic rocks consisting of phyllites and schists of chlorite and sericite. Over the metamorphic rocks, lies a group of Cretaceous rocks: limestone and clastic rocks. Finally Quaternaries conglomerates and basalts cover the volcano-sedimentary sequence (Alfonso et al., 2011). The host rock associated to the ore deposit is chlorite and sericite schist at the base and graphitic phyllite at the top (Figure 2). Phyllite rock has abundant content of calcite mineral ($CaCO_3$), which allows considering its usefulness in a treatment system to neutralize the AMD. Also, near the mine there is a small outcrop of limestone which can be used for treatment too.

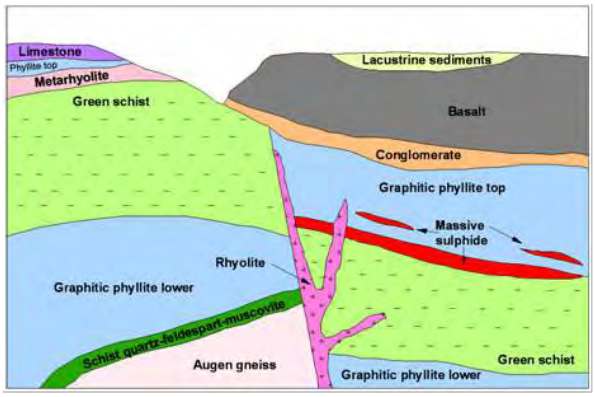

Figure 2 Mine stratigraphy and rocks associated to ore deposit

The aim of this work is to develop a passive treatment system using the phyllite rock, which could be installed inside the mine to control the AMD. Currently, work is carried out at laboratory level and conditions inside the mine are under study for the system installation.

METHODOLOGY

Identification and measurement of the AMD

Walks through the mine were performed to identify the AMD generating sites. The pH at each of these AMD generating sites was measured and located on the mine maps. The AMD flow rate was estimated by using the volumetric gauging method at each of the generating sites. The measurements were made three times, each one at different seasons of the year; the first one in May (end of low water season), the second one in July (in the middle of rainy season) and the third one in September (end of rainy season).

Water source

To determine from where the mine water is coming, analysis of the available information on rainfall (registered by a mine's weather station) and aquifers located in the area (information generated by the Water National Commission of Mexico) were conducted. Three infiltration tests were performed on the soil at the mine's surface, and the watershed runoff rate where the mine is located was determined. Furthermore, permeability tests were conducted on samples of three different rock types recovered by drilling cores: phyllite, shale and tuff. Finally, an analysis of the rock's fracturing, in places where acidic water is generated, was made.

AMD and rock characterization

Four mine's AMD samples were taken and analyzed to obtain the pH, electrical conductivity, and the concentration of major ions and trace elements. Trace elements were determined by Optical Emission Spectrometry with Inductively Coupled Plasma (ICP-EOS) on a Perkin Elmer instrument; and major ions by ion chromatography using an 883 Basic IC plus Metrohm chromatograph.

Three phyllite rock samples were taken inside the mine and a limestone sample was taken from an outcrop located outside the mine. The mineralogical composition of the rocks was determined by optical microscopy (parallel light and polarized light) and X-ray diffraction on a Shimadzu Lab X XRD-6000 equipment. The metal concentration was obtained by XRF on a Siemens SRS 3000 instrument. An analysis by scanning electron microscopy coupled with x-ray spectrometry by dispersive energy (SEM-EDS) was carried out.

Batch tests in flasks

Preliminary laboratory tests were made in batches; phyllite rock with acid drainage was stirred in 250 mL flasks at 200 rpm. During the first stage, the parameters evaluated were, the rock's grain size (2, 2.36 and 3.35 mm), the stirring time (18, 24 and 36 hours) and rock/AMD ratio (1/5, 1/10 to 1/20). With these tests, the schist's ability to neutralize acidity was determined. In the second stage, batch testing continued to determine the minimum time required to achieve a neutral pH; for this stage only rocks with a grain size of 3.35 mm was used, but the rock/AMD ratios remained (1/5, 1/10 and 1/20). The stirring was stopped every five minutes to measure the pH; tests were stopped when a pH value between 5 and 6 was achieved. The solutions obtained after neutralization were analyzed by ICP-EOS.

In a third stage, two step stirring tests were conducted. In the first step the AMD was stirred with phyllite rock until a pH value of 5 was reached, and in the second step the resulting solution was stirred with limestone to raise the pH above 7. The final solutions obtained were analyzed to determine the concentration of trace elements and major ions. Residual sediments obtained in both steps were analyzed by scanning electron microscopy coupled with x-ray spectrometry by dispersive energy (SEM-EDS) on a Hitachi Tabletop TM-1000

Filled cells testing

Currently, tests are carried out using an acrylic cell filled with the phyllite rock, through which the AMD flow passes. The cell can hold 3.5 L and 5 kg of rock with a size between 4.75 and 12.5 mm (Figure 3). The aim of these tests is to evaluate the retention time needed to raise the pH; therefore, the flow rate passing through the cell varies (2.5 to 12.5 ml/s).

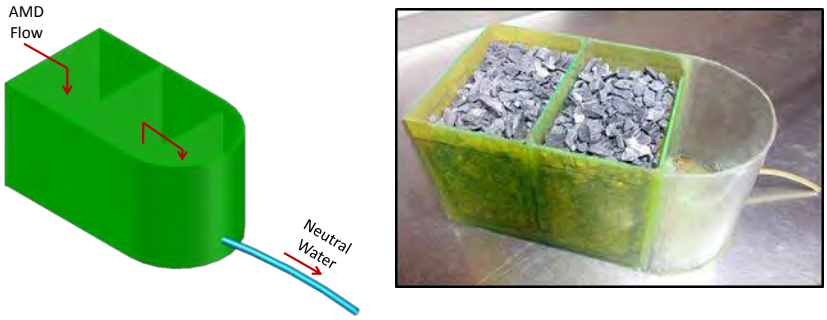

Figure 3 Testing in rock filled cell (currently in development)

The results are positive so far; however, are not reported in this paper because they are not yet considered conclusive. After these tests, the next step will be to upscale the system in order to perform a pilot test inside the mine.

RESULTS AND DISCUSSION

AMD generation

Eleven sites where AMD is generated were located within the mine, all of these connected to old mining works located between levels 1226 and 1040 m.a.s.l., and corresponding to the mine zone nearest to the surface. Measured pH varies from 2.4 to 4.6. All AMD runoff is driven by canals to the principal ramp where it is lead to the treatment plant.

The measured flow of AMD in May was 0.73 L/s, in July was 0.95 L/s, and in September was 1.74 L/s. Neutral water runoff was also found inside the mine and flows obtained were 2.05 L/s in May, 2.27 L/s in July and 1.8 L/s in September.

Water source

Infiltration tests on soils show that infiltration rates are slow to moderate (0.078 to 2.07 cm/h). Furthermore, measured permeability in the rock samples is very low; the average value is between 4.8 E-10 cm/s and 5.09 E-06 cm/s.

In order to determine rainwater infiltration volume in the study area, the average rainfall data recorded at the mine's meteorological station was used, and for the runoff coefficient the Mexican regulations methodology (SEMARNAT, 2002) was used. Furthermore, the subwatershed area was measured in the zone where AMD is generated. It was determined that the water runoff coefficient is 0.184 and, considering that subwatershed area is 0.151 km^2, it was estimated that rainwater infiltration volume is 0.031 Mm^3/year.

The maximum value of water running inside the mine, measured in September 3.54 L/s (AMD plus neutral water), was considered as a constant throughout the year, giving an estimation of 0.112 Mm^3 of water running inside the mine pear year. Comparing this value with the calculated stormwater infiltration value of 0.031 Mm^3/year, the rainwater represents only 27.7% of the total water in the mine.

In Zacazonapan town (4 km away from the mine) it is reported that the Temascaltepec aquifer is 1 to 2 meters deep and has a 1368 m.a.s.l. elevation (Conagua, 2008). This aquifer provides water to the stream "El Ahogado" which runs next to the mine at an elevation of 1226 m.a.s.l., and so, it is interpreted that the aquifer water flows over the old mining works which generate AMD.

Structural analysis of the rock where AMD is generated shows a high degree of natural fracturing at 1052, 1100 and 1200 m.a.s.l. elevations in two preferred directions: NW-SE and NE-SW.

From the information presented above it has been concluded that rainwater contribution to the water running through the mine is minimal, due the low permeability of soil and rock. From the information available about the aquifer, it is estimated that it runs close to surface level and above the mining works. Due the high fracturing level, water from the aquifer and rainwater flow through the fractures to the mining works thus generating AMD.

AMD and rock characterization

The pH values and electrical conductivity are shown in Table 1. The pH values obtained confirm the acidity of water and the high electrical conductivity is largely due the ions in solution and salts dissolved in water.

Table 1 Trace elements concentration in AMD

Sample	pH	EC (mS)	Al	Cd	Cu	Fe	Mn	Si	Zn
			mg/L						
DA 6	2.44	11.31	41	6	12	563	41	35	483
DA 6 - A	2.53	8.02	36	5	12	527	37	32	471
Pileta	2.9	4.72	9	2	2	178	26	17	363
DA 8	3.38	1.87	<LD	0.2	<LD	0.3	4	8	77

LD (mg/L): Al (0.08), Cu (0.12)

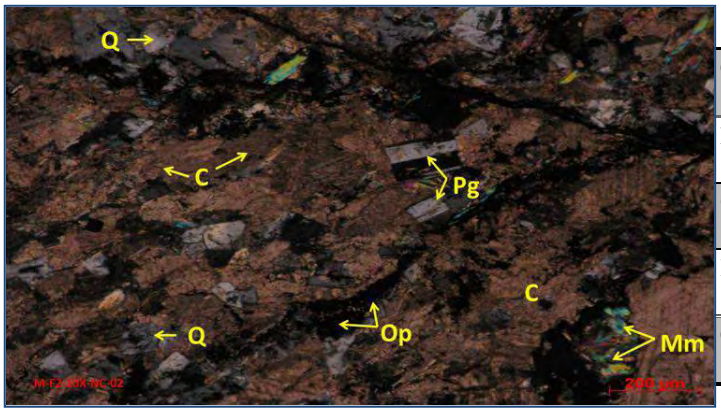
Significant concentrations of Al, Cd, Cu, Fe, Mn, Si and Zn were found (Table 1). Other elements, As, Cr, Mo, Sb, Se, Ti, Tl and V, were analyzed and are in concentrations below the detection limit.

Major concentrations of ions (Table 2) are high for Na, K, Ca and Mg cations due to the dissolution of silicate minerals present in the rocks which began to dissolve after the carbonates were consumed. A high concentration of sulphates indicates the chemical oxidation process of sulphides and is directly related to water soluble iron. Presence of chlorides is related to chlorite content in the schist rock.

Table 2 Major ion concentrations in AMD

Sample	Na^+	K^+	Ca^{2+}	Mg^{2+}	Cl^-	SO_4^{2-}
	ppm					
DA 6	228	21	438	1,759	92	18,732
DA 6 - A	197	4	369	1,674	82	16,555
Pileta	354	19	310	1,601	176	10,118
DA 8	114	14	252	380	35	2,896

Petrographic analysis showed that there is abundant calcite in the phyllite rock (Figure 4); however, the presence of plagioclase mineral is also interesting, since it is reported in literature that this could be used to neutralize AMD (Romero et al., 2007).



Op	Opaque minerals
Mm	Muscovite mica
C	Calcite
Pg	Plagioclase
Q	Quartz

Figure 4 Photomicrograph of phyllite rock 10 X magnification

XRD confirms that phyllite has high calcite content and abundant presence of plagioclase and micas. The mineralogy suggests that phyllite has potential to neutralize AMD. Limestone was also analyzed and dominance of calcite and quartz was observed; to a lesser extent, intermediate plagioclase and phyllosilicates (chlorite and mica) are also present.

Batch tests in flasks

In the first stage of the tests, pH values of 5.35 (3.35 mm, 18 hours, 1/20) to 7.36 (2 mm, 36 hours, 1/5) were achieved. The neutralization process is enhanced with smaller particle sizes, lower rock/AMD ratio, and increased stirring time. Figure 5 shows only the pH increase using 3.35 mm particle size; as larger particle sizes will be needed when moving forward in the research.

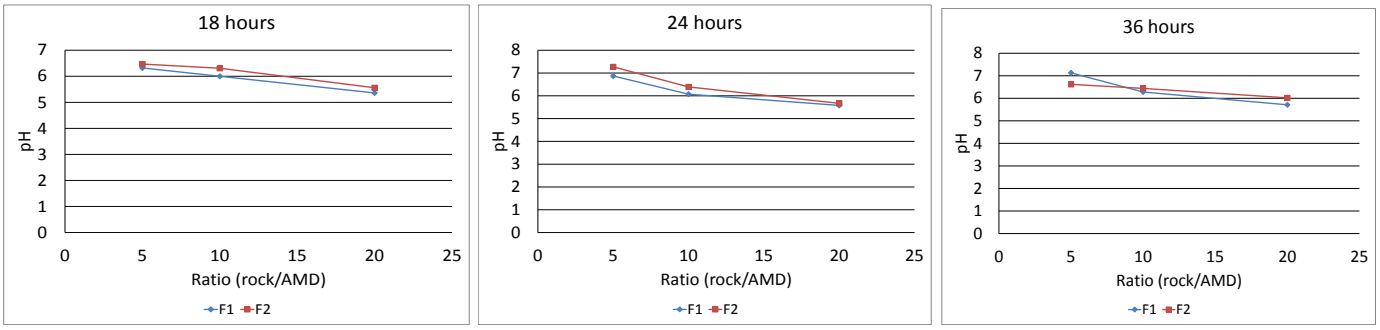


Figure 5 pH values reached in stirring tests with particle size of 3.35 mm

In the second stage of tests, the highest stirring time was necessary for the 1/20 ratio test, as 180 minutes were needed to reach a maximum pH value of 4.7. With the 1/5 ratio test, a minimum stirring time of 30 minutes was enough to reach a pH value of 5.55 (Figure 6).

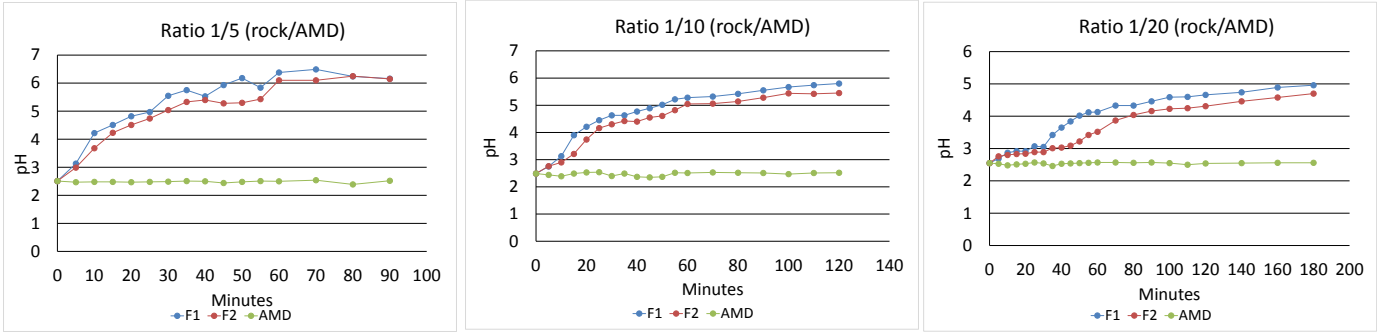

Figure 6 Minimum stirring times to achieve neutral pH values

Table 3 shows trace element concentrations in the solutions after neutralization; samples B-20, B-10 and B-5 correspond to acid drainage without treatment. A direct relationship between pH reached and rock/ AMD ratio is observed. The highest pH value was obtained with a 1/5 ratio. It is noted that with a 1/10 ratio, total removal of Fe, Al and Cu is achieved at a pH value of 4.97 (F1-10). Cd and Zn concentration decreases from pH values above 6.55 (F2-5), achieving at this value an 18% removal for Cd and 20% for Zn. In contrast, Mn remains practically at the same level, because this element requires pH values above 8 to precipitate (Luan, et al., 2012; Silva, et al., 2012.). Si removal is also high, between 65 to 76% with a 1/5 ratio.

Table 3 Trace element concentrations in neutralized solutions (second stage)

Sample	pH	EC (mS)	Al	Cd	Cu	Fe	Mn	Si	Zn
			mg/L						
B - 20	2.53	8.21	21	2	2	128	2	23	294

LD (mg/L): Al (0.08), Cu (0.12), Fe (0.01)

In the third stage, stirring was done in two steps, the first with phyllite rock and the second with limestone. Sample B corresponds to untreated AMD. Table 4 shows that pH values between 5.0 and 6.67 were reached with phyllite rock in the first step, and between 7.33 and 7.64 were reached in the second step with limestone rock. In the first step, 100% of Al, Cu and Fe was removed; and between 9 and 41% of Cd, 45 and 74% of Si, 2 and 12% of Zn and 0 and 32% of Mn, were removed. In the second step, almost 100 % removal of Cd was achieved, as well as a removal from 82 to 92% of Si, 95 to 99% of Zn and 89 to 97% of Mn.

Table 4 Trace elements concentration in neutralized solutions of 1st and 2nd steps (third stage)

Sample	pH		Al		Cd		Cu		Fe		Mn		Si		Zn	
			mg/L

LD (mg/L): Al (0.08), Cd 80.02), Cu (0.12), Fe (0.01), Mn (0.007), Si (0.008) y Zn (0.007)

Concentration of Al, Fe, Zn and Mn in the phyllite rock, determined by XRF, were of 7.28%, 2.95%, 0.02% and 0.05%, respectively; in the after neutralization phyllite sediment photomicrographs (Figure 7 – A), it is observed an increase in the concentration of Fe (40.5%) and Zn (2.7%). The limestone rock has in its composition 3.69% of Al, 2.09% of Fe, 0.01% of Zn and 0.14% of Mn; the after neutralization limestone sediment photomicrographs (Figure 7 – B), also show an increase on Fe (2.5%), Zn (16.8%) and Mn (1.1%) concentrations. These results indicate that Fe, Zn and Mn are been retained in the rock's sediments after the neutralization of AMD.

At this stage it was determined that it is appropriate to use phyllite rock to increase pH to values between 5 and 6, and precipitate Al, Cu and Fe; then use limestone to raise pH above 7 and remove the largest portion of Cd, Mn and Zn.

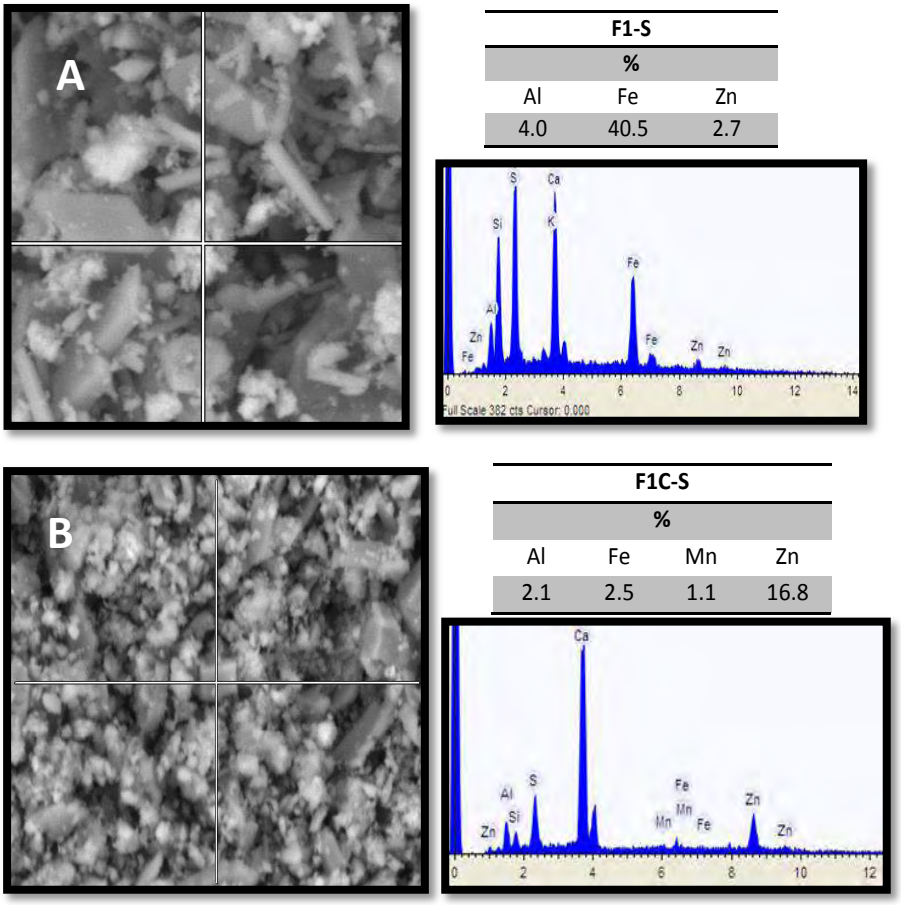

Figure 7 Photomicrographs obtained by SEM-EDS of phyllite (A) and limestone (B) sediments after neutralization.

CONCLUSIONS

The AMD inside the mine is generated in the old mining works, close to the surface level, due to the contact of exposed sulphide minerals with the water of a shallow aquifer and the rainwater flowing through fractured rock. It is possible to lead AMD through canals to the principal works of the mine for a subsequent treatment. The phyllite rock associated with the ore deposit is useful in neutralizing the AMD due to its high content of calcite. Laboratory tests results show that it is possible to achieve pH values between 6 and 7 with phyllite rock. The phyllite allows removal of 100% of Al, Fe and Cu at pH values between 5 and 6. Using limestone, available on an outcrop near the mine, it is possible to raise pH above 7 achieving removal of 100% of Cd, 95% of Zn and 89% of Mn. It is advisable to continue the tests with rock packed cells and then design a system that can be scaled to install it inside the mine.

Evaluation of Nanofiltration and Reverse Osmosis in the Treatment of Gold Acid Mine Drainage

Alice Aguiar, Laura Andrade, Wadson Pires and Miriam Amaral
Department of Sanitary and Environmental Engineering, Universidade Federal de Minas Gerais, Brazil

ABSTRACT

With the rising restrictive discharge standards, the reuse of effluents such as acid mine drainage (AMD) has become a viable option both environmental and economically. Membrane separation processes especially nanofiltration (NF) and reverse osmosis (RO) produces a permeate with high quality, which can usually be reused in the process. Therefore, the purpose of this study was to compare nanofiltration and reverse osmosis treating an acid mine drainage effluent from Minas Gerais, Brazil. Initially, a pretreatment study was conducted to compare the performance of the NF when operating with raw effluent and two pre-filtered effluents: one with qualitative filter and another using microfiltration. The performance was evaluated in terms of fouling and effluent quality (ions concentration, total solids and conductivity). The results showed that the type of pretreatment does not considerably affect membrane fouling, and effluent average flow was between 73 and 86% of the flow with water. The retention efficiency of major contaminants was very high: greater than 79% for solids, 98% for conductivity and 99% for sulphate. Moreover the pretreatment improved effluent quality in all aspects analyzed. Secondly, a comparative study of three membranes of NF and two membranes of RO was conducted. The membranes of NF analyzed were NF90, NF270 and MPS-34. The membranes of RO analyzed were TFC-HR and BW30. All five membranes showed high pollutants retention (sulphate >99% and conductivity >84%). The pollutants retention efficiencies of nanofiltration membrane (NF 270) were comparable to the retention efficiencies of the RO membranes; yet it was associated with the highest permeate flux (10 and 88 L/h.m² for RO and NF membrane respectively).

Keywords: Gold acid mine drainage; Nanofiltration; Reverse osmosis

INTRODUCTION

Gold is a substance of extreme important as monetary reserve and much of what was produced throughout history is now stored on national central banks or National Treasury of many countries. Its importance is also associated with the production of jewelry and its use in the electronic industry as well as its demand for dental and medical purposes (GFMS, 2014). Nevertheless, despite the clear economic benefits, exploitation and processing of gold are associated with various environmental impacts. Acid mine drainage (AMD) is one of the main environmental impacts related to gold mining, due to the difficulty of AMD control once initiated, the high volumes involved and associated treatment costs, and its perpetuity.

Mining effluents are usually treated by neutralization, precipitation and sedimentation (Langsch et al., 2012), although other technologies such as anaerobic bioreactors (Wildeman et al., 2006), sorption (Acheampong & Lens, 2014), coagulation and flocculation (Oncel et al., 2013), and crystallization (Fernández-Torres et al., 2012) may also be used. However, these methods may be insufficient to adjust the effluent properties to meet the discharge and/or reuse standards, require high consumption of chemical products, and may generate large sludge volumes (Wang et al., 2007).

Membrane separation processes (MSP) are promising technologies for treating acid mine drainage (AMD). According to Habert et al. (2006), MSP are technologies that use a selective barrier (membrane) that under a driving force can promote the separation of the components of a solution or suspension. Membrane separation process has significantly developed over the past few years, since it has unique characteristics compared to conventional separation processes. Some example of MSP characteristics are that they do not need phase transition to perform components separation (as in distillation), thus contributing to energy savings; do not require the addition of chemicals (as in liquid-liquid extraction); have high selectivity; can be easily scaled since they are modular; do not require extensive workforce, etc.

Among the MSP, nanofiltration (NF) and reverse osmosis (RO) stand out. These process are effective technologies to remove salts and metals from aqueous medium (Al-Rashdi et al., 2013) presenting high potential to treat mining effluents for reuse.

NF process is an intermediate process between RO and ultrafiltration (UF) that may retain dissolved molecules with molecular weight ranging between 200 and 1.000 g/mol and multivalent ions (Yu et al., 2010). Many works have shown that NF is an efficient system for secondary or tertiary treatment of effluents intended to supply water for industrial, agricultural and/or indirect reuse as drinkable water (Acero et al., 2010). The use of NF has been increasing due to advantages such as the ease of operation, reliability, low power consumption and high efficiency (Fu & Wang, 2011).

RO systems use membranes that are permeable to water, but substantially impermeable to salts, and therefore are suited to separate ions, dissolved metals and organic molecules of low molar mass (Baker, 2004). One of the main applications of RO membranes is seawater desalination, which accounts for more than 20% of all desalinated water supplied around the world (Fu & Wang, 2011). Moreover, RO membranes have become a promising technology for industrial effluents reclamation (Qi et al., 2011; Kurt et al., 2012).

Sierra et al., 2013 studied nanofiltration process for treating an acid mine drainage from an abandoned mercury mine. It was able to remove up to 99% of aluminum, iron and arsenic content,

and 97% of sulfate content. Chan & Dudeney, 2008 evaluated the treatment of wastewater from gold ore bioleaching treated by neutralization, precipitation and sedimentation followed by a post-treatment with GE Osmonics TFM-100 RO membrane. It was found that more than 90% of the arsenic that had not been removed by the first treatment was retained by the membrane. Another study evaluated NF and RO membrane performance to treat two synthetic acid mine drainage, including one with higher metal content (Al-Zoubi et al., 2010). It was found that NF membrane was more suited for such use as it handled higher permeate flux at lower power consumption, although its rejections were smaller than in RO membrane treatment.

Despite the successful cases using different membranes for treating mining plant effluents, there remains the need for further examination of the most appropriate system types, that is, NF or RO, membrane selection and operating conditions such as type of pre-treatment for each specific application. Such assessment would be targeted to find ways to increase retention efficiencies, decrease membrane fouling formation, reduce costs, and optimize the whole system.

Therefore, the aim of this study was to evaluate the use of MSP in the treatment of gold AMD. Initially, a study of pretreatment requirement was conducted. It compared the performance of the NF when operating with raw effluent, an effluent pre-filtered with qualitative paper filter (Fmaia - 8μm) and an effluent pre-filtered using microfiltration. After defining the appropriate pretreatment, the operation of two RO and three NF membranes was compared and the best membranes for the system studied were selected.

METHODOLOGY

Acid mine drainage

Acid mine drainage was collected in a gold mining company in the state of Minas Gerais, Brazil which has two underground gold mines and an industrial processing plant. AMD was collected in the underground mine, on the fourth level below ground. AMD characteristics vary throughout the year; the main characteristics of the AMD used in this study are presented on Table 1.

Table 1 AMD main characteristics

AMD	pH	Conductivity (μS/cm²)	Total solids (mg/L)	Sulfate (mg/L)	Chloride (mg/L)	Calcium (mg/L)	Magnesium (mg/L)
First collection	3.35	2,841	2,409	985	4.5	323	97
Second collection	2.74	2,744	2,926	1,406	1.6	282	125

Unit description

For the nanofiltration and reverse osmosis filtration tests a bench scale unit was used. The system is comprised of: one supply tank (ST); one pump; one valve for pressure adjustment; one rotameter; one manometer; one thermometer and one stainless steel membrane cell. Figure 1 shows a schematic of this unit.

The stainless steel membrane cell has 9.8 cm in diameter, providing a filtration area of 75 cm². The membranes tested were properly cut before being placed in the cell. A feed spacer was placed over the membrane to promote flow distribution. Permeate flow was measured by collecting the volume

of permeate in a measuring cylinder over 60 seconds for nanofiltration tests and 180 seconds for reverse osmosis tests. Permeate was collected for analysis and retentate was returned to the supply tank.

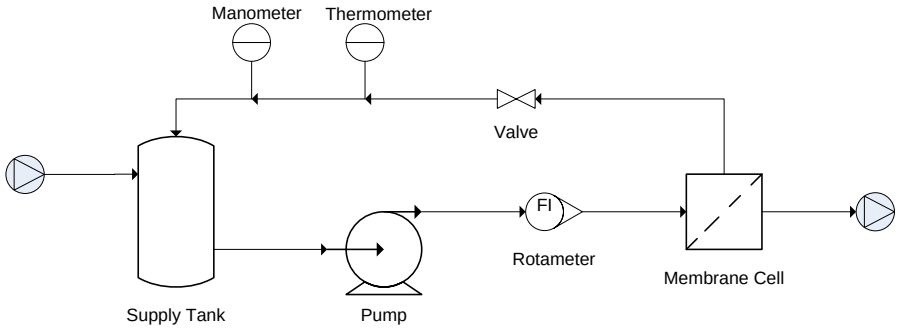

Figure 1 Schematic of NF and RO unit

Pretreatment study

Initially, a pretreatment study was conducted to compare the performance of the nanofiltration when operating with raw effluent and two pre-filtered effluents: one with qualitative filter paper (Fmaia - 8μm) and another using microfiltration. Microfiltration (MF) was performed using a submerged membrane module provided by Pam Membranas Seletivas Ltda., with filtration area of 0.04 m^2, average pore diameter of 0.4 μm and polyetherimide-based polymer. MF occurred at a pressure of 0.7 bar up to a recovery rate of 60%.

The nanofiltration tests were carried out with AMD from the first collection and used the NF90 membrane provided by the supplier Dow Filmtec. Initially, the membrane was washed in ultrasound bath first with citric acid solution at pH 2.5 followed by 0.1% NaOH solution for 20 minutes each. Water permeability at 25°C (K) was obtained by monitoring the normalized value of the stabilized permeate flux of clean water at pressures of 10.0; 8.0; 6.0 and 4.0 bar. Normalization to 25°C was accomplished by means of a correction factor calculated by the ratio of the water viscosity at 25°C and the water viscosity at the temperature of permeation:

$$K = \frac{J \cdot \mu(T)}{\Delta P \cdot \mu(25^{\circ}C)} \quad (1)$$

Where J is the permeate flux in $m^3/h.m^2$, μ is the permeate viscosity (water) in $N.s/m^2$ and ΔP is the system pressure in Pa. With the normalized water permeability, the intrinsic membrane resistance to filtration (R_m) was calculated:

$$R_m = \frac{1}{K \cdot \mu(25^{\circ}C)} \quad (2)$$

The nanofiltration of the acid mine drainage was carried out for two hours at fixed pressure of 10 bar, feed flow rate of 2.4 LPM and temperatures ranging between 25 and 35°C. Permeate flux and temperature were measured each 15 minutes. Final accumulated permeate was collected for analysis. Retentate was returned to the supply tank. The fouling resistance to filtration (R_f) was determined with the values of permeate flux and temperature obtained at the end of the experiment, as demonstrated by the equation:

$$R_f = \frac{\Delta P - \Delta \pi}{\mu(T) \cdot J} - R_m \quad (3)$$

Where (ΔP- Δπ) is the effective pressure of the system in Pa and Δπ is the osmotic pressure difference between the retentate and the permeate in Pa. The Δπ was calculated using the software ROSA 9.1 (The Dow Chemical Company, USA). The initial concentration of the main ions in solution inserted in the software were: 2,000 mg/L of sulfate, 10 mg/L of chloride, 150 mg/L of magnesium and 593 mg/L of calcium. These ions concentrations were typical values obtained for the AMD.

Feed and permeates were analyzed for conductivity (Hanna conductivity meter HI 9835), total solids and ions concentrations (Metrohm 850 Professional IC, Herisau, Switzerland, equipped with column type Metrosep C4-100/4.0 and Metrosep A Supp 5-150/4.0), in accordance with the Standard Methods for the Examination of Water and Wastewater (APPA 2005).

Evaluation of different NF and RO membranes

A comparative study of three nanofiltration (NF) membranes and two reverse osmosis (RO) membranes on the treatment of AMD was conducted. The NF membranes analyzed were NF90, NF270 and MPS-34. The RO membranes analyzed were TFC-HR and BW30. Table 2 shows the main characteristics of these membranes as provided by the suppliers, unless otherwise specified.

Table 2 Membranes characteristics as provided by the suppliers

Characteristic	TFC-HR	BW30	MPS34	NF90	NF270
Supplier	Koch Membranes	Dow Filmtec	Koch Membranes	Dow Filmtec	Dow Filmtec
Membrane Material	Composite Polyamide	Composite Polyamide	Composite	Composite Polyamide	Composite Polyamide

Membrane evaluation procedure was similar to the pretreatment study procedure. First the AMD was filtered using the MF submerged membrane module provided by Pam Membranas Seletivas

Ltda., at a pressure of 0.7 bar and up to a recovery rate of 60%. All five membranes were then washed in ultrasound bath first with citric acid solution at pH 2.5 followed by 0.1% NaOH solution for 20 minutes each.

AMD nanofiltration was carried out up to a recovery rate of 10% (defined as permeate volume by initial effluent volume) at 10 bar pressure, 2.4 LPM feed flow rate and temperatures ranging between 25 and 35°C. Permeate flux, temperature and permeate accumulated volume were measured from time to time and final accumulated permeate was collected for analysis. Retentate was returned to the supply tank.

Feed and permeates were analyzed for conductivity (Hanna conductivity meter HI 9835), total solids and ions concentrations (Metrohm 850 Professional IC, Herisau, Switzerland, equipped with column type Metrosep C4-100/4.0 and Metrosep A Supp 5-150/4.0), in accordance with the Standard Methods for the Examination of Water and Wastewater (APPA 2005).

RESULTS AND DISCUSSION

Pretreatment study

The initial osmotic pressure of the acid mine drainage calculated using the software ROSA 9.1 (The Dow Chemical Company, USA) was 0.75 bar.

The NF90 membrane water permeability (K), membrane resistance to filtration (R_m) and fouling resistance (R_f) obtained according to Equation 1, 2 and 3 respectively are presented on Table 3. The variations on water permeability are usual and often occur due to minute variations on membrane characteristics or the effectiveness of the membrane cleaning.

Table 3 Water permeability, membrane resistance, fouling resistance and average ratio of effluent flux by clean water flux of the NF90 for each of the pretreatment studied

	Water permeability ($m^3/s.m^2.Pa$)	Membrane resistance (m^{-1})	Final fouling resistance (m^{-1})	Effluent flux by water flux (%)
Raw effluent	9.6×10^{-12}	$1.2 \times 10^{+14}$	$3.6 \times 10^{+13}$	86.3
Qualitative filter	1.7×10^{-11}	$6.6 \times 10^{+13}$	$3.9 \times 10^{+13}$	73.6
Microfiltration	1.1×10^{-11}	$1.1 \times 10^{+14}$	$4.3 \times 10^{+13}$	78.5

To minimize the influences that variations on water permeability could have on the comparison of the effluent permeate fluxes, it is usual to express the ratio of the effluent flux by the water flux. The average ratios obtained are shown on Table 3. The average permeate flux of the microfiltered effluent was 26.4 $L/h.m^2$. Sierra et al., 2013 obtained with the NF2540 membrane a permeate flux of approximately 45 $L/h.m^2$ for mercury AMD at an effective pressure of 10 bar and feed flow rate of 1,000 LPM. Besides the difference in the applied membrane characteristics, the increase in feed flow rate increases the shearing forces and decreases membrane fouling which could explain the difference in permeate flux.

Moreover the small variations on fouling resistance indicate that the AMD do not cause severe fouling during nanofiltration. This is corroborated by the low initial concentrations of fouling components such as suspended solids and organic matter in the feed solution. One might think

then that it is best to use directly the raw effluent. However, it is important to consider that the presence of small quantities of fouling components (such as suspended solids and organic matter) can directly increase the frequency of cleaning and maintenance and therefore reduce membrane lifespan. Moreover, an industrial effluent such as AMD varies greatly throughout the year, which could cause an increase in fouling components and consequently damage the system.

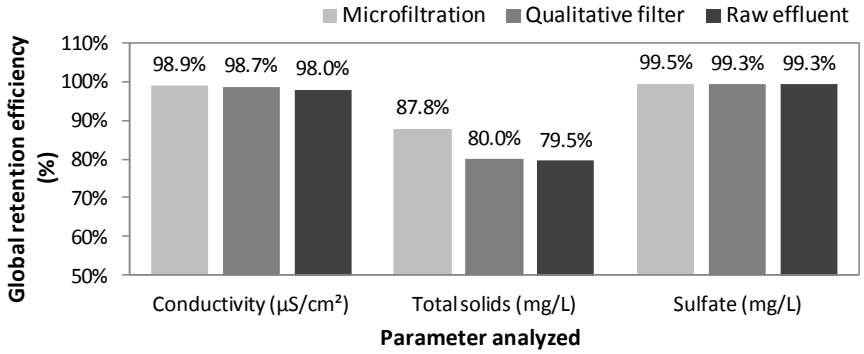

Figure 2 shows the global retention efficiencies of the main pollutants on the accumulated NF permeate for each pretreatment studied. These efficiencies comprised both the pretreatment efficiency as well as the NF efficiency and were called global retention efficiencies. All retention efficiencies obtained were very high, nevertheless it is observed that the stronger the pretreatment used, the better the final permeate quality. For instance, the total solids concentration on permeate with raw effluent was 495 mg/L, while the concentration with microfiltration was 293 mg/L, 41% smaller. The retention efficiencies for the microfiltered effluent were 98.9% for conductivity, 87.8% for total solids and 99.5% for sulfate.

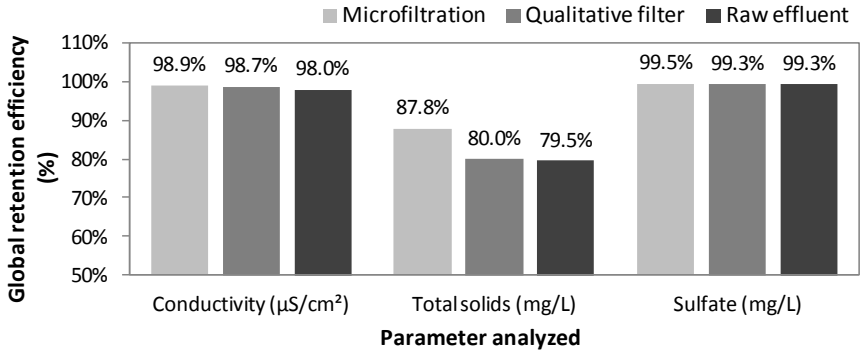

Figure 2 Pollutants retention efficiency for the three pretreatments studied

As the main objective of this treatment system is to obtain a permeate with quality appropriate for reuse as process water, the retention of sulfate and calcium must be optimized as these ions can precipitate in pipes and equipments, damaging systems. The increase in retention efficiency of sulfate corroborates that the use of microfiltration before the nanofiltration is ideal for the treatment system.

Evaluation of different NF and RO membranes

The normalized permeate fluxes for each of the five membranes as a function of effluent recovery rate is presented on Figure 3. The RO membranes (THF-HC and BW30) showed the lowest permeate flux during the filtration (the average permeate fluxes were 10.2 and 10.0 L/h.m² for THF-HC and BW30 respectively). These results are compatible with the structure of these membranes. RO membranes have a more closed polymeric structure, which increases membrane resistance and decreases permeate flux (Tu Nghiem et al., 2011). Among the NF membranes, the NF270 showed the highest permeate flux with average permeate flux of 88.6 L/h.m².

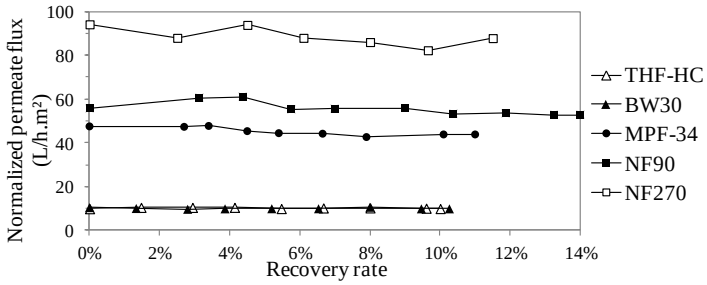

Figure 3 Normalized permeate fluxes of the five membranes as a function of effluent recovery rate

Table 4 shows the main pollutants final concentration of the accumulated permeates obtained for the five membranes tested. The final concentration of the permeate of the THF-HC membrane were the lowest for all parameters analyzed. This RO membrane is typically used on effluent treatment and water reuse due to its high efficiency (Fujioka et al., 2012). The BW30 membrane however showed higher permeate final concentration than the NF membranes studied. On the other hand pollutants concentrations of the NF membranes were only slightly higher than those of the THF-HC membrane. Permeate total solids may include other ions present in the AMD, especially monovalent ions which have smaller retention efficiencies.

Table 4 Pollutants final concentration on the permeate for the five membranes studied

	THF-HC	BW30	MPS-34	NF90	NF270
Conductivity (µS/cm²)	78	517	442	170	379
Total solids (mg/L)	38	849	295	146	207
Sulfate (mg/L)	2.2	9.7	4.1	4.5	2.6
Calcium (mg/L)	< 2.5	< 2.5	10.3	3.1	8.8

In the selection of the best membrane for a given application it should be considered the membrane area required since the cost of the NF or RO system directly depends on it. Given the low fluxes obtained for the THF-HC and BW30 membranes, its use on the treatment of gold AMD proved to be cost-prohibitive. Moreover, the pollutants retentions of the three NF membranes were similar to those of the THF-HC membrane, besides allowing for a much higher permeate flux. As a result, the NF membranes were selected over the RO membranes for this application, and among the NF membranes the NF270 was chosen as the membrane with the highest potential.

CONCLUSION

The pretreatment study showed that AMD filtration did not considerably affect initial membrane fouling resistance, indicating that the AMD initially does not cause severe fouling during nanofiltration. The average ratio of permeate flux by water flux were 86.3%, 73.6% and 78.5% for the raw effluent, the effluent filtered with qualitative filter and the microfiltered effluent respectively. On the other hand, the pretreatment of the AMD improved permeate quality in all aspects analyzed. The retention efficiencies of the microfiltered effluent were 87.8% for total solids, 98.9% for conductivity and 99.5% for sulfate.

Additionally, the five membranes studied showed high pollutants retention and the RO membrane THF-HC showed the highest pollutants retention among then. However, the NF membranes had a pollutant retention similar to the THF-HC retention associated with higher permeate fluxes. The NF270 membrane showed the highest permeate flux (88 L/h.m^2) and was chosen as the most indicated for this application.

Sorption/Oxidation of Manganese in Aqueous System

Fernanda Camargo, Henrique de Leucas and Ana Cláudia Ladeira
Center for the Development of Nuclear Technology, Brazil

ABSTRACT

Manganese is considered one of the main contaminants of effluents from the mineral industry in Brazil. In some regions, mainly the ones with generation of acid mine drainage; the manganese concentrations in the acid effluent reach values up to 150 mg/L. However, the Brazilian Standard Limit for effluent discharging is 1.0 mg/L and the pH must be at 5 to 9. This study aims to evaluate the reduction of high levels of manganese contained in synthetic solutions simulating an acid effluent (about 150 mg/L) to the level required by the legislation. The manganese removal experiments were carried out by the adsorption of soluble Mn (II) in the presence of a solid substrate; manganese dioxide (MnO_2), which is a residue from the zinc electro winning process. The pH of the experiments was around 7, adjusted with NaOH or lime at room temperature (25 °C). The addition of NaClO and $KMnO_4$, during the experiments, was employed with the purpose of continuous activation of the surface sites of the substrate MnO_2. Batch experiments showed no difference between the levels NaClO added. The greatest Mn uptake was around 80 % and occurred when the initial pH solution was adjusted with lime. For the column experiments filled with solid MnO_2 and the residence time of 3.3 h, the manganese levels remained as low as 1 mg/L up to bed volume (BV) number 60. During the experiment, the pH of the out coming effluent decreased from 9.9 to 7.1. The maximum loading capacity of the solid was 18.6 mg/g. Attempts to regenerate the bed with $KMnO_4$ and NaOCl proved to be not possibly to achieve the total loading capacity of the fresh substrate. The loading capacity after regeneration was 11.6 mg/g and 6.3 mg/g, respectively.

Keywords: Manganese, manganese dioxide, acid mine drainage

INTRODUCTION

Acid mine drainage (AMD) is one of the most serious environmental problems faced by the mining industry in Brazil. The sulphide minerals such as pyrite when exposed to water and oxygen are oxidized producing sulfuric acid. The acidic water promotes the dissolution of metals of the soils which represent an important source of contamination to watercourses (Johnson & Halberg, 2006). In Brazil, Mn (II) has been found in concentrations up to 150 mg/L in acid drainage, as a consequence of high levels of this metal in the soils, while in the other countries the levels are up to 10 mg/L (Aguiar, Duarte & Ladeira, 2013). The standard limit for effluent discharge, according to Resolution CONAMA 430/2011, is 1.0 mg/L. Generally, liming procedure is used to remove dissolved Mn but in the case of high Mn concentration the pH must be above 10, to complete precipitate the metal. This stability of the Mn (II) in a wide range of pH increases the cost of the process and, moreover, the final pH of the effluent does not comply with the legislation which requires a pH at 5.0 to 9.0 for discharge (Aguiar, Duarte & Ladeira, 2013). Many studies have considered the removal of soluble manganese, although in these works the initial Mn levels are much lower than in the present investigation. Removal techniques include physical and chemical treatments such as addition of oxidants (chlorine, potassium permanganate, chlorine dioxide, ozone) to oxidize the Mn (II) to Mn (IV) and precipitating it (Islam et al., 2010), , ion exchange resins (Tafarel & Rubio, 2010), adsorption methods using zeolites, limestone (Silva et al., 2010), (Aziz & Smith, 1996), (Thornton, 1995), pyrolusite and oxides manganese (MnO_x). It is important to stress that MnO_x can be considered as a catalyst for the oxidation of manganese and it can be used either as a solid adsorbent or it can be formed onto the surface of a filter medium when the Mn (II) is oxidized by oxidants, such as permanganate ($KMnO_4$) and chlorine (Cl_2), or even by natural process. The soluble Mn (II) can be sorbed on the MnO_x coated filter media followed by surface oxidation. This removal process has been named as "natural greensand effects". Knocke et al. (1991) studied the kinetics of oxidation of manganese with potassium permanganate and chlorine dioxide and observed that the amount of Mn (II) removed from the system was slightly higher than that predicted by stoichiometry, due the presence of MnO_x. Hue, Cam & Nam (2008) developed a method for removing manganese from ground water using natural MnO_2. The experiments showed that using 10 g of ore, around 99.9 % of the manganese was removed from groundwater. According Knocke & Hargette (2001) the sorption capacity is proportional to the number of available sorption sites and also to the existing form of MnO_x, i.e., highly oxidized MnO_x, has greater removal efficiency. Moroever, they showed at pH 5-7, removal capacity of Mn (II) by MnO_x decreased by 80 % as compared to at pH 8. The present study aims to evaluate the reduction of high levels of Mn (II), around 150 mg/L, to the level required by legislation (1 mg/L) by simulating an acid effluent. Experiments were performed in the presence of a manganese dioxide (MnO_2), a residue from the zinc electrowinning process and two different oxidants were used in order to reactivate the MnO_2 sorption sites.

METHODOLOGY

Liquid samples

Laboratory solutions were prepared by diluting 0.461 g $MnSO_4.H_2O$ (Vectec Brazil) in 1.0 L of deionized water and the pH was adjusted by adding sodium hydroxide (NaOH) or lime. The Mn (II) concentration was determined by atomic absorption spectrophotometry – AAS (VARIAN, model AA240FS).

Solid samples

The MnO_2 was a residue from the zinc electro winning process. The specific surface area was 38.35 m^2/g, determined by Brunauer Emmett Teller (BET) method multiple point technique (Quantachrome Corp., NOVA-2200). MnO_2 content in the residue was around 64 %, determined by Energy Dispersive X-ray - EDX (SHIMADZU model EXD -720). In order to prepare the sample to the column experiments, 5 % of cement was mixed to the residue to obtain pellets with particle size between 1.19 and 1.68 mm.

Batch experiments

Experiments were conducted in glass beakers containing 200 mL of about 150 mg/L of Mn (II) solution, in the presence of 2.000 g MnO_2, under stirring and at room temperature (25 ºC ± 0.5). The pH was adjusted by adding sodium hydroxide or sulphuric acid during the first two hours. Sodium hypochlorite (NaOCl) was added at 12 min of reaction in order reactivate the MnO_x sorption sites. The amount NaOCl used corresponded to 5 %, 15 % and 25 % of the stoichiometry amount. Samples were collected at pre-established time and filtered in 0.45 μm membranes. Sulphuric acid and sodium bissulfite 5% (w/v) was added to the filtrate to avoid late precipitation of Mn.

Column experiments

Column experiments were carried out in a glass column with a 1.9 cm inner diameter and 35 cm of length. The glass columns were packed with a volume of 40.0 mL of MnO_2 pellets and fed with laboratory solution of Mn(II), at pH 7.0, adjusted with lime. After neutralization, the solution was filtered to remove some MnO_x that could have precipitated. The operation was performed at room temperature by downstream flow rate at 0.2 mL/min (residence time of 200 minutes), using a peristaltic pump Master Flex L/S model 7519—20. Liquid samples from the column outflow were collected periodically, by means of Spectra/Chrome Fraction Collector (model CF-1), acidified and analyzed to determine Mn by AAS. In order to reactivate the bed of MnO_2, each fixed bed was washed with oxidizing agent: $KMnO_4$ (4 % w/v) and NaOCl which chlorine content was 96.0 mg/L. After that, the fixed beds were washed with deionized water and then they were fed with a new laboratory solution of Mn(II), under the same experimental conditions.

RESULTS AND DISCUSSION

Influence of NaOCl on Mn removal

According to Knocke & Hargette (2001) the uptake of soluble manganese by sorption onto MnO_x coated filter media and its subsequent reactivation using free chlorine is an effective technique for

continuous removal of Mn (II). In the presence of chlorine, the sorption sites on the oxides surfaces can be regenerate increasing the removal of soluble Mn (II). When no oxidant is added, the uptake of Mn (II) occurs until all available adsorption sites are filled. According to Islam et al. (2010), chlorine is able to regenerate the adsorption sites of the oxide by the oxidation of the Mn (II) to Mn (IV), or Mn (III) to Mn (IV), both previously adsorbed on the oxide surface. Figure 1 shows the concentrations of Mn(II) in solution using MnO_2 and the addition NaOCl. The influence of sodium hypochlorite was assessed by adding different stoichiometric doses of NaOCl after 12 min of reaction with MnO_2 (time corresponding to a local raise in Mn concentration) in an attempt to make the removal more effective. For all the experiments, the curves present similar profile. Manganese removal without the addition of NaOCl was 29.0 mg/L, after two hours. It is observed that for the first eight minutes the kinetic is rapid and manganese concentration drops to values around 60 to 80 mg/L. After 8 minutes, the concentration increases slightly with a maximum at 12 minutes and then falls again until the ending of the experiment. It seems that low doses of NaOCl (0.05 and 0.15) have no effect on the oxidation process; the final concentration is slightly higher in the latter experiments if compared to the one without oxidant. However, there was an improvement on manganese uptake when the dose of NaOCl was equal to 0.25 and the pH initial solution was adjusted with lime, about 80 % manganese was removed. The authors understand that the chlorine in solution in fact oxidizes the soluble Mn(II) favoring the precipitation and that it is not able to regenerate the sites of the solid sorbent.

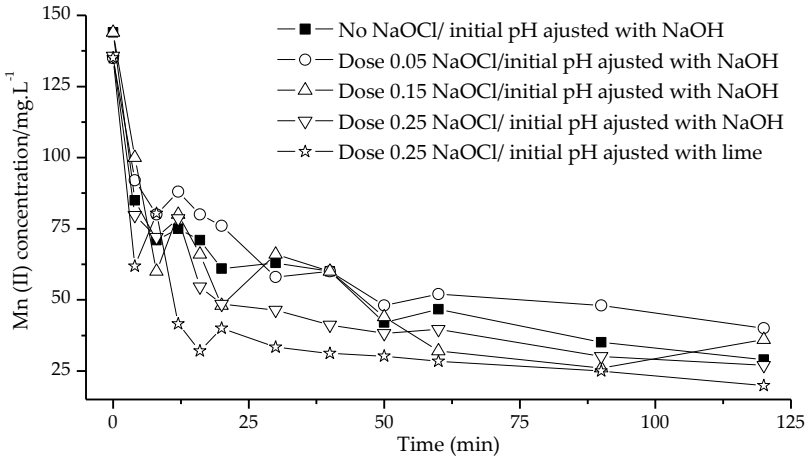

Figure 1 Manganese removal from solution at pH 7.0, T=25 °C , using different doses of NaOCl, 2.000 g of MnO_2, 200 mL of fresh solution

Although the experiment with lime proves to be the most effective in all its extension, the concentration of Mn remained in solution, i.e., 20 mg/L, was above the standard limit for discharging (1 mg/L) leading to a conclusion that the addition of the NaOCl was not effective. One possibility is that the doses of chlorine used were not sufficient to regenerate the adsorption sites of MnO_2, another possibility can be that the oxidation of the adsorbed Mn (II) by chlorine is slow and the reaction time was insufficient for the attainment of the desired value and comply with the legislation. Despite the sodium hypochlorite being not effective, others authors show that it is able to activate and regenerate the sites of MnO_2, making them available for the subsequent adsorption. Another oxidant commonly used for this purpose is $KMnO_4$. The ability of regeneration of this

reagent is reported in studies of Mn removal in fixed beds consisting MnO_2 and in the present study it was evaluated by means of column experiments described below.

Column experiments and regeneration.

Column experiments were carried out in fixed beds of MnO_2 pellets, at pH 7.0. Figure 2 shows the profiles where the Mn (II) concentration in the outflow was plotted versus cumulative bed volume (BV). The solid squares represent the column with fresh MnO_2 that was loaded up to the BV 190. The breakthrough point of the curve, chosen according to the standard limit of 1.0 mg/L, was attained at BV 52. From this point the manganese concentration gradually increased and reaches the feed value of 135 mg/L. This means that the saturation of the column was achieved for the inflow is equal to the outflow.

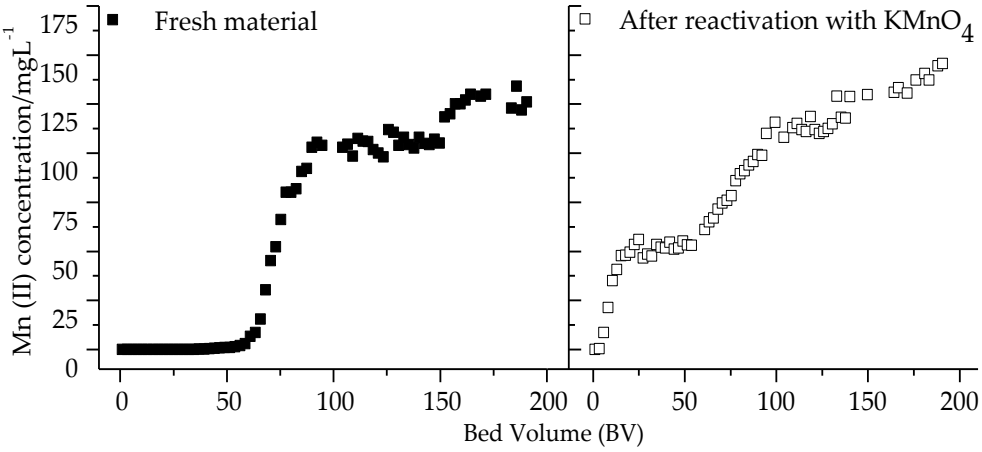

Figure 2 Sorption profiles for Mn removal with 40 mL of MnO_2, $[Mn]_{initial}$ = 140 mg/L, $pH_{initial}$ = 7.0 adjusted with lime; T = 25 °C; flow rate = 0.2 mL/min, reactivation with 4% w/v $KMnO_4$ solution.

The loading capacity of the first column from Figure 2, calculated by integrating the area above each curve, is 13.6 mg/g of MnO_2. The value was lower than the loading capacity obtained by Aguiar, Duarte & Ladeira (2013) 17.9 mg/g of MnO_2 whose initial concentration was 95 mg/L. The pH of the outflow solutions from Figure 2 was 8 in the first initials BVs and then increased slowly and reached the value of 9.5 up to BV 23. The pH enhancement was caused by the alkalinity of the cement; a component used to prepare the MnO_2 pellets. After BV 23, the pH of the outflow dropped and reached 7.1 at the end of the experiment. This pH decrease may indicate the oxidation of the Mn (II) because the oxide formation reactions produced H^+ ions in solution according to the reaction:

$$Mn^{2+} + 1/2O_2 + H_2O \rightleftharpoons MnO_2 + 2H^+ \quad (1)$$

The loading capacity calculated by Hue, Cam & Nam (2008) to manganese removal in underground water using as sorbent a manganese dioxide ore is 12.7 mg/g. This value is close the loading capacity shown previously (13.6 mg/g). Subsequently, it was washed with a solution of 4 %(w/v) $KMnO_4$ and then the experiment was run again under the same conditions of first loading. The

second curve from Figure 2 (open circle) shows the loading of Mn after regeneration of the fixed bed. It is observed that the bed was reactivated, however, the loading capacity (11.6 mg/g) is 15 % lower than the one determined for the fresh material. Despite the fixed bed had been reactivated, the breakthroug point was reached quickly at 4 BV, therefore the standard limit established by legislation (1.0 mg/L) was exceeded at the initial of the loading. The profile of manganese uptake after regenerations was not favorable.

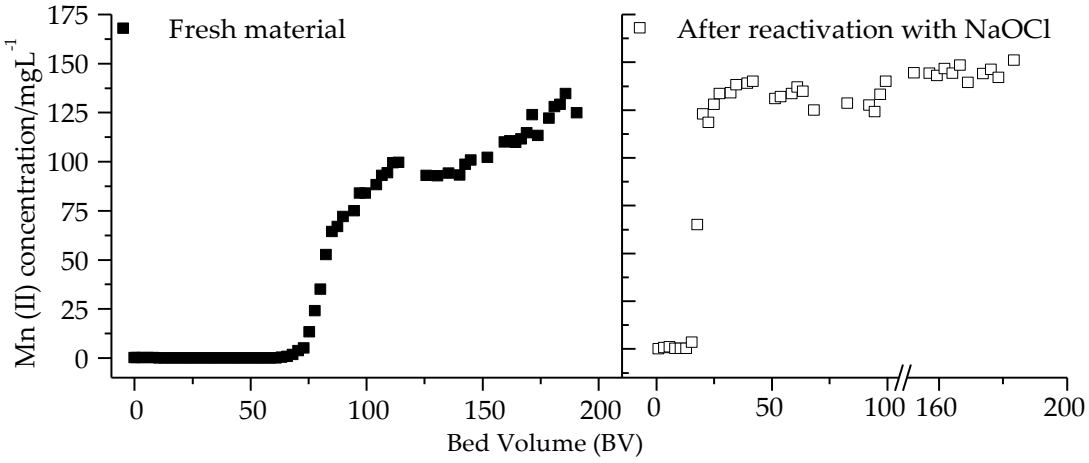

Figure 3 Mn removal with MnO_2, $[Mn]_{initial}$ = 150 mg/L, $pH_{initial}$ = 7.0 adjusted with lime; BV of 40 mL, T = 25 °C; flow rate = 0.2 mL/min, reactivated with NaOCl solution and flow rate 1.3 mL/min

Figure 3 shows the profiles for column filled with MnO_2 where the Mn (II) concentration in the outflow was plotted versus cumulative BV. It shows the loading experiment with fresh material and after regeneration with NaOCl. The experimental conditions were kept the same as in the experiment using $KMnO_4$. The breakthrough point was reached at BV 66, and the loading capacity of the fresh material was 18.4 mg/g of MnO_2; as previously determined. This value is close to the loading capacity obtained by Aguiar, Duarte & Ladeira (2013) 17.9 mg/g. After the reactivation with NaOCl (open circles), the loading capacity was 6.3 mg/g and the standard limit was reached at BV 12. Compared to Figure 2, the loading capacity of the column reactivated with NaOCl is lower than the one reactivated with $KMnO_4$, once the saturation point of the column is achieved at BV 98 in which the manganese concentration in the outflow is 140 mg/L. Despite the reactivation with $KMnO_4$ being more efficient, the discharging limit for both experiments was attained extremely quickly which makes the regeneration unfeasible. Data obtained through XPS spectroscopy (not shown) suggested that the soluble Mn(II) is converted into Mn(IV) during the removal process and the MnO_2 is perhaps the most likely form to be present on the surface of the Mn oxide.

CONCLUSION

The removal of Mn (II) at pH 7.0 in laboratory solutions was possible using MnO_2, allowing lower costs, since it is not necessary to raise the pH to 10 to attain the level of Mn (II) required by Brazilian legislation to discharge the effluent. The maximum loading capacity achieved was 18.4 mg/g of

MnO_2. Despite the reactivation with $KMnO_4$ being more efficient than the one with NaOCl, the loading capacities were respectively 11.6 mg/g and 6.3 mg/g which is considered not viable.

Effect of Feed Ph in the Nanofiltration of Gold Acid Mine Drainage

Alice Aguiar, Laura Andrade, Wadson Pires and Miriam Amaral
Department of Sanitary and Environmental Engineering, Universidade Federal de Minas Gerais, Brazil

ABSTRACT

Acid mine drainage (AMD) is knowingly one of the greatest problems caused by mining activities, not only for the associated environmental impacts, but also due to the large volumes produced and the related costs, the difficulty of its control once started, and its perpetuity. Due to the large volume associated with AMD, membrane separation processes especially nanofiltration (NF) are of great interest. Typically, NF produces a permeate with high quality, which can then be reused in the process. The present work aims to study the effect of different feed pH in the treatment with NF of a gold acid mine drainage effluent. The membranes studied were NF90, NF270 and MPS-34, which were chosen in a previous work for its high potential for AMD treatment. The results showed that the MPS-34 and NF90 membranes operating at natural AMD pH (3.2) obtained higher permeate fluxes than in other conditions. However, the conductivity retention efficiency of the MPS-34 membrane was very low, below 45% for all conditions. The NF270 membrane presented the highest permeate fluxes. Moreover, the retention of conductivity and sulfate were higher with the NF270 membrane than with the NF90 membrane. The fouling resistance of the NF270 at pH 5.5 was slightly smaller than at pH 4.2, indicating that this might be the most adequate condition for the treatment of gold AMD.

Keywords: Gold acid mine drainage; Nanofiltration; Feed pH

INTRODUCTION

Gold mining and gold ore processing are activities of great economic importance. Gold has been used in various applications, ranging from the manufacture of jewelry to the protective covering of satellites and medicinal use due to its distinguished physicochemical properties, such as high corrosion resistance, high electrical conductivity and high infrared radiation reflectance (Kwon et al., 2011; Savage, 2013).

On the other hand, gold mining and processing leads to many environmental impacts. They may vary from natural habitat destruction and consequent loss of biodiversity to the inappropriate disposal of large amounts of waste on the environment (Getaneh & Alemayehu, 2006). Soil, water and plants in areas near gold mining regions can become contaminated by many heavy metals, such as copper, manganese, aluminum, iron, zinc, nickel, chromium, lead, cobalt, etc (Abdul-Wahab & Marikar, 2012). This contamination is most pronounced when the mined rock contains significant amounts of pyrite and other sulfide minerals. These minerals can be oxidized leading to acid generation and consequent increase of heavy metals leaching (Abdul-Wahab & Marikar, 2012).

Metal sulfides oxidation is responsible for the formation of acid mine drainage (AMD), recognized as one of the greatest environmental impacts of mining (Hilsona & Murck, 2001; Akcil & Koldas, 2006). Several authors mention that AMD results from a complex series of chemical reactions involving direct and indirect mechanisms and microbial action (Costello, 2003; Akcil & Koldas, 2006). AMD environmental impacts include acidification of surface and groundwater, soil acidification, biodiversity loss, solubilization of harmful elements such as heavy metals (which could reach human food chain through bioaccumulation and biomagnification), generation of precipitates in water bodies harming benthic flora, etc (Borma & Soares, 2002; Campaner & Silva, 2009).

Therefore, the application of AMD control measures is essential for preservation of environmental quality. AMD traditional treatment consists of adding lime to neutralize the free acidity, oxidize metals and precipitate them as hydroxides (Costello, 2003; Akcil & Koldas, 2006). These technologies may be sufficient to adjust water characteristics to discharge standards; however they are unlikely to generate water with reuse quality, as salts concentrations in the treated effluent are still high.

Membrane separation processes (MSP) are technologies of great potential for mining effluent treatment, especially if the generation of reuse water is also the aim (Al-Zoubi et al., 2010; Sierra et al., 2013; He et al., 2014). Among the MSP, nanofiltration (NF) importance must be highlighted. Nanofiltration is considered an energy efficient and environment-friendly process. NF offers higher fluxes than reverse osmosis and significantly better retentions than ultrafiltration for small molecules such as sugars, amino acids, peptides and even ions (Luo & Wan, 2013).

Solutes separation by NF membranes occurs by several mechanisms including steric hindrance, Donnan and Dielectric effects (Nguyen et al., 2009). Therefore pore size and surface charge of the membrane pores influence salts and molecules retention. As the commercially available NF membranes are usually hydrophilic and prone to be hydrated and ionized in aqueous solution, the conformation and ionization of the membrane's polymer chains will change under different surrounding conditions, especially at different pH and ionic strength. Due to the nanoscale pore dimensions (~1 nm) and electrically charged materials of the NF membranes, even a minor change in pore size or charge pattern would have a clear impact on membrane permeability and molecules

retention (Luo & Wan, 2013). Hence, literature findings reveal that membrane separation performance can be highly dependent on solution pH, which in turn can significantly affect the operational conditions selection for a given type of effluent (Capar et al., 2006).

The effect of pH on NF performance is quite complicated as membrane properties and solutes diversity largely varies with pH, and these variations are dependent on membrane material and solute type. Although the behavior of NF membranes in both, single or multi-element solutions of a known composition has already been extensively studied and modeled (Szoke et al., 2003; Teixeira et al., 2005; Nguyen et al., 2009; Dalwani et al., 2011; Luo & Wan, 2013), the operational performance of these processes to treat actual effluents cannot easily be predicted.

Some authors have evaluated the NF of real effluent or water at different pHs (Qin et al., 2003; Capar et al., 2006; Wang et al., 2007), however retention mechanisms and fouling resistance were not thoroughly discussed. As a result, understanding and then manipulating the effect of feed pH on NF can improve effluent treatment, by enhancing separation performance and reducing membrane fouling.

The aim of this study was to evaluate the treatment of a gold acid mine drainage by nanofiltration. Three different commercial NF membranes were tested at feed pH ranging from 3.2 (natural pH) to 6.0.

METHODOLOGY

Acid mine drainage

Acid mine drainage was collected from a gold mining company in the state of Minas Gerais, Brazil which has two underground gold mines and an industrial processing plant. AMD was collected in one of the underground mines, on the fourth level below ground. The AMD characteristics vary over the year, in this study the effluent was characterized by a high conductivity (4,510 μS/cm²) and sulfate concentration (2,625 mg/L), and initial pH of 3.2.

Unit description

A bench scale unit was used during the nanofiltration tests. The system is comprised of: one supply tank (ST); one pump; one valve for pressure adjustment; one rotameter; one manometer; one thermometer and one stainless steel membrane cell. Figure 1 shows a schematic of this unit.

The stainless steel membrane cell has 9.8 cm in diameter, providing a filtration area of 75 cm². The membranes tested were properly cut before being placed in the cell. A feed spacer was placed over the membrane to promote flow distribution. Permeate flow was measured by collecting the volume of permeate in a measuring cylinder over 60 seconds for nanofiltration tests and 180 seconds for reverse osmosis tests. Permeate was collected for analysis and retentate was returned to the supply tank.

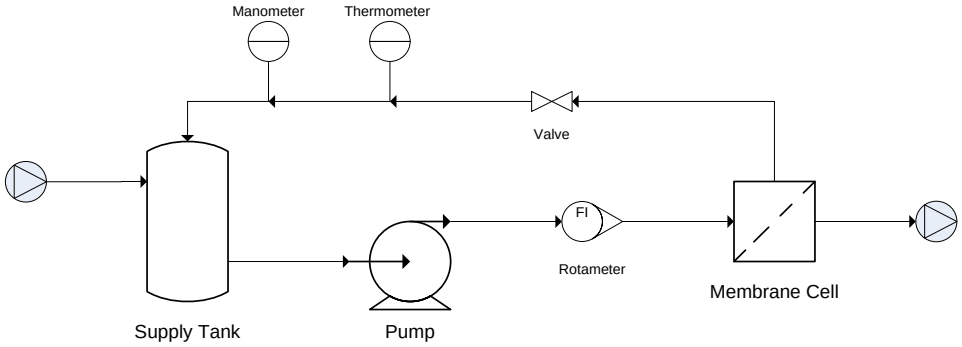

Figure 1 Schematic of NF unit

Evaluation of different feed pH values

A comparative study of three nanofiltration (NF) membranes on the treatment of AMD at feed pH ranging from 3.2 (natural pH) to 6.0 was conducted. The membranes of NF analyzed were NF90, NF270 and MPS-34. Table 1 shows the main characteristics of these membranes as provided by the suppliers, unless otherwise specified.

Process water cannot have acidic pH to prevent possible wear and corrosion of equipment and piping. Thus, for the reuse of the treated effluent, its pH must be adjusted to approximately 7.0 (Asano et al., 2007). Such adjustment can be performed before or after the membrane treatment system. Therefore, the membranes were tested at different pH values, namely 3.2, 4.2, 5.0, 5.5, and 6.0. Tests with pH above 6.0 were not performed as higher pH values did not enabled better process performance, as will be shown later. A solution 5.0 N of NaOH was used for pH adjustment.

After pH adjustment, six liters of the AMD was ultrafiltered using a commercial submerged membrane (ZeeWeed) with a filtration area of 0.047 m², PVDF-based polymer and average pore diameter of 0.04 micrometers. UF occurred at a pressure of 0.7 bar up to 4 liters of permeate recovery.

The NF membranes were initially washed in ultrasound bath first with citric acid solution at pH 2.5 followed by 0.1% NaOH solution for 20 minutes each. Water permeability was obtained by monitoring the normalized value of the stabilized permeate flux of clean water at pressures of 10.0; 8.0; 6.0 and 4.0 bar. Normalization to 25°C was accomplished by means of a correction factor calculated by the ratio of water viscosity at 25°C and water viscosity at the temperature of permeation:

$$K = \frac{J}{\Delta P} * \frac{\mu(T)}{\mu(25^{\circ}C)} \quad (1)$$

With the calculated value of water permeability, intrinsic membrane resistance to filtration (R_m) was calculated:

$$R_m = \frac{1}{K * \mu(25^{\circ}C)} \quad (2)$$

Nanofiltration was carried out using four liters of pretreated acid mine drainage, during four hours at fixed pressure of 10 bar, feed flow rate of 2.4 LPM and temperatures ranging between 25 and 35°C. Permeate flux, temperature and accumulated permeate volume were measured each 15 minutes. Final permeate was collected for analysis. Retentate was returned to the supply tank. The fouling resistance to filtration (R_f) was determined with the values of permeate flux and temperature obtained at the end of the experiment, as demonstrated by the equation:

$$R_f = \frac{\Delta P - \Delta \pi}{\mu(T) * J} - R_m \quad (3)$$

Effluent osmotic pressure (π) for different recovery rates were calculated using the software ROSA 9.1 (The Dow Chemical Company, USA) up to a recovery rate of 65%. The recovery rate is defined as the ratio of the accumulated volume of permeates to the initial volume of effluent. Table 2 shows a summary of the main ions in solution and its respective concentration. These ions concentrations were typical values obtained for the AMD.

Table 2 Main ions in gold's acid mine drainage and its concentrations

Ions	Concentration (mg/L)
Sulfate (SO_4^{-2})	2,000
Chloride (Cl^-)	10.0
Magnesium (Mg^{+2})	150
Calcium (Ca^{+2})	593

Feed and permeates were analyzed for conductivity (Hanna conductivity meter HI 9835), total solids and ions concentrations (Metrohm 850 Professional IC, Herisau, Switzerland, equipped with

column type Metrosep C4-100/4.0 and Metrosep A Supp 5-150/4.0), in accordance with the Standard Methods for the Examination of Water and Wastewater (APHA 2005).

RESULTS AND DISCUSSION

Effluent osmotic pressure

A simulation of the acid mine drainage osmotic pressure calculated using the software ROSA 9.1 (The Dow Chemical Company, USA) for a recovery rate up to 65% is presented on Table 3.

Table 3 Osmotic pressure of gold's acid mine drainage

Recovery Rate	Osmotic pressure of retentate (bar)	Recovery Rate	Osmotic pressure of retentate (bar)
0%	0.75	35%	1.07
5%	0.78	40%	1.15
10%	0.82	45%	1.24
15%	0.86	50%	1.34
20%	0.90	55%	1.46
25%	0.95	60%	1.62
30%	1.01	65%	1.81

As expected, the osmotic pressure of the retentate increases with the increase in the recovery rate, as the concentration of ions in solution increase. The driving force of the nanofiltration is the effective pressure, defined as the operation pressure minus the osmotic pressure. Therefore, an increase in the recovery rate increases the osmotic pressure decreasing the filtration driving force and consequently decreasing the permeate flux.

However, it is important to point out that this software does not provide a full description of the system as it does not have all ions in solution. Hence, small variations in the effluent osmotic pressure are expected.

Membrane separation

To minimize the influences that variations on initial membrane water permeability could have on the comparison of the effluent permeate fluxes, it is usual to express the ratio of permeate flux to water flux. Figure 2 shows the ratio of permeate flux to water flux as a function permeation time and feed pH for membranes NF90 (Figure 2a), MPS-34 (Figure 2b) and NF270 (Figure 2c).

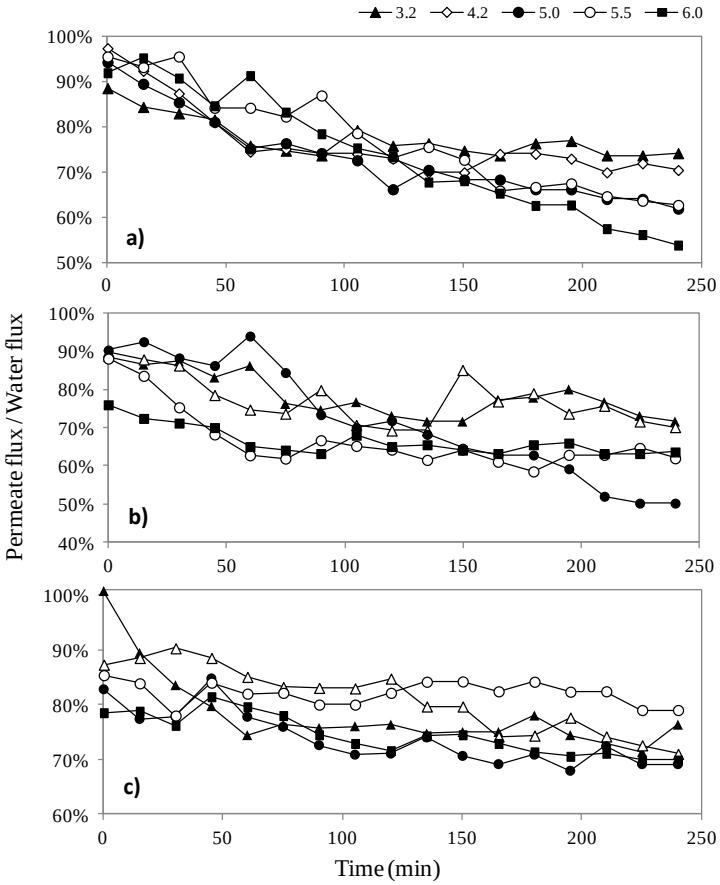

Figure 2 Ratio of permeate flux to water flux as a function permeation time and feed pH for membranes a) NF90, b) MPS-34 and c) NF270

The NF90 membrane operated best at natural pH (3.2). At this pH the average permeate flux obtained was 52.0 L/h.m^2 and the average ratio of permeate flux to water flux was 77.4%. However, as can be seen from Figure 2a, there is a considerable decrease in permeate flux at the beginning of the filtration. At the end of the filtration (recovery rate near 40%) the permeate flux was 49.5 L/h.m^2. At higher pH (6.0) the initial ratio of permeate flux to water flux was very high (91.9%) but it decreased rapidly and at a recovery rate of 40% its value had fallen to 67.9%.

The MPS-34 membrane obtained permeate fluxes similar to the NF90 membrane; and the best feed pH was also 3.2. At this pH the average permeate flux obtained was 51.9 L/h.m^2 and the average ratio of permeate flux to water flux was 78.3%. Even so, its retention efficiencies were very low, as will be shown later.

Finally, the NF270 membrane presented the highest ratio of permeate flux to water flux of all three membranes. This result is expected as the NF270 membrane has higher water permeability and larger pores than the other membranes (Wang & Tang, 2011; Nghiem & Hawkes, 2007). The NF270 membrane operated better at pH 4.2 and 5.5, as can be seen from Figure 2c the ratio of permeate flux to water flux for these two pH's are consistently higher than the rest. At pH 4.2 the average permeate flux obtained was 68.5 L/h.m^2, the average ratio of permeate flux to water flux was 81.0% and near the end of the filtration (recovery rate of 40%) the permeate flux was 62.7 L/h.m^2. At pH 5.5 the average permeate flux obtained was 64.2 L/h.m^2, the average ratio of permeate flux to water

flux was 82.1% and near the end of the filtration (recovery rate of 40%) the permeate flux was 64.4 L/h.m^2.

Table 4 shows the water permeability, membrane resistance and fouling resistance for the NF270 membrane at feed pH of 4.2 and 5.5 obtained from Equations 1, 2 and 3 respectively. For these two conditions, the values obtained for the water permeability and membrane resistance were very close, which means that the initial conditions of the system were similar. The lower fouling resistance with pH 5.5 indicates that this operational condition might be the most adequate in the treatment of the gold AMD.

Table 4 Water permeability, membrane resistance and fouling resistance of the NF270 at feed pH of 4.2 and 5.5

pH	K (m^3/s.m^2.Pa)	R_m (m^{-1})	R_f (m^{-1})
4.2	2.56×10^{-11}	$4.40 \times 10^{+13}$	$1.35 \times 10^{+13}$
5.5	2.53×10^{-11}	$4.44 \times 10^{+13}$	$1.20 \times 10^{+13}$

The conductivity retention efficiencies obtained for the MPS-34 with all the pH studied were very low (e.g. below 45%). The small permeate fluxes and low retention efficiencies indicate that this membrane is not the most appropriate for this specific application. Table 5 shows the main permeate characteristics for the NF90 membrane at pH 3.2 and NF270 membrane at pH 4.2 and 5.5.

Table 5 Permeate conductivity, sulfate and calcium concentrations for the NF90 membrane at pH 3.2 and NF270 membrane at pH 4.2 and 5.5

Membrane	pH	Conductivity (µS/cm^2)	Sulfate (mg/L)	Calcium (mg/L)
NF90	3.2	770	549	< 2.5
NF270	4.2	370	258	< 2.5
NF270	5.5	405	257	< 2.5

It is noted that the retention of conductivity and sulfate were better with the NF270 membrane than with the NF90 membrane. For the NF270 membrane at pH 5.5, the retention efficiencies of conductivity and sulfate were 91.0 and 90.2%, respectively. Calcium retention was high for all three conditions and final concentration was below the method's lowest detection limit.

CONCLUSION

Average permeate flux for the NF90 and the MPS-34 membranes operating at AMD natural pH (3.2) were very similar, equal 52.0 and 51.9 L/h.m^2 respectively. However, the permeate flux decrease in the NF90 membrane was considerably higher than the permeate flux decrease in the other membranes. The NF270 membrane showed the highest overall permeate flux and best fluxes were obtained at pH 4.2 and 5.5. At these pHs the average permeate flux were 68.5 and 62.7 L/h.m^2 respectively for pH 4.2 and 5.5 but permeate flux decline was smaller at pH 5.5 than at pH 4.2. Moreover, fouling resistance was lower at pH 5.5 than at pH 4.2. The retention efficiencies of conductivity and sulfate for the NF270 membrane at pH 5.5 were 91.0 and 90.2%, respectively.

Fulfilment of EPA Discharge Requirements for ARD Using Co-Precipitation Iron Process at Neutral PH

David Pascual[1] and Michael McPhee[2]

ABSTRACT

The dissolution of soluble metal compounds from ore and waste rock and the presence of contaminants in industrial and mining process water are a major concern for water treatment standards.

An improvement of alkaline precipitation methods to remove metals was the focus of this study. This system was based on iron co-precipitation technology, taking advantage of the beneficial characteristics of iron, such as natural coagulation, natural adsorption of heavy metals, good clarification and increased dewatering properties of solids.

Based on this iron co-precipitation technology, two different configurations were evaluated at Leviathan Mine Superfund Site (California, USA) for treatment of ARD containing the following metal concentrations (μg/L): Aluminium (107,800), Arsenic (3,240), Copper (2,150), Iron (456,430), Nickel (2,560), Cadmium (26,100), Chromium (341,000), Lead (6,200), Selenium (16,600), Zinc (538,000).

The objectives of the technology evaluation were to determine the removal efficiencies for target metals, verify reduction under discharge standards, document operating parameters, assess critical operating conditions, evaluate operational efficiency of solid separation and dewatering systems.

The treatment system was shown to be extremely effective in neutralizing acidity and reducing the concentrations of the target metals to below EPA discharge standards.

The mechanisms of this technology, combined with the characteristics of iron and operation at neutral pH, showed beneficial results that include less amount of base requirement, no requirement of final pH adjustment to fulfil discharge limits, better clarification with less settling area, and better solids dewatering.

Keywords: metal, precipitation, ARD, iron, neutral

INTRODUCTION

Conventional Alkaline precipitation

Alkaline Precipitation is an extensively used technology for removal of heavy metals. It is based on the occurrence of the following reaction:

$$M^{+2}{}_{(aq)} + 2(OH^-) \leftrightarrow M(OH)_{2\,(S)} \quad (1)$$

In this equation, the M^{2+} represents any divalent heavy metal. As it is indicated, the metal ion combines with hydroxide ion to form the insoluble metal hydroxide solid. This reaction is pH dependent; as more base is added, the reaction is driven further to the right to precipitate more of the metal complex. Conversely, as the pH is decreased, the thermodynamic equilibrium moves to the left, causing more of the metals to resolubilize. This reaction is fully reversible and results in a solubility curve (blue curve) similar to that shown in Figure 1.

The limitations of alkaline precipitation technologies result from secondary reactions which occur as more hydroxide is added. One common reaction is the combination of the metal hydroxide precipitate with additional hydroxide ion:

$$M(OH)_{2\ (s)} + OH^- \leftrightarrow M(OH)_3^-{}_{(aq)} \quad (2)$$

The metal hydroxide precipitate combines with additional hydroxide to form a soluble metal complex. Thus as the pH increases, the reaction proceeds to the right and the metal becomes more soluble. The solubility curve of this reaction (purple curve) approximately mirrors the curve of the first reaction as shown in Figure 1.

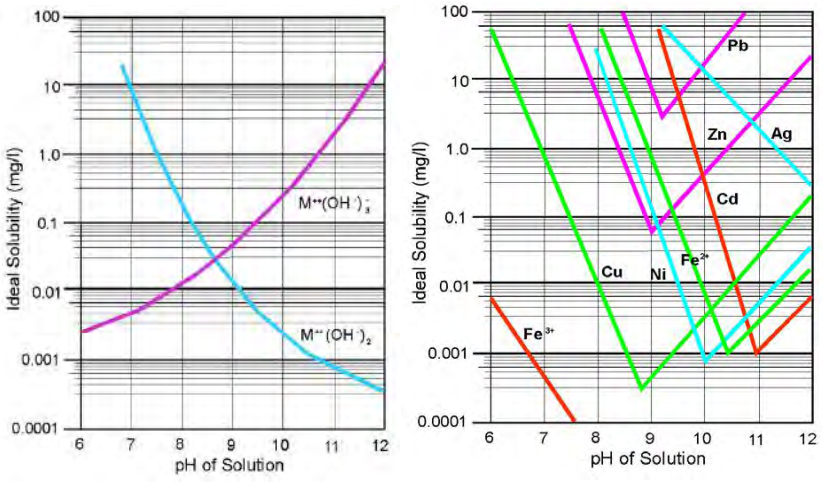

Figure 1 Solubility of metal hydroxides

By overlaying these two curves as shown in Figure 1, and then combining the effects of all the reactions which take place, the familiar V-shaped solubility curve for metal hydroxides is obtained as shown in Figure 1. The lowest point of this curve identifies the absolute lowest concentration of a particular metal which can be achieved, under ideal conditions, by alkaline precipitation technology. To obtain this concentration, pH must be maintained within a specified range to reduce the metal resolubilisation. In a wastewater stream with multiple metals, this problem becomes more challenging due to solubility dependence of metals on pH. Any operating pH is chosen to be optimal in reducing the solubility of dissolved species (Figure 1).

Iron co-precipitation process technology

Iron co-precipitation technology is based on the beneficial characteristics of iron: natural coagulation, adsorption of heavy metals onto iron solids, good clarification and increased dewatering properties solids formed.

Ferrous iron (Fe^{2+}), existing or added to water, tends to form a soluble chain-like structure in solution due to the weak ionic attractions between molecules. This close association between the heavy metals species and the iron species provides the mechanism by which the iron can be targeted to most efficiently remove the heavy metals (McPhee, n.d.).

After the soluble association is formed, base is added to control the pH and form a suspension of metal hydroxides; then, air is added to oxidize Fe (II) to Fe (III) and form crystals containing ferric ions as ferromagnetic oxides, such as Fe_3O_4, and/or oxyhydrates (or oxiyhydroxides) FeOOH, and further containing the metal ions originally in solution. Many kinds of heavy metals in the solution are substituted in the metal sites of the ferric crystal lattice to form various kinds of ferrites or of FeOOH crystal lattice. Other kinds of heavy metals are firmly adsorbed by the ferrites thus formed (Sugano, Tsuji, Kanamori, 1976).

These metals are "occluded" in the iron solids and are effectively enveloped in iron as shown in Figure 2. The occluded metals are insulated from the solution by the iron, and so are not allowed to resolubilize as solubility curves in Figure 1 would indicate. This phenomenon makes it possible to remove heavy metals from water to concentrations well below their thermodynamic solubility limits. The precipitates, ferric iron solids, can then be separated from the treated water by chemical coagulation, flocculation, and clarification processes (McPhee, n.d.).

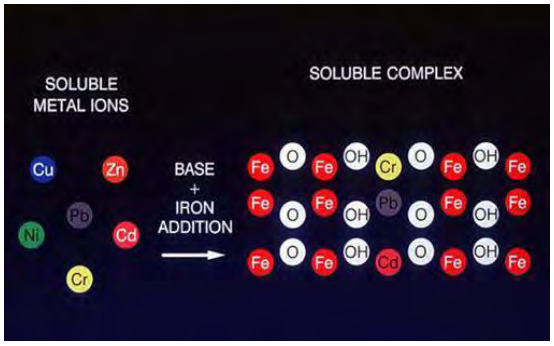

Figure 2 Soluble iron complex formation in iron co-precipitation process

Other metals which may not be removed by occlusion are adsorbed; ferric iron solids tend to adsorb heavy metals to their surface and acts as a catalyst for the oxidation of Fe(II) to Fe(III).

Process description

A treatment system based on iron co-precipitation technology was designed to treat ARD from holding ponds from an inactive underground copper mine and an open pit sulphur mines in the State of California (Siskind, 2002).

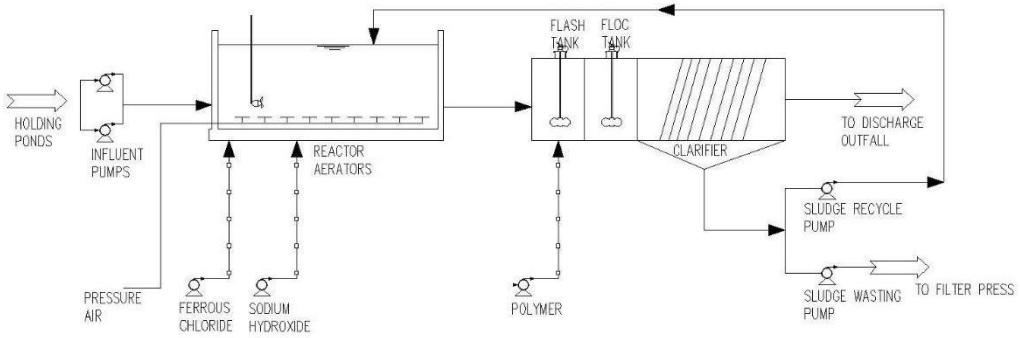

Figure 3 Co-precipitation metals treatment process flow diagram. One-stage system

The system was operated in two different modes, one-stage and two-stage. Operated as a one-stage system, the active treatment system was evaluated for its ability to treat a combined, moderate ARD flow without regard to the type of metal or concentration. Operated as a two-stage system, the active lime treatment system was evaluated for its ability to treat a high ARD flow where concentrations of arsenic were relatively high.

The treatment system for both modes involves reaction of lime with ARD (usually at a pH of 2 to 3), to raise the solution pH to 7.9 to 8.2. In one-stage mode, pH is rise to 7.8 to 8.2 in one stage. In two-stage mode the overall chemical reaction is the same as for the one-stage mode; however, metals precipitation is conducted in two steps. In stage I, the active treatment system is held at a pH of 2.8 to3.0 creating a small quantity of precipitate. In stage II, the pH is raised to 7.9 to 8.2 and the remaining metals are precipitated, creating a much larger quantity of solid waste.

The equipment for each stage consists of an aerated reaction tank (30 minutes retention time), flash and flocculation mixing tanks, plate clarifiers (settling rate of 1 m^3/m^2 h), filter press (only for first step of two-stages configuration) and a settling pond as shown in Figure 3 and Figure 4. Treatment chemicals used were lime and anionic polyacrylamide as polymer; no ferrous chloride or sulphate addition was needed due to a high concentration of iron in the ARD flow.

Ferric iron solids are present in the process as a result of the oxidation of ferrous iron, and as a result of recycle from the clarification step as shown in Figure 3 and Figure 4. The solids, due to a very high shear environment in the reaction vessel, are highly fractured resulting in a very high surface area and many active adsorption sites. The heavy metals in solution adsorb to the surface of these solids in the reactor. As ferrous iron enters the reactor with the contaminated stream, the iron

preferentially precipitates, due to the autocatalytic effect, on the solids which have already formed. This layering of iron precipitate on top of adsorbed heavy metals produces results similar to those achieved by the first mechanism; the heavy metals are effectively removed from solution and are isolated from the solution so that they cannot freely follow their solubility curves as the pH varies. This reaction mechanism also results in extremely dense solids since the precipitation is occurring directly on the surface of other solids (McPhee, nd).

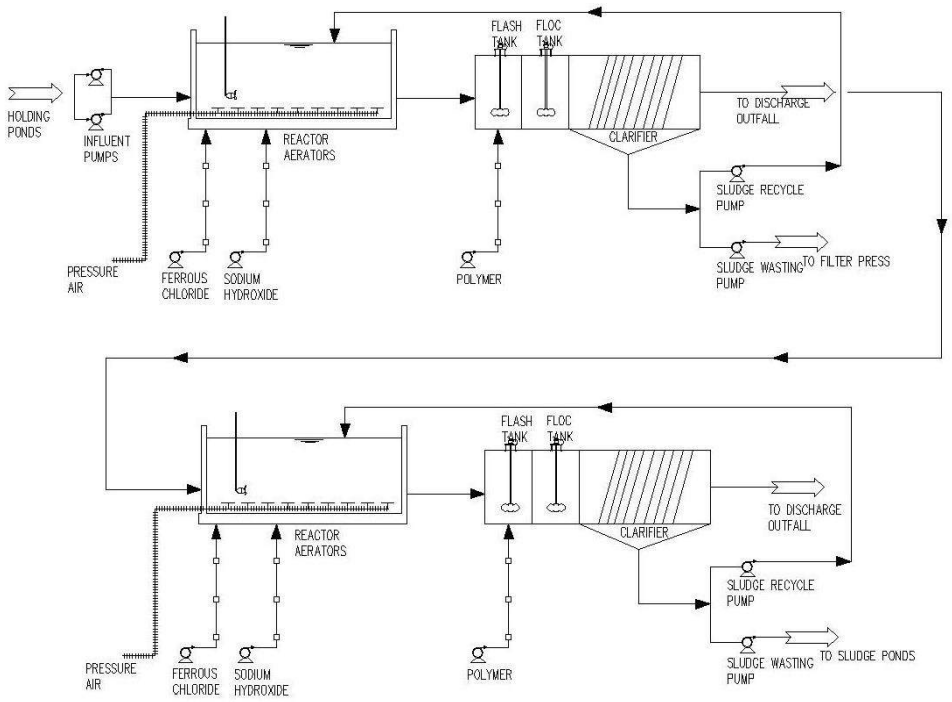

Figure 4 Co-precipitation metals treatment process flow diagram. Two-stage system

The principal objectives of the technology evaluations carried out by EPA (Bates, 2006) were: ability to neutralize acidity, determine removal efficiencies of ten metals (Al, As, Cu, Fe, Ni, Cd, Cr, Pb, Se and Zn) , determine the concentrations of the primary and secondary metals in effluent are below EPA-mandated discharge standards, document operating parameters, optimize system performance, monitor chemical composition of ARD as it passes through the treatment system, operational performance of solids separation systems, document solids transfer, dewatering, and disposal operations.

RESULTS AND DISCUSSION

The study was carried out over a two-year period. A total volume of 83,600 m^3 of ARD was treated with both systems, 93% of this volume with the two-stage system, 7% with the one-stage configuration. Three tables summarizing the outcomes are provided in Table 1 – 3.

Table 1 and 2 show the results of influent, effluent concentrations and removal efficiencies for the considered metals. This included one-stage and two-stage operations. Table 3 shows the amounts of waste generated during the evaluation and its composition.

Table 1 Active lime treatment system removal efficiencies: two-stage operation in 2002 and 2003

Target metal	Avg. influent conc. (µg/L)	Std. Dev.	Avg. effluent conc. (µg/L)	Std. Dev.	Exceeds discharge standards (Y/N)	Avg. removal efficiency (%)	Range of removal efficiencies (%)
Aluminium	381,000	48,792	1,118	782.00	N	99.70	99.20 to 99.90
Arsenic	2,239	866.00	8.60	1.90	N	99.60	99.20 to 99.80
Copper	2.383	276.00	8.00	2.50	N	99.70	99.40 to 99.80
Iron	461,615	100,251	44.90	66.20	N	100.00	99.90 to 100.00
Nickel	7,024	834.00	34.20	15.40	N	99.50	99.20 to 99.90
Cadmium	54.40	6.10	0.70	0.28	N	98.70	99.20 to 99.90
Chromium	877.00	173.00	5.70	12.20	N	99.30	93.80 to 99.90
Lead	7.60	3.60	2.00	1.10	N	78.30	69.20 to 86.70
Selenium	4.30	3.90	3.80	1.50	N	Not Calculated	Not Calculated
Zinc	1,469	176.00	19.30	8.90	N	98.70	97.40 to 99.40

In one-stage operation, the resulting solid waste stream exhibited hazardous waste characteristics due to high arsenic and nickel concentrations, and must be disposed of in an off-site treatment, storage and disposal (TDS) facility. In step I of two-stage operation, a small quantity of precipitate containing high arsenic concentrations is produced, which when dewatered, exhibits hazardous waste characteristics and requires off-site disposal in a TDS facility. In step II, a much larger quantity of solid waste is generated; however, arsenic concentrations are low enough that the step II solid waste is not classified as a hazardous waste and can be disposed of on site

Table 2 Active lime treatment system removal efficiencies: one-stage operation in 2003

Target metal	Avg. influent conc. (µg/L)	Std. Dev.	Avg. effluent conc. (µ/L)	Std. Dev.	Exceeds discharge standards (Y/N)	Avg. removal efficiency (%)	Range of removal efficiencies (%)
Aluminium	107,800	6,734	633.00	284.00	N	99.50	99.00 to 99.80

Table 3 Determination of hazardous waste characteristics of solid waste streams at Leviathan mine

Mode of Operation	Operational year	Solid waste stream evaluated	Total solid waste generated (DryTons)	TCLP	Waste handling requirement
Biphasic	2002	Phase I Filter cake	22.70	Pass	Off-site TSD facility
Biphasic	2002	Phase II Pit clarifier Sludge	118.00	Pass	On-site disposal
Biphasic	2003	Phase I Filter cake	21.10	Pass	Off-site TSD facility
Biphasic	2003	Phase II Pit clarifier Sludge	93.60	Pass	On-site disposal
Monophasic	2002	Filter cake	20.40	Pass	Off-site TSD facility

CONCLUSION

Both treatment systems were shown to be extremely effective at reducing metal concentrations of the ten target metals in the ARD flows to below EPA-mandated discharge standards. In general, removal efficiencies for the ten target metals exceeded ninety percent at a maximum pH value of 8.2.

In addition, the active two-stages treatment system was shown to be very effective at separating arsenic from ARD prior to precipitation of other metals, subsequently reducing the total volume of hazardous solid waste produced. Solids generated in stage II of two-stage configuration pass the EPA Toxicity Characteristic Leaching Procedure TCLP 1311, and the solids were allowed to be

disposed of in a municipal landfill or on-site, with a reduction in the cost of disposal from about 500 US$ per metric ton to as less as 20 US$ per metric ton.

In Table 4, a process and cost comparison is shown between the iron co-precipitation technology and High Density Sludge (HDS) technology, a common technology applied to treat ARD.

Table 4 Process comparison. Iron co-precipitation vs. HDS

Technology	Reactor TSS(mg/L)	Reactor HRT(min)	Process pH	Minimum Process No. steps
Iron Co-precipitation	500-3,000	20-30	6-8.2	1
HDS	10,000-25,000	30-60	6-11	2

Regarding capital cost comparison between Iron co-precipitation and HDS, for a regular metal-removal system for ARD, an HDS system will need 2 series-reactors and an sludge conditioning step where the lime or base is added to a sludge conditioning reactor prior to being returned to the primary reactor; on the other hand, an iron-co-precipitation system can be implemented in only 1 reactor step. Regarding expenditure costs, in a HDS system is needed to maintain a higher pH than in iron co-precipitation, with an increase in base consumption. It is important to remark the importance of running pilot test to ensure treatment characteristics in order to develop a complete installation.

Solving Mine Water Problems with Peat-Based Sorption Media

Paul Eger[1], Peggy Jones[2] and Doug Green[2]
1. *Global Minerals Engineering, USA*
2. *American Peat Technology, USA*

ABSTRACT

Mine water often contains trace metals that must be removed prior to discharge. Conventional technologies exist but generally are labor intensive and expensive. Peat-based sorption material can be a less expensive alternative and is easily deployed in either "semi-active" or passive treatment designs. The media is a hardened uniform granular material produced from reed sedge peat. It has a hydraulic conductivity of around 1 cm/sec, metal removal capacities ranging from 1 - 15% dry weight and been used successfully to remove suspended and dissolved metals from the Soudan iron mine in Minnesota and base metal mines in North America.

In November 2012, a pilot test was initiated at the Soudan mine. Since startup, over 62.4 million liters (> 32,000 bed volumes) have been treated with an average removal of around 75% for suspended copper and 60% for dissolved copper. Backwash is required at about 4000 bed volumes, but with a combination of air sparging and high flow backwash, the suspended material is effectively removed from the bed. The APTsorb media produced equivalent removal to the existing system but reduced the size and complexity of the system and reduced operating costs by 50%.

In October 2013, a pilot test began at a base metal mine in North America. The pilot was designed to model both a "semi-active" (pressurized tank) and passive (biocell) treatment system approach. Lead removal in both pilot systems was generally greater than 99%. Excessive solids in the mine discharge contaminated the pressurized tank and affected treatment at 6400 bed volumes. This reduced dissolved metal removal efficiency in the media from 99% to about 85% and caused the discharge to exceed the permit limit of 11.5 ug/l lead. The biocell was not affected and it continued to meet discharge limits up to 20000 bed volumes.

Keywords: Copper, lead, zinc, cadmium, ion exchange, passive treatment, adsorption,

INTRODUCTION

Mine water often contains trace metals above regulatory limits. For many situations, lime treatment is the preferred treatment since it is effective with most mine waters. However, it is expensive, generally requires a large infrastructure and has substantial ongoing operation and maintenance costs. Commercial ion exchange resins can provide an alternative treatment approach but the media is expensive and typically cannot effectively handle water containing suspended solids.

Peat is a natural material and has long been known for its ability to remove metals from water. As a result, metal concentrations in peat have been used as a geochemical prospecting tool and peat has been tested for its ability to treat wastewater (Lapakko & Eger, 1988, Salmi, 1959, Brown et al., 2000). Up to 10% copper was measured in peat from the Tantramar Swamp in New Brunswick and copper concentrations up to 8.9 % have been reported in samples used to treat wastewater (McDonald, 1976; Premi, 1970).

Peat, although relatively inexpensive, tends to be non-uniform and somewhat difficult to handle. Although loose, fibrous peat can have hydraulic conductivities on the order of 10^{-1} cm/sec, more decomposed and compacted peat can have conductivities of 10^{-3} to 10^{-4} cm/sec. These lower conductivities reduce the overall flow rate and increase the potential for channelization.

American Peat Technology (APT) has developed a granulation and low temperature hardening process to convert loose peat into an engineered sorption media (Figures 1, 2). The granules maintain their structure when wet and can be sized to any specification, which makes them readily adaptable to a variety of treatment systems. The standard media is 0.6 to 2 mm and has an estimated hydraulic conductivity around 1 cm/sec. Metal removal capacities measured in laboratory equilibrium tests have ranged from 1 to 15% dry weight metal.

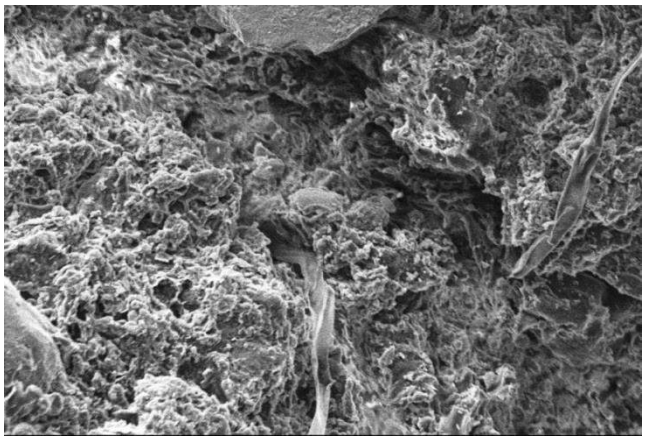

Figure 2 Sorption media surface at 1500X

APPROACH

Pilot tests were conducted at several sites to evaluate the ability of peat-based sorption media) to remove trace metals from mine drainage.

Soudan Mine; Suspended and Dissolved Copper

The Soudan Mine is an abandoned underground iron mine located in northeastern Minnesota. Mine water is discharged at an average flow rate of 227 L/min. The pH of the discharge is generally around 7 but contains low levels of copper and cobalt. Metals concentrations range from 30-50 ug/l copper and 10-15 ug/l cobalt, which exceed the permit limits of 17 and 4 respectively. About 75% of the copper is suspended but all the cobalt is dissolved. Water is currently treated with a commercial ion exchange system that employs prefiltration with bags, cartridge filters and activated carbon (Figure 3).

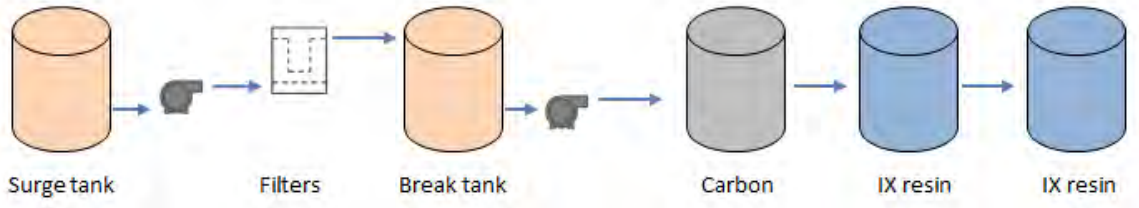

Figure 3 Existing water treatment, Soudan Underground mine

At the Soudan Mine, a pilot test was conducted to evaluate the ability of the peat-based sorption media to remove both suspended and dissolved metals from the overall mine discharge. About 1900total liters of media were installed in a 3785 liter treatment tank that was designed to be periodically backwashed (Figure 4).Typical flow rate was 189 L/min, but flow rates varied over the course of the pilot from 114 to 378 L/min.

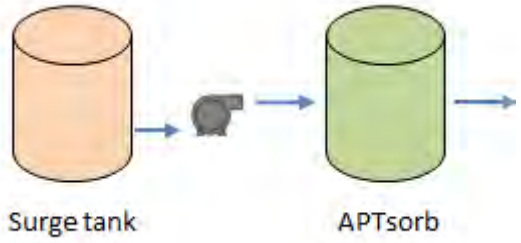

Figure 4 Pilot test, Soudan Underground Mine

Water quality samples were taken roughly on a weekly basis and analyzed by APT using a Perkin Elmer PinAAcle 900 graphite furnace. Periodic quality control samples were run by Pace Laboratories.

RESULTS

During the initial testing, samples were collected from before and after the media tank as well as after each component in the existing system. During this time, total copper in the mine discharge generally varied from 20 to 40 ug/l and dissolved ranged from 5 to 10 ug/l. A total of about 17 million liters was treated by the peat based sorption media system during the comparative test.

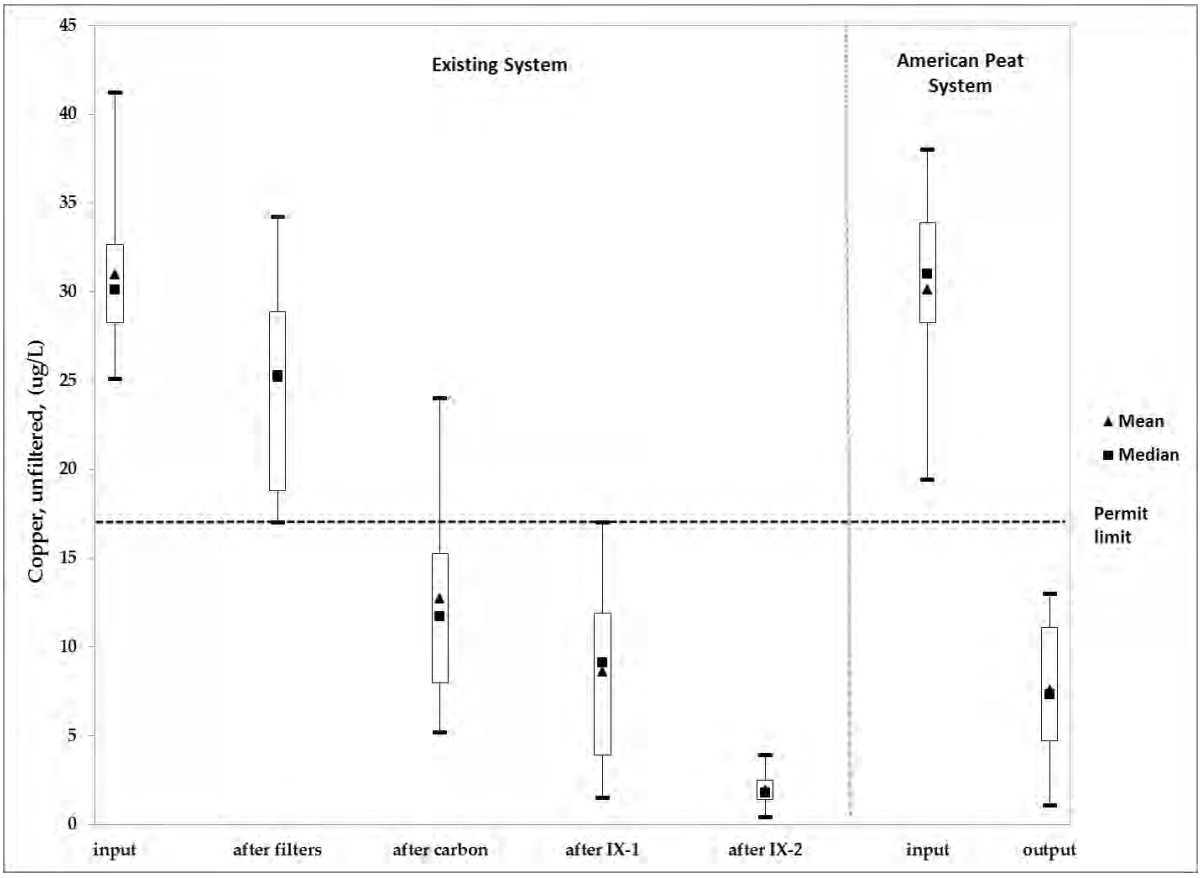

Figure 5 Comparison of existing system and APTsorb, November 2012 – April 2013

In the existing system, total copper concentrations decreased after each component, and were less than 5 ug/l after the last ion exchange tank. (Figure 5). After the peat media tank, total copper ranged from 4 to 13 ug/l and was always less than the permit limit of 17 ug/l.

Starting in May 2013, there were problems with an in-mine treatment system that pre-treated a small but concentrated flow, and the copper concentrations in the overall mine discharge began to

increase. It reached a maximum of 364 ug/l in July. The problems with the in-mine system were corrected by October, and concentrations returned to the typical range of 30 – 50 ug/l (Figure 6).

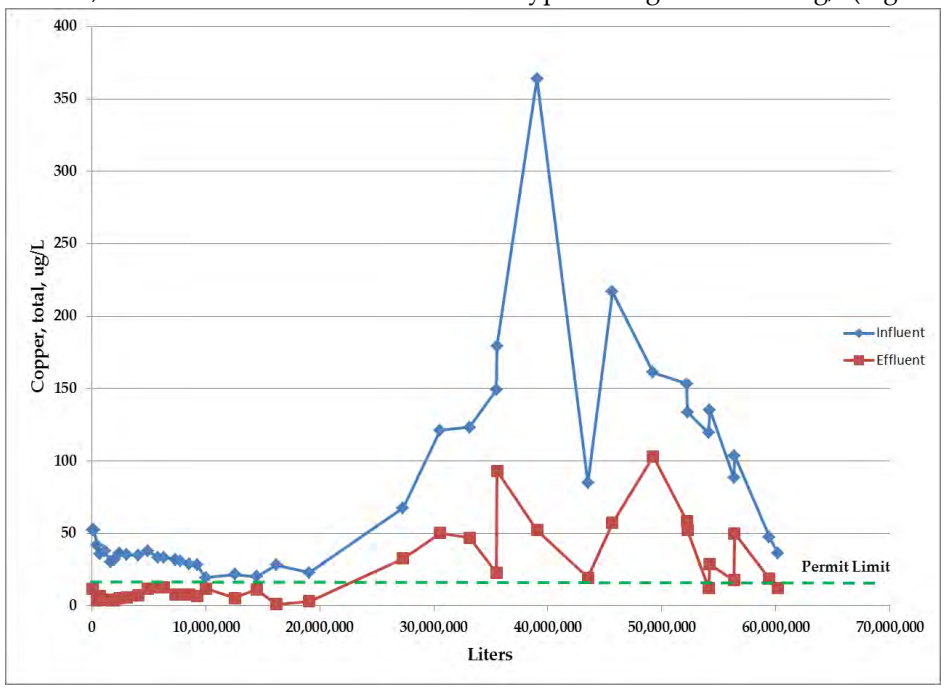

Figure 6 Total copper removal at the Soudan Mine, November 2012-2013

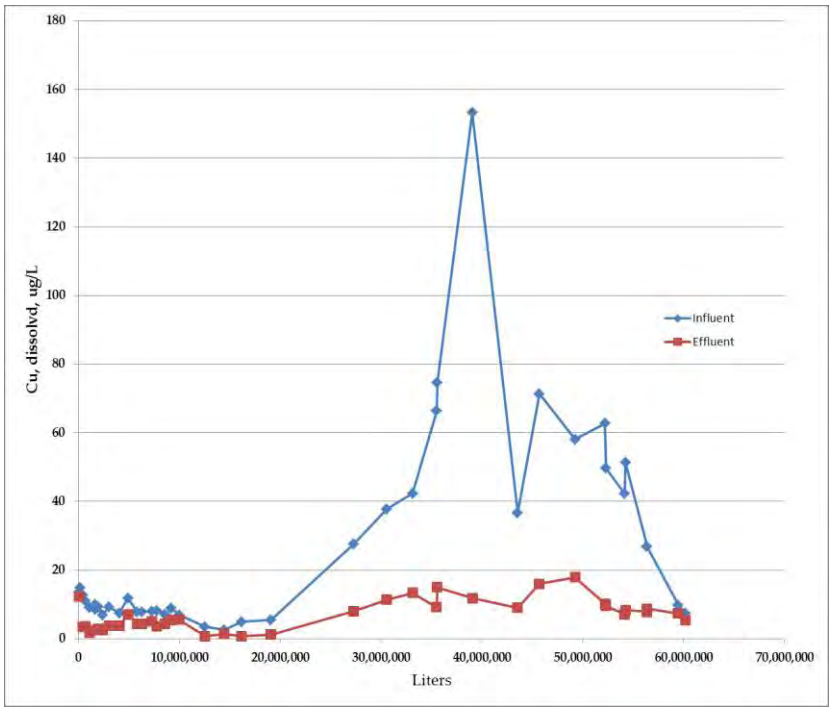

Figure 7 Dissolved copper removal at the Soudan Mine, November 2012-2013

When concentrations in the mine water increased, the peat media continued to remove both total and dissolved copper, but concentrations exceeded the permit limit of 17 ug/l. (Figures 6, 7). When

the influent copper concentrations decreased in the fall, the effluent concentrations also decreased and the discharge met the permit limit. Dissolved copper was removed continuously throughout the study despite an order of magnitude variation in input concentration. Treatment continued until November 2013 when the system had to be shut down and moved to a new treatment location. During the treatment period, about 62.4 million liters of water had been treated.

Base Metal Mine; Lead, zinc, cadmium

The second site is an active underground base metal mine in North America. The suspended solids in the mine water vary substantially but average around 30 mg/l. The water is circumneutral with average total metal concentrations of 2100 ug/l lead, 115 ug/l zinc and 0.8 ug/l cadmium; average dissolved concentrations were 150 ug/l lead, 70 ug/l zinc and 0.2 ug/l cadmium. Typical discharge is around 18,900 L/min. Water is currently discharged to a clarification basin.

Two pilots were constructed; one using a pressurized tank similar to the Soudan mine and the second a gravity flow system to simulate a passive treatment approach (biocell). Since the media has a high hydraulic conductivity, hydraulic loading rates of 40.8 L/min/m^2 are possible with minimal head pressure. The pressurized flow tank typically treated 189 L/min, but flow rates up to 378 L/min were tested. The biocells were operated at loading rates of 10.2, 20.4 and 40.8 L/min/m^2 (2.3 to 9.5 L/min). Since the discharge was directly from an active underground mine a sand filter was installed prior to both pilots to avoid excessive solids loading.

Pressurized tank

Treatment began in October of 2013. Lead concentrations in the input water were typically around 1000 ug/l, but spiked as high as 40,000 µg/l in December (Figure 8). The sand filter essentially removed all the suspended lead, although it plugged quickly during the high solids discharge. The peat media removed about 99% of the remaining lead with effluent concentrations well below the current permit limit of 11.5 ug/l (Figure 8).

Although the sand filter removed most of the suspended material, an excessive solids load plugged the sand filter within 30 minutes and solids were pushed into the media tank. In an effort to remove these solids, the peat media was backwashed.

The backwash did not effectively remove the solids but instead distributed them throughout the bed and contaminated the media. After the backwash, Lead concentrations immediately jumped to around 20 ug/l.

Biocell

Only the results from the biocell with the highest loading are presented. Treatment was similar in all biocells; those with lower flows just treated less volume.

The biocell removed about 99% of the lead for the first 10 weeks of the study (Figure 9). Concentrations increased gradually and reached the permit limit at about 30 weeks. Although suspended solids did enter the biocell, they were retained in the upper layer of the media.

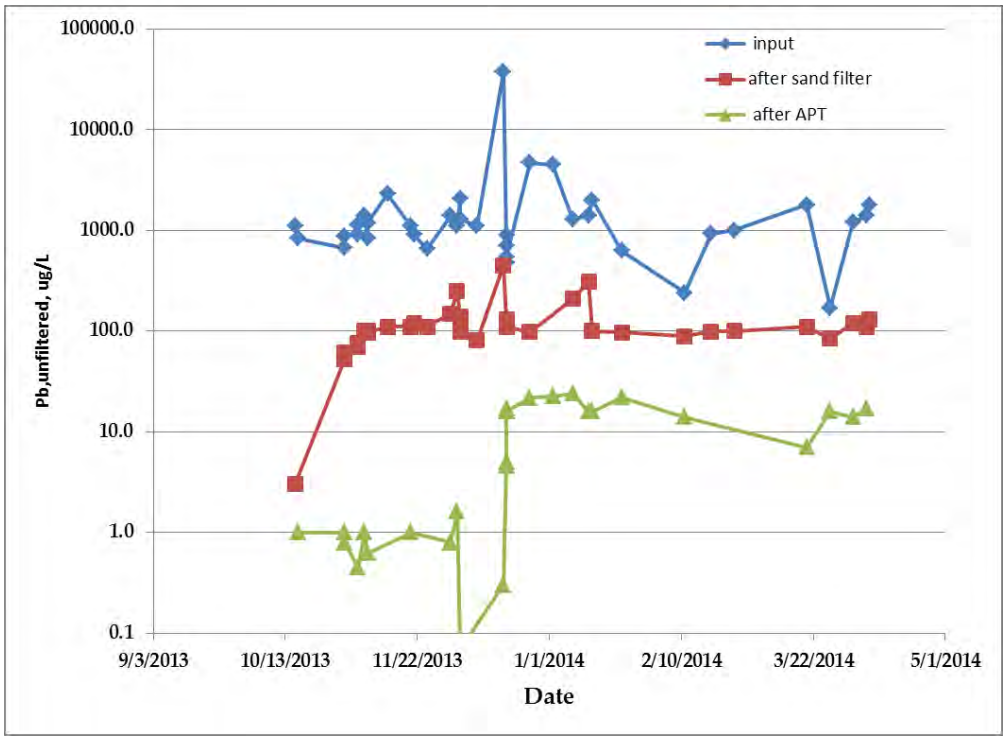

Figure 8 Lead removal, pressurized tank, October 2013-February 2014

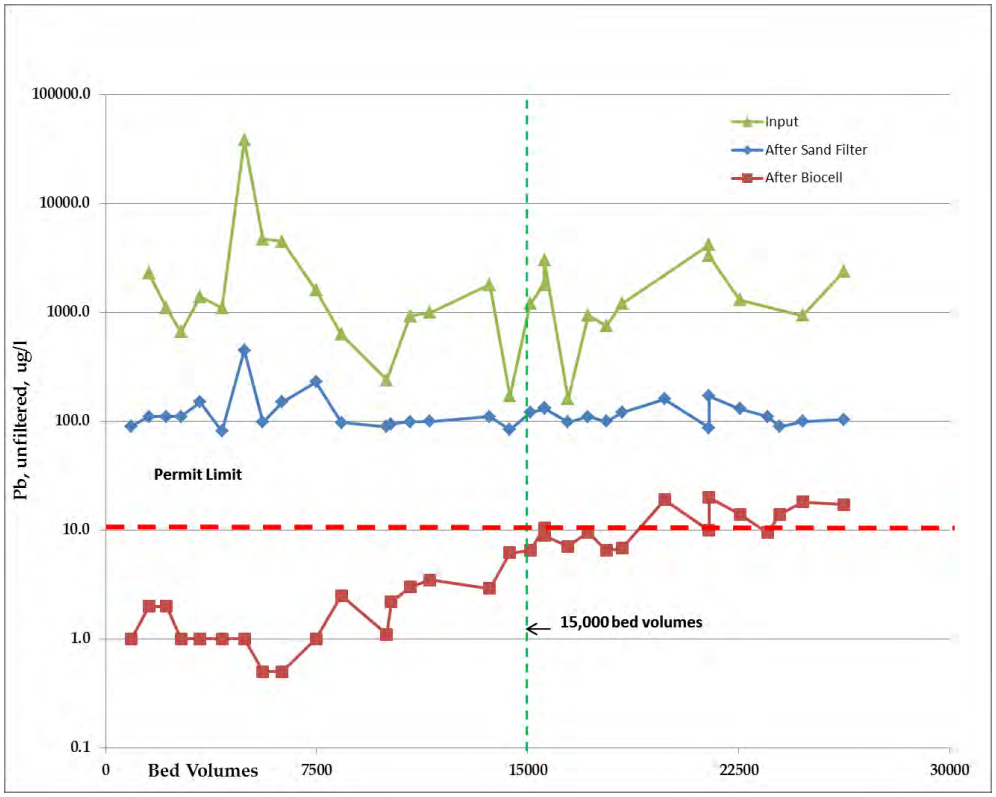

Figure 9 Lead removal, biocell October 2013 – August 2014

This caused a slight increase in head but the flow rate remained constant. No backwash was conducted on the biocell and the system continued to treat water until the test was terminated in August 2014. At the end of the experiment, Lead removal was still greater than 80%.

DISCUSSION

Lifetime

Treatment lifetime is often measured by the number of bed volumes treated. One bed volume is equal to the volume of the media; which in the pressurized tank is about 1890 liters. At the Soudan Mine, over 32,000 bed volumes have been treated, while the biocell at the base metal mine treated over 26,000 bed volumes (Figure 10). In both cases, the media was still removing substantial amounts of metal when the pilot ended.

At the base metal mine, the media treated 15,000 bed volumes before effluent concentrations approached the permit limit. The first sample that actually exceeded the permit limit of 11.5 ug/l was at 20,000 bed volumes. The standard procedure in media treatment is to employ a two-tank (lead/lag) design. The first tank would treat the first 15,000 bed volumes then a second or lag tank would be added to polish the effluent from the first tank to reduce the concentration below the permit limit. This extends the life of the media in the first tank. Although lead exceeded the permit limit in the biocell, the overall lead removal was still over 80% and the rate of increase in the lead concentration in the effluent was gradual, which suggests that breakthrough would be manageable and allow for methodical replacement of media.

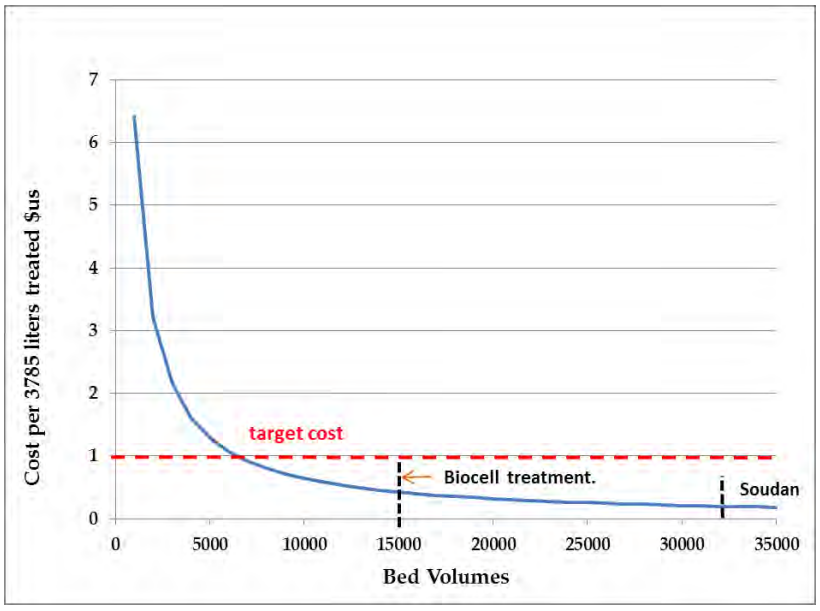

Figure 10 Treatment cost

Costs

As the number of bed volumes treated increases, the treatment cost (cost per liter treated) decreases (Figure 10). For copper treatment at Soudan the operating cost is on the order of 0.25 US$ per 3785 liters. For lead, the treatment cost using a single bed of media would be 0.43 US$ per 3785 liters.

At the Soudan Mine, a single tank of peat based sorption media provided equivalent (or better) copper treatment than the first four components of the existing system. Reducing the complexity of the system also reduced the overall cost associated with treatment. The estimated annual operating cost for the existing system was around 163,000 US$; this could be reduced to around 70,000 US$ by replacing the first part of the system with a tank of peat media.

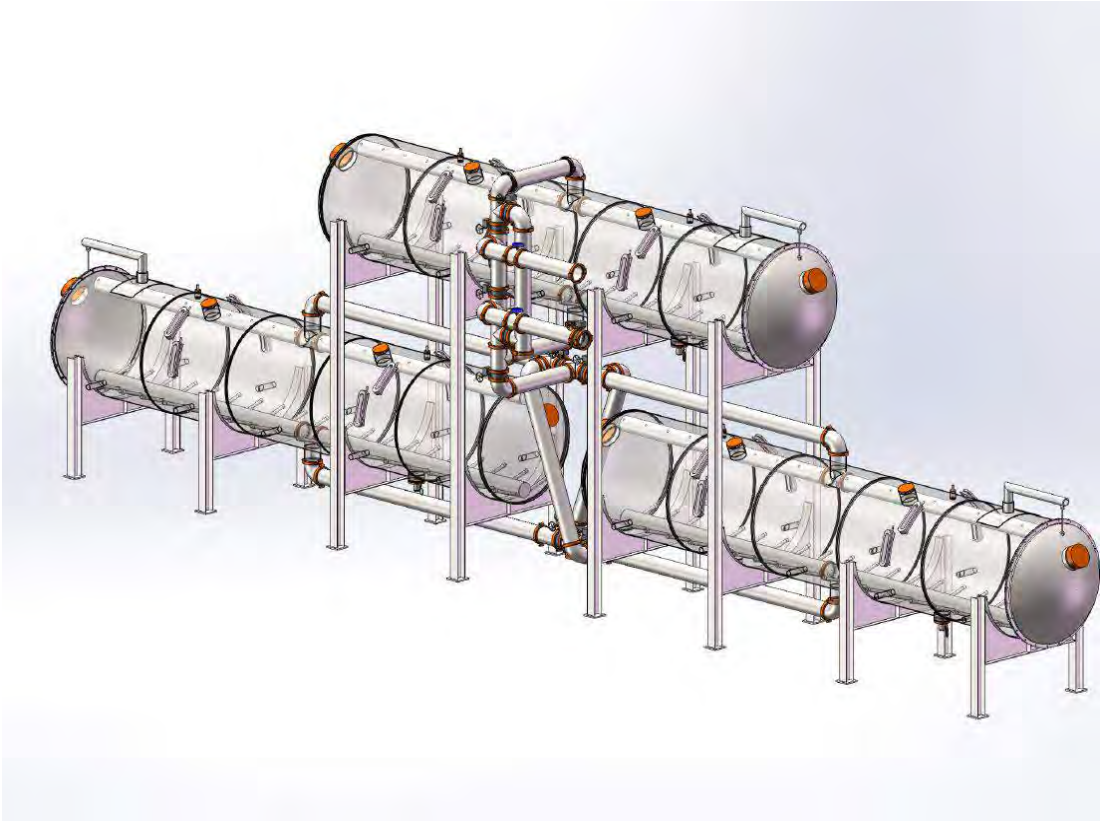

Figure 11 Three -tank module

At the base metal mine, a conceptual treatment approach was developed using a three tank modular system, containing a sand filter, and two tanks of media in a lead/lag configuration (Figure 11). Each module would be capable of treating up to 4540 L/min. The projected capital cost for the system was less than half that of a chemical treatment plant and the projected operating cost of 0.43 US$ per 3785 liters was significantly less than the company's target cost of 1 US$ per 3785 liters.

CONCLUSIONS

A variety of metal removal mechanisms occur in peat and include adsorption, ion exchange, complexation and chelation (Brown et al., 2000). This variety of mechanisms makes peat a very effective natural treatment media with the ability to cost-effectively remove a wide range of trace metals.

Peat resources are plentiful in Minnesota and the northern portion of the state still retains over 90% of its presettlement wetlands. Peat used to produce the media is harvested from an area that was drained in the early 1900's when there was a major effort to develop agriculture in northern Minnesota. The use of peat as a water remediation media is an example of using a resource in a sustainable, thoughtful way to maximize its best use potential.

Technically and politically, peat is described as a slowly-renewable resource and given the large area of wetlands in northern Minnesota overall accumulation exceeds the small extractive use. Peat accumulation rates are very slow but American Peat Technology is currently investigating methods to increase the rate of accumulation as part of its reclamation program.

ABSTRACT

Acid mine drainage (AMD) poses a serious threat to water quality in the Witwatersrand region (South Africa), owing to extensive mine voids that have been abandoned, and subsequently flooded. In response to the severity of the situation, the South African government has undertaken construction of facilities to lower the water level to a safe depth (e.g. where no AMD decants into the surrounding surface- or groundwater) through pumping and treatment. It is proposed that the infrastructure that is currently being installed could better manage the problem by pumping from a greater depth than originally intended. It is hypothesised that the anoxic conditions at greater depth (ca. 2 km) will preclude the generation of AMD and hence reduce the need for treatment, while maintaining the desired water level below ground. The increased energy required for pumping from 2 km was calculated relative to the intended depth (just below the environmentally critical level). The expected energy increase was ≈10%, suggesting that it is feasible to use the existing/planned pumping infrastructure at greater depth. The effects of pH, temperature and initial availability of oxygen in reaction water on the formation rate of AMD from Witwatersrand coal waste rock have been quantified.

No statistically significant effects of initial oxygen availability, pH, or incubation temperature on the production of SO_4^{2-} from coal mine waste rock were observed. In particular, decreased availability of O_2 in incubation water did not inhibit production of SO_4^{2-}. However, dissolved oxygen (DO) in many of the low DO treatment replicates increased, even though the incubation vessels were sealed, suggesting contamination.

The potential effects of pumping from depth on the aquifer were also investigated. In both cases, where oxygenated or low DO water was added to the surface and pumped from the bottom of an experimental column, the result was improved water quality with time (pH, EC, Fe, and SO_4^{2-}). However there is still considerable uncertainty as to whether this is a result of dilution without any formation of AMD or a result of dilution and no generation due to insufficient sulphide present to cause an ongoing reaction.

Keywords: Acid Mine Drainage (AMD), Acid Rock Drainage (ARD), Remediation, Pumping, Johannesburg.

INTRODUCTION

Extensive gold mining activity around the Witwatersrand Basin (South Africa) has resulted in the formation of acid mine drainage (AMD). It is estimated that the potential AMD decant is in excess of 200 Ml/day, and contains high levels of sulphate and dissolved metals (McCarthy, 2011; Council for Geoscience *et al*., 2010). The South African government has awarded tenders to various industrial partners to mitigate the problem by pumping the water table down to just below the Environmentally Critical Level (ECL) by pumping from the ECL, and treating the resulting effluent using the High Density Sludge Process (HDSP) (Odendaal, 2013). This process is energy intensive, as it requires transport of large quantities of lime to the treatment site, pumping between tanks and treatment ponds, and disposal of the treatment residues. Pumping and treatment can only, however, be a temporary solution to the problem, as fresh AMD will continue to be generated in the mine voids for an indefinite length of time and will continue to require treatment.

In this work it was hypothesised that if water were to be pumped from a lower level, whilst holding the same ECL, acid might not be generated (following removal of the initial acid present in the void) as opposed to pumping from the ECL, where acid would continuously be generated by freshly aerated water. This hypothesis is based on the premise that at depth, oxygen is very limited in water. This effect can be observed in marine environments, where corrosion (due to oxidation) occurs in the surf zone, as well as in deep lakes, where the deep levels in the lake are anaerobic. This project sought to simulate anaerobic, subsurface conditions with a view to testing this hypothesis.

LITERATURE

Background

Acid mine drainage is generated in mine voids, primarily where pyrite-containing minerals are exposed to oxygenated water. The result is acidic water that is rich in sulphates and dissolved metals; in South Africa this frequently includes uranium (Cukrowska *et al*., 2008). Acid mine drainage poses a particular danger to the local environment of the Witwatersrand owing to the high number of abandoned mines and characteristics of the water table in this semi-arid region (Durand, 2012). Decant of AMD is a serious threat to the safety of communities and the environment of the Witwatersrand (Council for Geoscience *et al*., 2010).

The immediate geological region of the Witwatersrand is named the Witwatersrand Supergroup, and consists of sedimentary rock approximately 7500 m thick (Durand, 2012). The Witwatersrand groundwater table is mainly supplied by karst aquifers located in the adjacent Transvaal Supergroup. Water flows from these dolomite-rich aquifers into the Witwatersrand Supergroup, and many of the gold mines in the area are located below the water level of karst aquifers. Hence, millions of litres of water were pumped out daily during peak mining activity periods. Mining activity depressed the water table by as much as 3 km (Durand, 2012). Following cessation of mining activities and associated pumping, groundwater has ingressed into pyrite-rich mine voids left behind, and is currently discharging into rivers in the provinces of Gauteng and the North West.

Mine voids in the Witwatersrand region are classified into the western basin, central basin and eastern basin. The western basin alone has an estimated void volume of at least 45 Gl. Durand (2012) reports that decant of approximately 36 Ml of AMD per day was released from this basin into

the Tweelopiesspruit river in Krugersdorp in 2010, although pumping undertaken at Rand Uranium has since reduced the decant considerably (Odendaal, 2013).

The severity of the AMD decant varies substantially with location. The water quality in the Witwatersrand Basin is seen to be most affected nearest mining operations, with some samples having pH < 2 and sulphate concentrations exceeding 7 000 mg/l in the worst cases (Cukrowska *et al*., 2008). High concentrations of iron (up to 1 010 mg/l), as well as other metals including copper, nickel, cobalt and uranium were also reported.

In some cases, there are sufficient concentrations of uranium and other radioactive elements in mine decant and water bodies to pose serious risk to human health. For example, samples from some lakes near mining operations have been found to contain 14.8 mg/l of uranium, more than 1000× the safe limit for irrigation water of 10 μg/l (Durand, 2012).

Mechanisms of AMD Generation

The mechanisms of AMD generation are extensively reported in literature. The principal process involved occurs when pyrite-containing rocks (FeS_2) are contacted by oxygenated water, where the overall reaction (Equation 1) occurs (Hallberg and Johnson, 2005):

$$FeS_2 + 15O_2 + 14H_2O \rightarrow 4Fe(OH)_3 + 18SO_4^{2-} + 16H^+ \quad (1)$$

The above reaction occurs in multiple stages, and the primary oxidant is ferric iron instead of molecular oxygen – the attack of the ferric iron on the pyrite mineral occurs first, then the resulting ferrous iron is converted back to ferric iron by re-oxidation using oxygen dissolved in the mine water. Oxygenated water is therefore, essential for continuation of the cycle that produces acidity (Hallberg and Johnson, 2005). While this is a naturally occurring reaction, it is accelerated when large surface areas are exposed in mine voids and water and oxygen gain access to the minerals. While the reaction can occur in the absence of bacterial activity, micro-organisms such as *Acidithiobacillus ferrooxidans* can substantially increase the rate of generation (Akcil and Koldas, 2006). As a result of the low pH, metals leach out of the solid state further contaminating the water. In the Witwatersrand, the primary metals of concern are manganese, aluminium, iron, nickel, zinc, cobalt, copper, lead, radium, thorium, and uranium (Durand, 2012).

Current Management Strategies

Three priority areas have been defined in the Witwatersrand (Council for Geoscience *et al*., 2010):

- Prevent uncontrolled decant. This is to be accomplished by pumping water out of the voids to keep the water table below the ECL.
- Limit the ingress of water into the mineshafts. This is to be accomplished by sealing as many large openings as possible.
- Treat the water removed from the voids before being released to the environment. This could be through neutralisation with lime, passive remediation in limestone beds, bioremediation using aerobic wetlands, bioreactors and more (Hallberg and Johnson, 2005). In situ and passive methods are currently regarded as unfeasible for the Witwatersrand Basin due to the size and complexity of the voids as well the large decant rates expected. The expected cost of active treatment of the discharge is ZAR11 /m^3 (Council for Geoscience *et al*., 2010); approximately USD1.1 /m^3.

In response to the AMD problem, these strategies are currently being implemented. The state-owned Trans-Caledon Tunnel Authority (TCTA) awarded a R319 million contract to Group Five Engineering in December 2012 (Odendaal, 2013) to construct pumping stations and HDSP treatment facilities for the central basin. In the western basin, upgrades are being carried out on the existing pumping and treatment facilities at Rand Uranium in order to expand capacity. Due to cost constraints, construction of pumping systems in the eastern basin has been postponed (Odendaal, 2013).

Increasing Pumping Depth

Previous work has shown that by increasing the pumping depth (Figure 1), the energy requirements do not increase as much as might be expected, *e.g.* depending on the initial conditions, doubling the pumping flowrate may only result in a 10% increase in the energy requirement (Figure 2) (Janet et al. 201x). In this paper, we present results of experiments conducted to determine if it is in fact possible to prevent the formation of AMD by using this strategy.

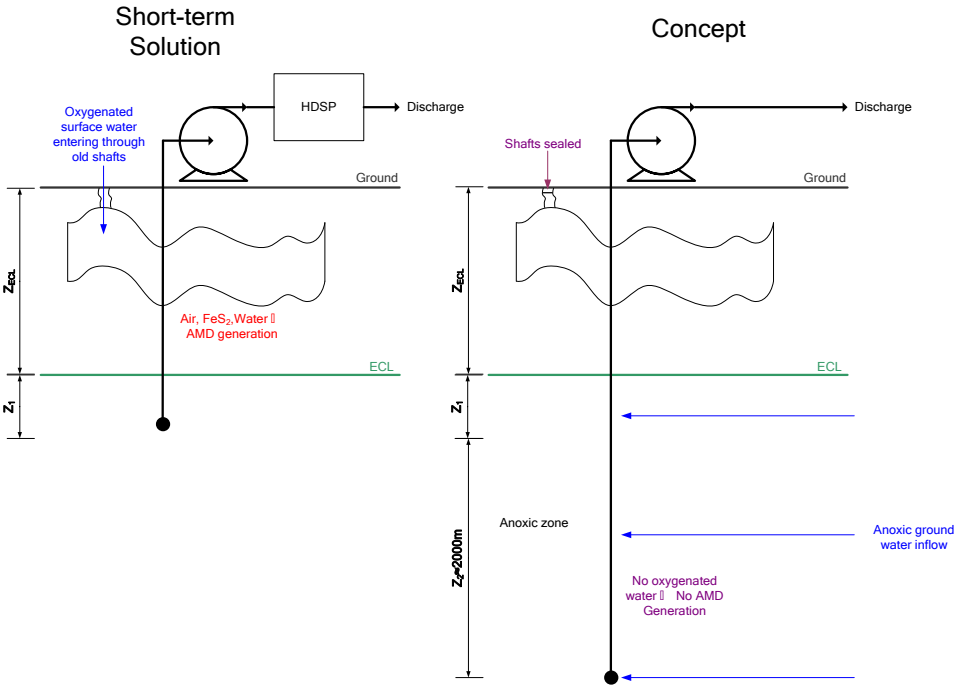

Figure 1 Schematic comparison of current short term intervention plan (left) and the proposed concept of pumping from depth (right) From Janet *et al.*, 201x

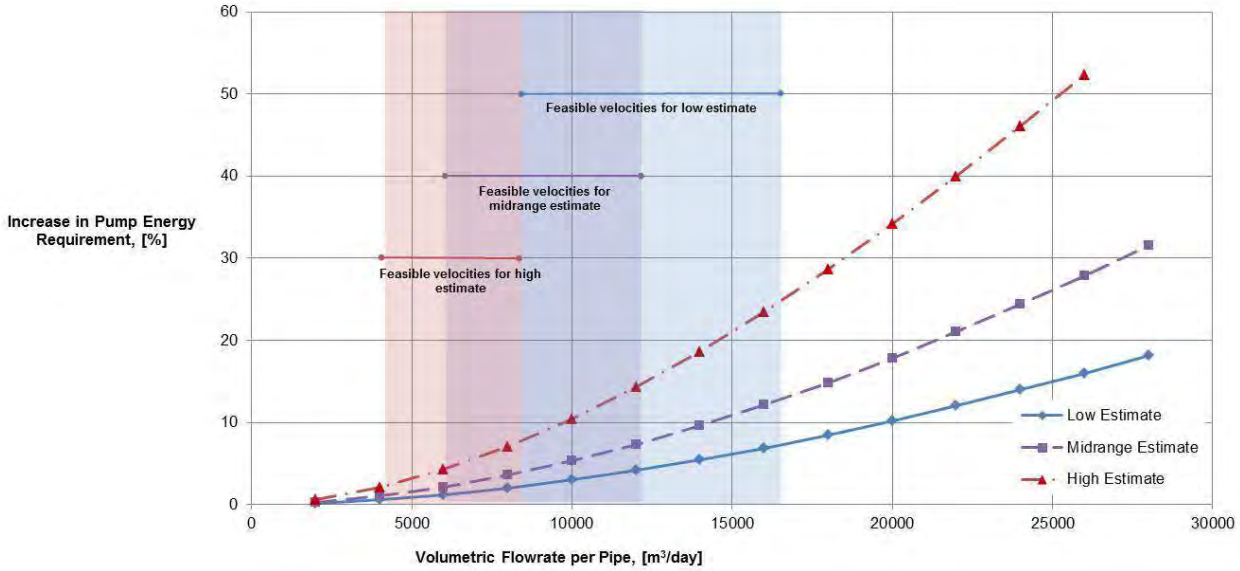

Figure 2 Comparison of percentage increase in pumping energy when increasing pumping depth for three scenarios (low, mid and high estimates) (Janet *et al*., 201x)

METHODOLOGY

Three PVC column reactors (6 m × 30 cm) were set up with pyrite-rich waste rock representative of an AMD-generating ore body (Figure 3), kindly provided by Optimum Coal. Each reactor had a solid casing installed in the centre, in which a peristaltic pump suction line could be inserted. The reactors had a cap at the surface to prevent air entering the system. Deoxygenated water was prepared by continuously bubbling nitrogen through a feed tank. Double head Watson and Marlow peristaltic pumps drew water from the base of each column whilst pumping deoxygenated water into the top of the column at the same flow rate of 31 ml/hour (equal to the net rainfall in the Witwatersrand). This equated to a 9 week hydraulic residence time.

The three columns were set up as follows:

- Column 1: Potable water added to surface, effluent (mimicking groundwater) removed from the base and DO, pH and SO_4^{2-} measured. This investigated what would happen if the only source of water was percolation from the ground surface, mimicking the generation of AMD at the surface. The experiment was also designed to demonstrate potential remediation of AMD as the recharge passed through the aquifer.
- Column 2: De-oxygenated water added to the surface, effluent (groundwater) removed from the lowest level and DO, pH and SO_4^{2-} measured. This experiment was designed to indicate whether AMD formed under anaerobic conditions.
- Column 3: De-oxygenated water added to different depths along the side of the central casing, effluent (groundwater) removed from the lowest level and DO, pH and SO_4^{2-} measured. The column was initially filled with previously boiled water and purged with nitrogen prior to and during filling to minimise DO. This experiment sought to reproduce ingress of DO-poor water at different depths, as would be expected in an aquifer.

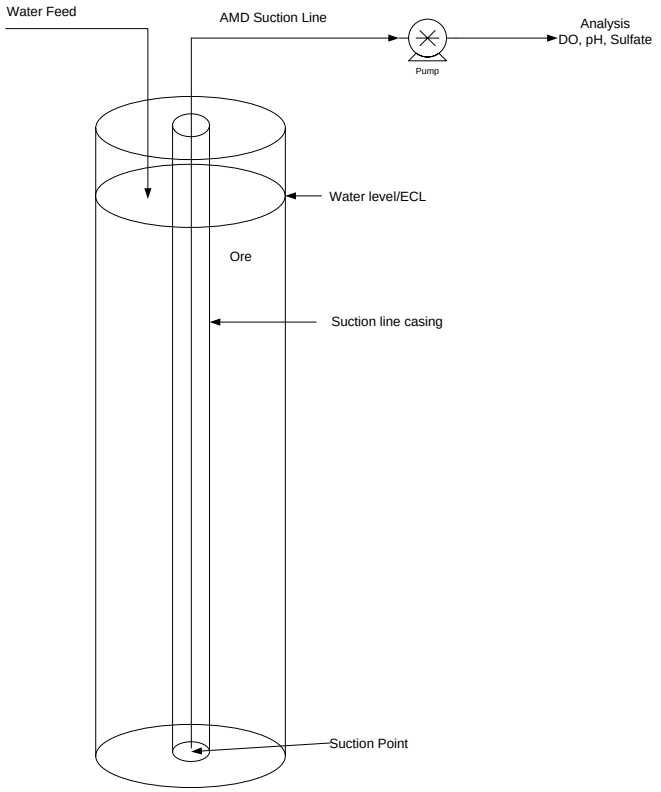

Figure 3 Column reactor, showing feed ingress at the top and effluent removal via a casing in the centre of the column

Upon completion of the initial experiments, Columns 1 and 3 were purged with air whilst still full of water for a period of 30 min in an attempt to generate additional acid such that it could be assured that the results seen were not as a result of the rate of dilution being greater than the rate of acid generation.

Sample DO, EC and pH values were measured using a handheld Consort C5010 multiprobe, which was calibrated prior to each use. Iron and sulphate were measured using a Merck Pharo 300 spectroquant, using test kit 1.14671.0002 for iron and test kit 1.14791.0001 for sulphate. Samples were prepared and analysed according to the manufacturer's directions. Measurements inside the columns (temperature and pH) were taken using a Hydrolab MS5 EC-pH probe.

RESULTS AND DISCUSSION

Comparison of Column 1 (oxygenated feed) with Column 3 (de-oxygenated water feed)

The change in pH of the columns' effluent is shown in Figure 4. Acid was rapidly generated in both columns and the pH gradually rose thereafter. The low DO column (Column 3) had a slightly higher pH than Column 1 after 5 weeks.

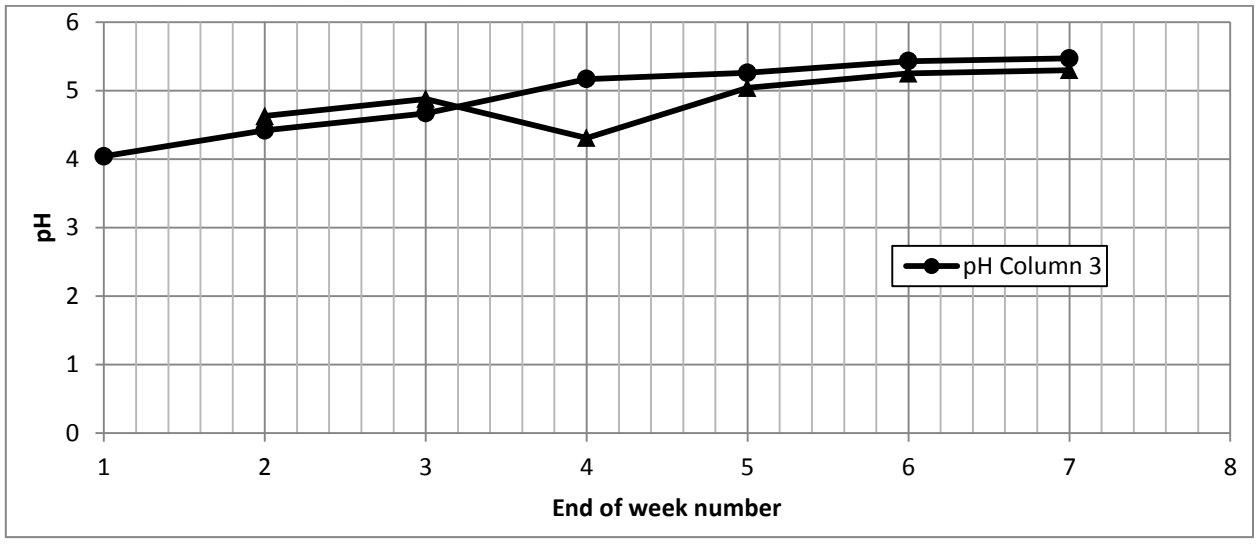

Figure 4 The pH in both columns over time

The DO concentrations in columns 1 and 3 are presented in Figure 5. The values were erratic, although there seemed to be a decrease in DO with time, suggesting that available oxygen was utilised as the reactions proceeded. However, the DO probe was adversely affected by low pH and high sulphate values; these data are not reliable.

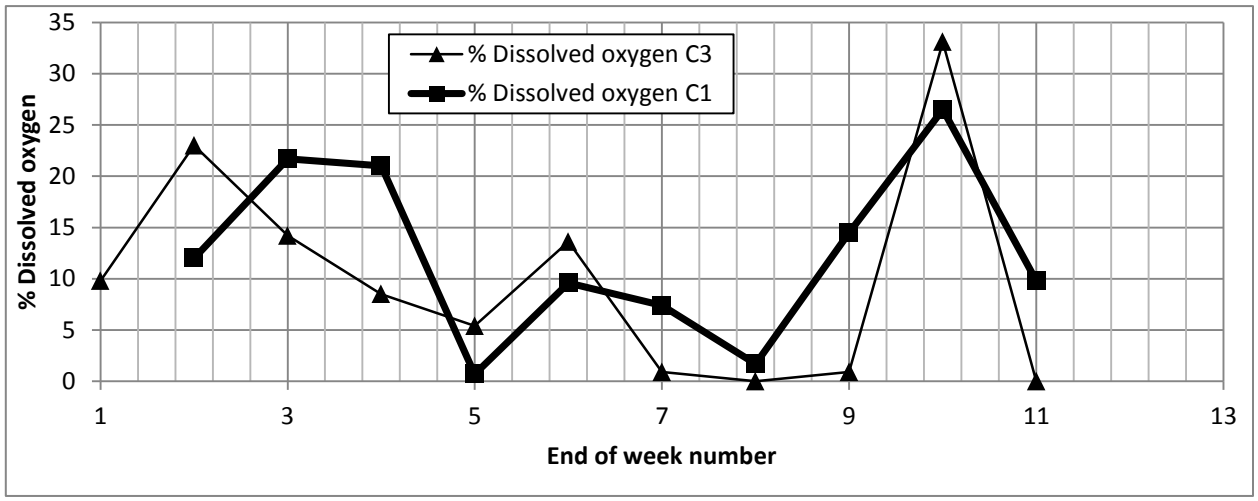

Figure 5 Dissolved oxygen in Columns 1 and 3, showing erratic nature of the data.

Both sulphate and iron concentrations in Column 1 rose rapidly and then decreased (Figure 6). The sulphate values fluctuated substantially throughout the experiment. It is believed that this is a result of the type of analysis used. It is understood that the BaCl test would give significantly more accurate results, and this is recommended for future work. The iron was shown to decrease.

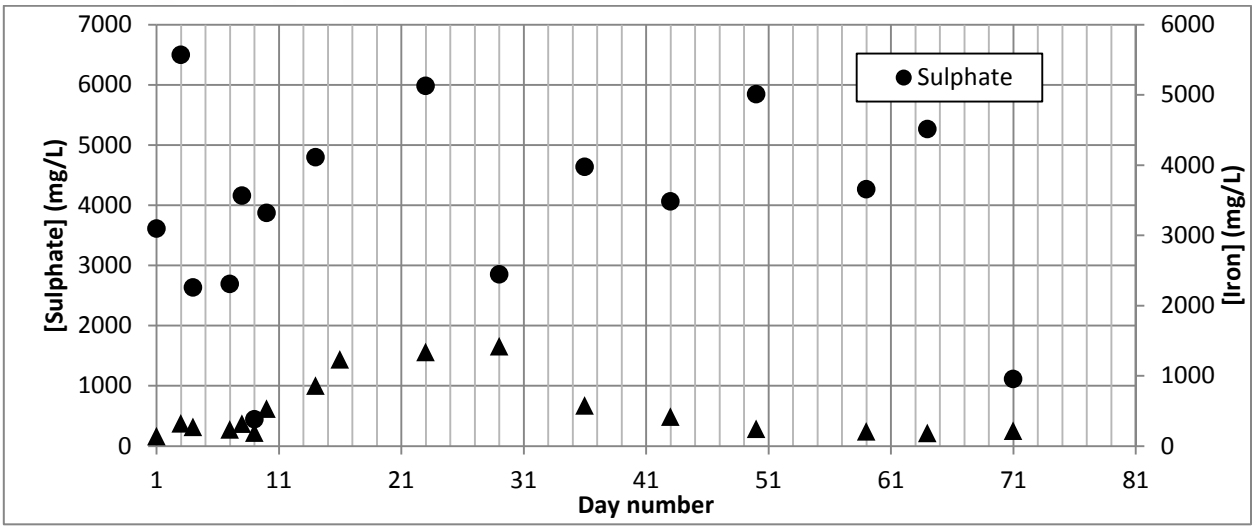

Figure 6 Variation of sulphate and iron in Column 1

The change in sulphate and iron in Column 3 is shown in Figure 7. Similarly to Column 1, concentrations rose rapidly within the first day and subsequently decreased. The two columns reached similar initial values and both showed a decreasing trend with time. The variation of the sulphate concentrations is once again observed.

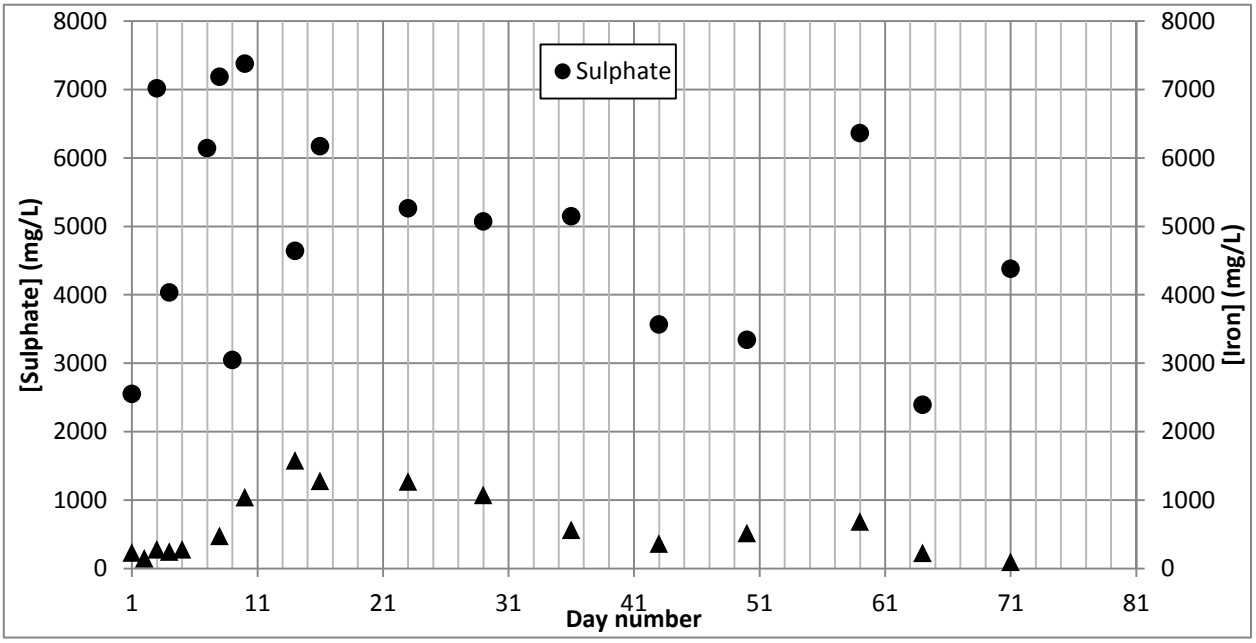

Figure 7 Variation of sulphate and iron in Column 3

Figure 8 illustrates the results when we inserted a Hydrolab MS5 autoprobe onto Columns 1 and 3. The Hydrolab MS5 auto probe, able to measure and record pH, EC and temperature was initially placed in Column 3 from 28 March 2014 to 16 April 2014 and then transferred to Column 1 from 16 April to 23 April. Whilst the probe did not record the beginning of the experiment in Column 1, the data recorded clearly showed an increase in pH, and a decrease in EC (Figure 8), and in Figure 9 the

data are presented for Column 3. The rise in pH is particularly evident in the low DO experiment where the pH increased by 1.5 and EC decreased by approximately 25% .

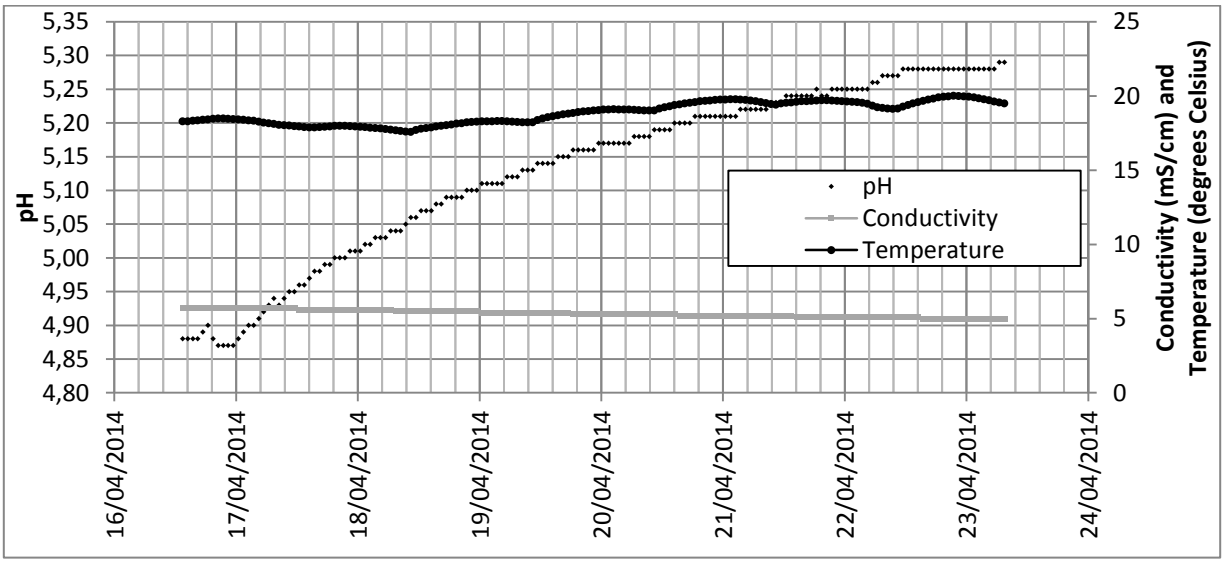

Figure 8 Temperature, pH, and EC profiles within Column 1

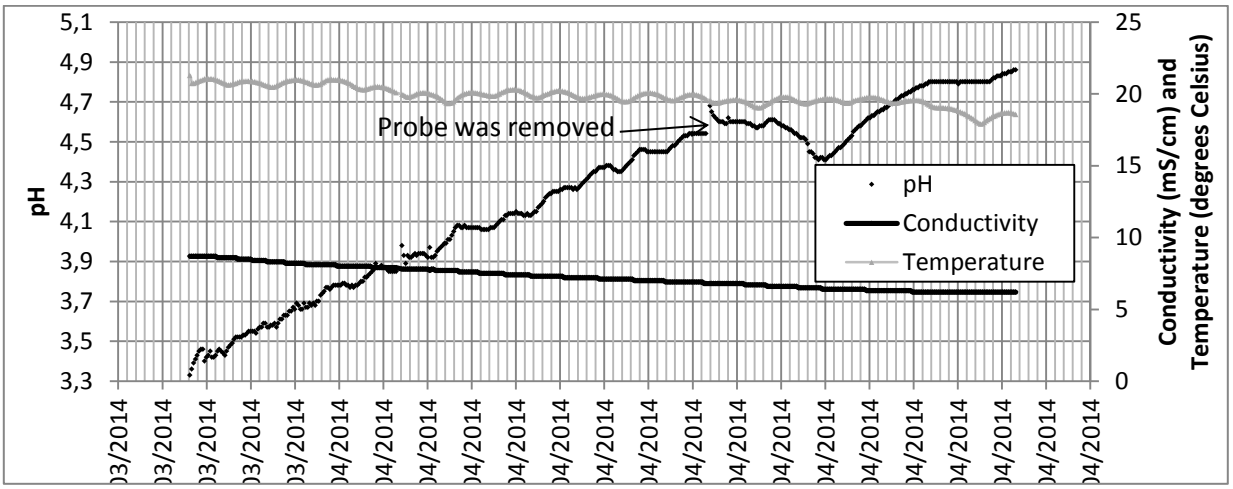

Figure 9 Temperature, pH, and EC profiles within Column 3.

The long-term measurements obtained from use of the Hydrolab probe indicated that by pumping from the bottom of the column, water quality improved and that improvement occurred regardless of the oxygen content of the feed.

CONCLUSION

It has been shown that the energy to pump water from 2 km below surface is not substantially different from removing water from just below the ECL. It has further been demonstrated that acid is rapidly generated by waste rock. With time, all water quality parameters improved significantly by pumping water from the base of the columns where AMD was unable to form. It was not

possible to conclude whether this improvement in quality was a result of dilution due to depletion of the mineral or if AMD was no longer being generated due to the establishment of anaerobic conditions. Future work to assess this will proceed.

Diffusive Exchange System with Internal Precipitation for Acid Mine Drainage Treatment

Gustavo Chaparro, Norma Perez and Alex Schwarz
Centre of Water Resources for Agriculture and Mining (CRHIAM), Universidad de Concepción, Chile

ABSTRACT

Copper extraction is the principal mining activity in Chile. Acid mine drainages (AMDs) and mining effluents are characterized by high concentrations of copper, which can be recovered. Existing biochemical reactors utilize homogeneous substrates as percolation media to immobilize metals. However, microbial communities are exposed to the acid drainages within these systems and their toxicity often limits reactor reactivity.

Diffusive exchange systems on the other hand avoid direct contact of microorganisms with the AMD, significantly expanding the treatment range of biochemical reactors to include higher metal concentrations and lower pHs. A key innovation of this research is the use of vertical tubular screens to convey the AMD through the substrate while simultaneously allowing transverse diffusion of dissolved species and acting as reactors for precipitate formation and settling. This design minimizes clogging and facilitates the recovery of valuable metal. Furthermore, biochemical reactors with passive systems can be built taller and much smaller footprints can be achieved.

This work studied the performance of a 2-m long vertical diffusive exchange column with internal precipitation, allowing the simultaneous removal and recovery of copper from a synthetic AMD. Detailed insight was gained into reactions and transport processes within the tubular screen by the use of several sampling points along the column.

During the first two months the reactor was fed with increasing concentrations of sulfate and no metals, to determine its sulfate reduction potential. Then the reactor was fed with the AMD for one month; during this test effluent metals, sulfate, sulfide, acidity, alkalinity, pH, conductivity and ORP were monitored periodically. The sampling points allowed pH, ORP and metal concentrations to be measured throughout the reactor. High sulfate reduction rates of 0.2-0.6 moles/m^3-day were obtained. Also, during the first month of operation with influent metals, constant removal rates were achieved and precipitates were harvested.

Keywords: biochemical reactor; acid mine drainage; diffusion; copper; sulfate.

INTRODUCTION

Acid mine drainages (AMDs) are an environmental problem which has serious effects on the quality of both surface and ground water. These include acidification and increased concentrations of toxic metals and sulfate.

AMDs are produced by the oxidation of mineral sulfides, resulting in the dissolution of heavy metals and sulfate (Scheoran *et al*, 2010). The reaction involving the oxidation of pyrite is known and can be represented by the following equation (EPA, 1994):

$$FeS_2(s) + 14Fe^{3+} + 8H_2O \rightarrow 15Fe^{2+} + 2SO_4^{2-} + 16H^+. \quad (1)$$

AMD and mining operation effluents generated by the copper extraction industry contain high concentrations of copper which may in some cases be recovered. The complete oxidation of chalcopyrite can be written as (Dold, 2010):

$$CuFeS_2 + 4O_2 \rightarrow Cu^{2+} + Fe^{2+} + 2SO_4^{2-}. \quad (2)$$

Sulfate-reducing bioreactors or biochemical reactors (BCR) have proved to be an effective way of treating AMD (ITRC, 2012). The effectiveness of BCRs relies mainly on the activities of sulfate-reducing bacteria, which produce sulfide and bicarbonate inside the reactor. This leads to the formation of sulfides of metals such as copper, zinc and iron, which precipitate and can then be removed.

$$H_2S + M^{2+} \rightarrow MS\downarrow + 2H^+. \quad (3)$$

However, existing BCRs use a homogeneous bed as a percolation medium for immobilizing the metals in the system. This exposes the microbial communities to AMD, limiting the reactivity of the BCR.

Sulfidic diffusive exchange systems (SDES) avoid direct contact between the AMD and the microbial communities by separating the percolation medium into alternate layers or zones of high and low hydraulic conductivity (Schwarz & Rittmann, 2010). The idea of using this configuration is to separate the advecting contaminated water from the reactive material; in this way the microbial communities in a BCR are not exposed directly to the toxic metals in an AMD. This will enable the range of substrates treated in BCRs to be extended to high metal concentrations and lower pH values (Schwarz & Rittmann, 2007a).

The solutes are exchanged between the layers or zones of a SDES by diffusive processes, so solute exchange occurs because of the concentration gradient between the layers. In order for solute transport to be controlled by the diffusive processes, there should be a difference of at least two orders of magnitude between the hydraulic conductivity values of the reactive and conductive layers.

Using a SDES configuration for the substrate in a BCR allows certain disadvantages suffered by homogenous substrate BCRs to be overcome, such as: loss of organic matter reactivity due to metal crusting and precipitation; problems with blockages and preferential hydraulic flows; limitation of microbial activity due to toxic concentrations of metals; and limits on the height of the BCR because of diminished hydraulic conductivity (Schwarz & Rittmann, 2007b).

In view of the above, it would be of interest to find out whether a new prototype BCR with SDES would enable the equipment to be used to treat an AMD with a high copper concentration, which is impossible with a homogeneous bed BCR. This research developed a prototype BCR with SDES which may allow copper and other metals to be removed from an AMD by simultaneous

precipitation and sedimentation. We also evaluated whether the concentration of influent sulfate is a limiting factor for the functioning of a BCR with SDES, and determined the sulfate reduction rate.

METHODOLOGY

Design of a BCR with SDES

The proposed BCR with SDES uses vertical diffusive exchange columns as conductive zones, surrounded by the organic substrate (reactive zone). With this configuration it is expected that the majority of the metals will be removed by precipitation and accumulate at the bottom of the column.

The idea of using vertical columns as the AMD conductive zone is to promote precipitate formation and establish the exact area where the metals removed by the BCR would accumulate. The object of this is to project a BCR with SDES which would enable metals to be recovered from an AMD. Figure 1 shows the differences between a homogenous bed BCR and the proposed BCR with SDES.

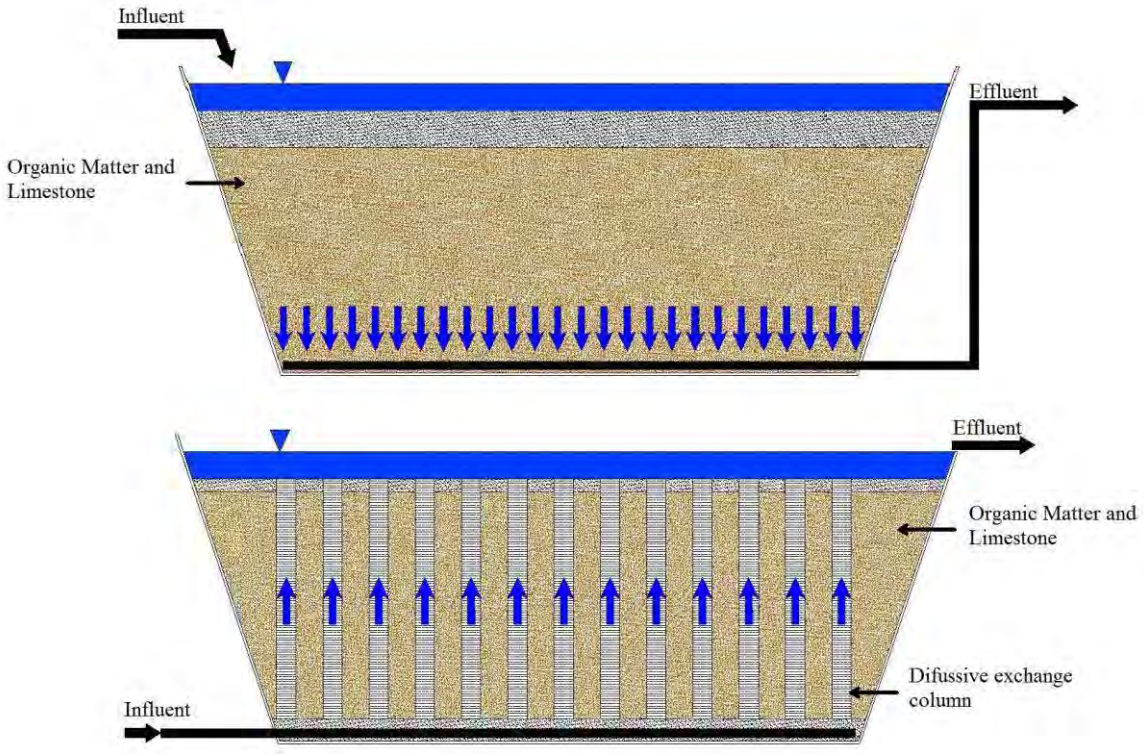

Figure 1 Diagram of a homogenous bed BCR (above) and a BCR with SDES (below). In the SDES reactor, the reactive mixture is crossed by screened tubes for the transport of fluid through the reactive bed. The screens retain the reactive mixture while allowing the lateral exchange of solutes between the advecing fluid and the bed pore space. Precipitates are expected to accumulate at the bottom of the screened tubes.

In the proposed BCR with SDES we decided to use an ascending flow to help sedimentation of the metal sulfide precipitates. The laboratory-scale BCR with SDES represents one of the several

reaction columns that may be found in a full-scale BCR with SDES. Figure 2 is a diagram of the laboratory-scale BCR with SDES constructed for the experiment.

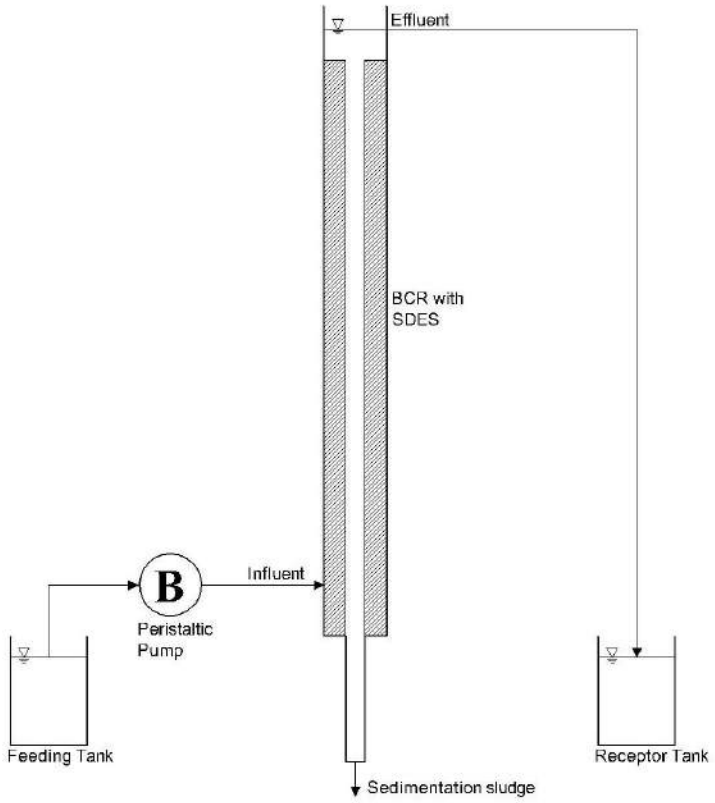

Figure 2 Diagram of the up-flow column reactor that simulates the processes that occur within a column of a BCR with SDES and its associated bed material. The reactor is made up of two concentric columns of which the interior one is screened. The reactive material is located in the inter-column space. The influent is feed into the inner column at the reactor bottom. Formed precipitates can be captured by sedimentation within the bottom extension of the screened tube.

ITRC (2012) recommends a maximum height of 1.8 m for the BCR, to avoid problems of reduced hydraulic conductivity in the lower layers of the substrate as a result of the excessive weight above. This problem does not apply to BCRs with SDES, but for practical reasons it was decided to make the laboratory-scale reactor 1.95 m high. The internal screened column is made of stainless steel, 6 cm in diameter and with aperture 0.75 mm. The outer column is made of PVC tubing, 19.3 cm in diameter. As a result, the volume occupied by the conductive central column in the reactor is 9.7%. A PVC tube 60 cm long, of the same diameter as the screened column, was placed below the column to collect the precipitates.

In order to study the reactor processes, five sampling points were fitted along the screen; these points were set at 6, 50, 100, 150 and 195 cm from the start of the reactive layer.

Organic matter

An important assumption in the choice and design of the substrate for the reactive layer was that microbial activity is sufficient to raise the pH of the AMD, because sulfate-reducing reactions produce bicarbonate and thus generate alkalinity (Scheoran, 2010). For this reason the reactive layer does not contain limestone or any other material to add alkalinity. Table 1 shows the materials used and their percentage by weight.

Table 1 Materials used in the reactive layer (% weight)

Function	Material	Percentage
Long term electron donor	Pure cellulose	50%
Short-medium electron donor	Manure	18.8%
	Leaf compost	31.2%

15 kg of organic matter were needed to fill the reactive layer in the reactor. The mixture was inoculated with 19 L of anaerobic digester content from the local sewage treatment plant. In addition, 15 L of distilled water were added to facilitate mixing and to saturate the organic matter. Figure 3 shows the organic matter used before and after mixing.

Figure 3 Organic matter utilized in the reactive mixture, before (left) and after (right) mixing

Finer organic matter can be used in BCR with SDES, since the substrate does not have to be kept permeable. The organic matter used in these reactors therefore has a larger contact area, with greater bio-availability to the microorganisms.

Experimental Tests

Four continuous experimental tests were carried out. In the first three, only the sulfate concentration in the influent was increased, while in the fourth metals were added. The purpose of

this was to study first whether sulfate is a limiting factor in the operation of a BCR with SDES. Table 2 shows the characteristics of the influent in the experimental tests.

The influent metal concentrations in the fourth test were: 568 mg Cu/L, 137 mg Zn/L, 35 mg Al/L and 0,8 mg Fe/L. These correspond to representative conditions of AMDs generated by large-scale copper mining in central Chile.

To characterize reactor functioning, samples were taken once per week from the effluent, the interior (bed pore water at a depth of 30 cm) and the five points along the screened column (numbered in the direction of flow). The sulfate and sulfide concentrations, the pH and the ORP were measured in the effluent, sampling point 5 (SP 5) and the interior. At SP 1 to SP 4, the sulfide concentration, the pH and the ORP were measured.

Table 2 Experimental tests

	Duration (weeks)	pH	Sulfate (mg/L)	Flow (L/day)
Test 1	6	5-5.5	2,218	2
Test 2	4	5-5.5	4,437	2
Test 3	4	5-5.5	6,655	2
Test 4	4	4-4.5	3,300	3

For three weeks before starting tests, 18 L of a solution with initial concentrations of 2,218 mg/L sulfate and 0.9 ml/L of lactate were recirculated through the reactor. The reactor was then fed for one week with a solution with the same initial concentrations as above, but without recirculation, at a flow of 2 L/day. This month of acclimatization is important in reactors of this type, to enable the bacteria to adapt and the communities to grow sufficiently to spread throughout the substrate.

RESULTS AND DISCUSSION

Variations in Sulfide, ORP and pH

Based on the interior screened column volume, the hydraulic residence time in the first three tests is 2.76 days, and in the fourth, 1.84 days. Table 3 shows the most important results of each test.

The results for SP 2 to SP 5 show the increase in sulfide concentrations as the contact time of the solution inside the reactor increases. All the sampling points reacted to the increased sulfate in the influent. SP 2 to SP 5, and the interior, present an increase in the average sulfide concentration as the influent sulfate increases.

At SP 2 to SP 5, when the sulfate concentration was doubled, the sulfide concentration increased on average by 51%. At these points, when the sulfate concentration was tripled, the sulfide concentration increased on average by 97%. It may therefore be concluded that the sulfide production in the reactor is limited to the influent sulfate. When the concentration of sulfate in the influent is increased, the sulfide inside the reactor also increases, in a proportion of two to one (percentage ratio).

The ORP measurements obtained during the tests at the five sampling points inside the reactor present similar behavior and appear to oscillate around the same average ORP regardless of the

sulfate concentrations in the influent. The ORP at SP 1 to SP 5 during these three tests was -108 mV on average, indicating that the reactor provides optimum conditions for anaerobic sulfate-reducing reactions, and that these conditions do not vary significantly along the reactor.

In the design it was assumed that the sulfate-reducing microbial reactions were sufficient to raise the pH of the influent. However, the average pH of the effluent during the three tests was 5.36, an average increase of only 0.06 over the pH of the influent.

Table 3 Variations in sulfide, ORP and pH during the tests with influent sulfate only (Tests 1-3)

		Sulfide average concentration (mg/L)	Sulfide maximum concentration (mg/L)	ORP (mV)	pH
	Effluent	2.4	5.5	-14.1	
	Interior	6.7	15.1	5	
	SP 1	16.9	23.0	-120.9	
Test 1	SP 2	15.2	21.1	-112.2	
	SP 3	14.5	21.5	-112.7	
	SP 4	14.8	22.8	-113.4	
	SP 5	14.7	21.1	-115.6	
	Effluent	9.5	12.5	-86.1	5.4
	Interior	8.8	14.8	22.3	5.1
	SP 1	11.2	21.5	-93.0	5.1
Test 2	SP 2	20	28.6	-94.3	5
	SP 3	24.7	30.7	-104.3	4.9
	SP 4	22.7	24.3	-106.5	5
	SP 5	21.9	23.2	-115.3	5
	Effluent	5	11.2	-71.5	5.4
	Interior	18.9	26.1	-22.7	5
	SP 1	9.2	20.7	-98.0	5.1
Test 3	SP 2	21.8	35.6	-109.5	4.9
	SP 3	32.8	33.9	-114.6	4.8
	SP 4	30.4	35.2	-113.0	4.9
	SP 5	31.2	43.6	-112.1	5.1

Variations in the Sulfate

Figure 4 shows the sulfate concentrations obtained during the three tests in the effluent, SP 5 and inside the reactor.

In the first test it was observed that the reactor reached a state of equilibrium immediately. This was because during bacterial acclimatization the reactor was fed with the same concentrations used in

Test 1. It had therefore already reached equilibrium for the concentration used in Test 1. In Tests 2 and 3, equilibrium was reached after 15 days' operation. The interior (organic matter) never reaches equilibrium because transport in this layer is diffusive, so the test times are too short for concentrations to equalize throughout the bed material within the reactor. However it is observed that the sulfate concentration in the interior increases, and that it is dependent on the concentration in the influent.

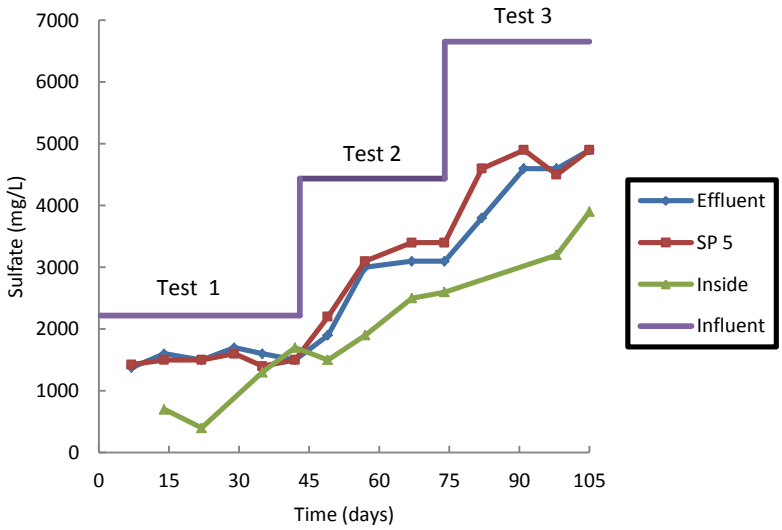

Figure 4 Variation of sulfate concentrations during the treatments with influent sulfate only (Tests 1-3). SP 5 is at the bed surface within the screened interior tube and the "inside" point is within the bed material at a depth of 30 cm.

For a homogeneous BCR, the volumetric sulfate-reduction rates are between 0.1 and 0.3 moles/m^3 of substrate/day (Gusek, 2002; ITRC, 2012; Wildeman & Schmiermund, 2004). The BCR with SDES constructed for this experiment presented average volumetric sulfate-reduction rates of 0.25, 0.5 and 0.72 moles/m^3 reactor/day for Tests 1, 2 and 3 respectively, based on total reactor volume (bed volume plus screened volume) (see Figure 5). Therefore the volumetric sulfate-reduction rate for a BCR with SDES depends on the influent sulfate concentration, and is directly proportional. In other words, if the influent sulfate concentration is doubled, the volumetric sulfate reduction rate will increase in roughly the same proportion.

The average sulfate removal percentages were 30.3, 30.9 and 29.4% in Tests 1, 2 and 3 respectively (see Figure 6). Thus the removal percentage did not vary significantly when the influent sulfate concentration was increased, remaining fairly constant at around 30%.

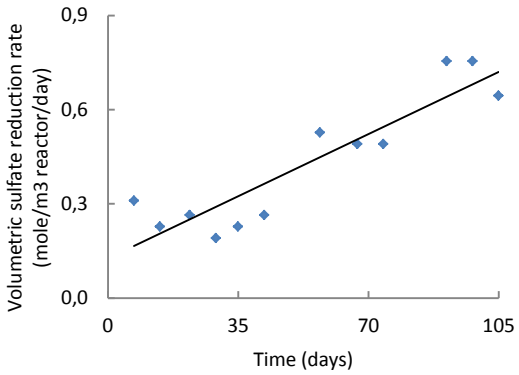

Figure 5 Volumetric sulfate reduction rates during treatment with influent sulfate only (Tests 1-3)

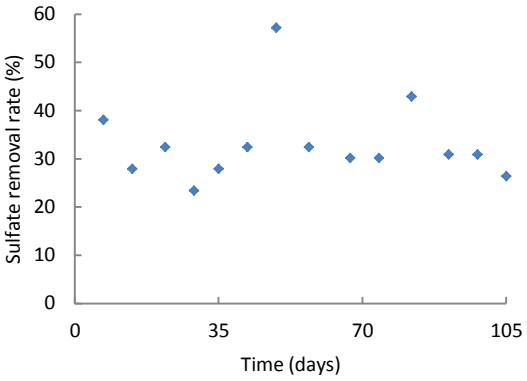

Figure 6 Sulfate removal rates during treatment with influent sulfate only (Tests 1-3)

Metal removal

In the fourth test the column was exposed to high concentrations of metals, particularly Cu and Zn, representative of AMD in central Chile. The flow was also increased by 50% to 3 L/day, to keep the reactor overloaded with metals. Under these conditions, the metal removals were 57% for Cu, 37% for Zn, and 50% for Al (Fig. 7). The overall volumetric metal removal rate was 300 mmol/m^3 reactor/day (Fig. 8). This experiment is continuing, to see whether the reactor can maintain these removal rates over time. Blackish precipitates were found in the bottom effluent, which may be mostly Covelite.

Based on sulfate reduction and metal removal rates one can compute the metal removal to sulfate removal yield, which is about two thirds or 67%. That is in average sulfate reduction would be only 67% effective in contributing to metal removal as sulfides.

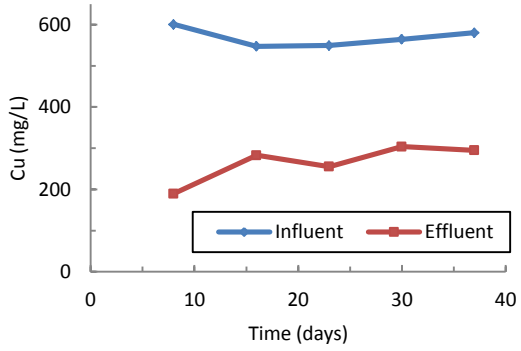

Figure 7 Influent and effluent copper concentrations during treatment with synthetic AMD (Test 4)

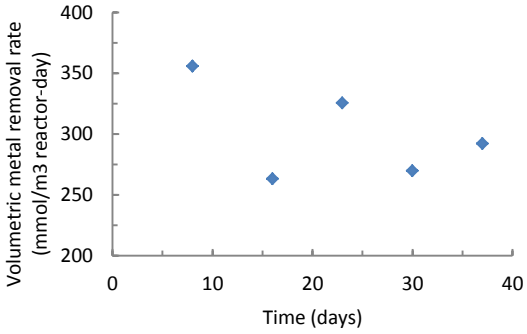

Figure 8 Overall volumetric metal removal rates during treatment with synthetic AMD (Test 4)

CONCLUSIONS

The BCR with SDES constructed at laboratory scale presented sulfate reduction rates of up to 0.75 moles/m^3 of reactor/day. This value is 2.5 times higher than the average sulfate reduction rate found in homogeneous BCRs, showing that the use of SDES in regard to substrate, can improve BCR functioning significantly.

The BCR with SDES reacted to increases in the influent sulfate concentration. The volumetric sulfate reduction rate increased proportionally with the sulfate concentration. On the other hand the sulfide inside the reactor increased by 50% on average when the sulfate concentration was increased by 100%. Thus the sulfate concentration in an AMD is a limiting factor in the operation of a BCR with SDES.

The BCR with SDES cannot raise the pH of the influent. Thus to neutralize the pH of an AMD it may be necessary to add limestone or some other alkaline material to the mixture.

During the first month of feeding with metals, the reactor removed a significant percentage of copper and zinc; however it remains to be seen whether this removal can be maintained over time. A precipitate was recovered from the bottom of the reactor, the purity of which is to be determined for copper recovery purposes.

Hence BCR with SDES hold promise for the treatment of AMD. Biological processes and chemical reactions are separated within theses systems. This zonation allows independent optimization of key processes. The biological system can be optimized for resistance and reactivity, while de chemical system can be optimized for metal precipitation and recovery.

Designing a Mine Water Treatment Facility to Remove Sulfate

H. C. Liang, Joseph Tamburini and Frank Johns
Tetra Tech, USA

ABSTRACT

Due to the effects of weathering and oxidation of sulfide–containing ores, acid rock or acid mine drainage (ARD or AMD) from mining activities can generate sulfate–contaminated waters. Although sulfate has long been considered relatively harmless to human health and to the environment compared to other contaminants common in ARD or AMD, regulations for sulfate in mine water discharge have become more common, necessitating more advanced sulfate–removal processes at many mining operations. Where they apply, sulfate discharge standards in the United States typically range between 250 and 1,000 mg/L, with proposals in certain areas to apply sulfate discharge standards as low as 10 mg/L. The presentation highlights the design of a full–scale mine water treatment facility to remove sulfate in AMD–impacted waters at a mine in North America with a design flowrate of approximately 5 million gallons per day (MGD), where the average sulfate concentration is approximately 2,000 mg/L and would need to be treated to below 600 mg/L sulfate for discharge. The evaluation of chemical precipitation for sulfate removal such as gypsum and ettringite formation as well as the use of membrane filtration and the decision processes used to arrive at the final design are discussed.

Keywords: Sulfate, ettringite, gypsum, mine water

INTRODUCTION

Sulfate (SO_4^{2-}) is often produced in acid mine drainage (AMD) as a result of exposing pyritic rocks to air due to mining activities, which leads to a cascade of reactions forming both acidity and sulfate that can be summarized by Equation 1:

$$2FeS_2(s) + 7O_2(g) + 2H_2O(l) \rightarrow 2Fe^{2+}(aq) + 4SO_4^{2-}(aq) + 4H^+(aq) \quad (1)$$

Although acid mine drainage (AMD) is a major environmental concern (Liang & Thomson, 2010), and many AMD–impacted waters contain high levels of sulfate, most mine water treatment facilities have not been designed to remove the sulfate anion. Instead, when sulfate removal does occur at mine water treatment facilities, it usually occurs as an unintended consequence of using lime to raise the pH of the solution, which provides a source of calcium ions (Ca^{2+}) to precipitate and remove some of the dissolved sulfate ions as gypsum ($CaSO_4{\cdot}2H_2O$). One of the reasons why sulfate has been mostly ignored in mine water treatment is that it is traditionally considered a benign, non–toxic inorganic contaminant. For example, the U.S. Environmental Protection Agency (U.S. EPA) has not established an enforceable primary drinking water standard for sulfate and only has a non–enforceable secondary drinking water standard of 250 mg/L for sulfate. Because of the perception that sulfate is relatively harmless, mine water treatment has typically focused more on pH adjustment and the removal of more acutely toxic inorganic contaminants such as copper, cadmium, arsenic, antimony, selenium, and other inorganic contaminants that often occur as a result of AMD instead of on sulfate removal. Recently, however, research has shown that sulfate–reducing bacteria (SRB) can generate highly toxic and bioavailable methylmercury in the environment by methylating inorganic Hg^{2+} and converting inorganic mercuric compounds into methylmercury (Jeremiason et al, 2006). In addition, research has also shown that high sulfate levels in wetlands can induce the liberation of precipitated, bound phosphates in the sediment and lead indirectly to the eutrophication of wetland systems (Lamers, Tomassen & Roelofs 1998). Because of these issues, and because sulfate typically accounts for much of the total dissolved solids (TDS) in mining–impacted waters that need to be treated to acceptably low TDS levels to reduce the impact of mining waters on the salinity of the receiving waters, sulfate removal has become much more important in mining water treatment in recent years.

METHODOLOGY

The major criteria used to select the sulfate–removal treatment process were, in order of importance: 1) Capability to remove sulfate consistently to < 600 mg/L; 2) Treatment costs, which included examining the amounts of wastes generated by the treatment process; 3) Ease–of–operations. Any treatment process that in–and–of–itself cannot practically be expected to remove sulfate to < 600 mg/L on a consistent basis was not examined further.

As the stability diagram of sulfur in water shows (Figure 1), the sulfate anion is the predominant sulfur species under most conditions encountered in surface waters. Because of the high design

flowrate (~5 MGD) and fluctuating water quantities and qualities for the mine water treatment facility, it was determined that it would not be practical to pursue biological sulfate reduction. Therefore, assessment of the treatment options focused on chemical precipitation or membrane filtration to remove the sulfate.

Assessment of treatment options

Chemical precipitation to remove sulfate

Adding hydrated lime to neutralize acidic mine waters and for chemical precipitation of gypsum to remove sulfate is one of the more common practices encountered in mine water treatment. The hydrated lime ($Ca(OH)_2$) is added to supply Ca^{2+} ions for removing sulfate as gypsum, as represented by Equation 2:

$$Ca(OH)_2(s) + SO_4^{2-}(aq) + 2H_2O(l) \longrightarrow CaSO_4{\cdot}2H_2O(s) + 2OH^-(aq) \quad (2)$$

Because gypsum is slightly soluble in water ($K_{sp} = 3.14 \times 10^{-5}$), both theoretical calculations and field results show approximately 1,500 mg/L or higher of calcium would remain dissolved in solution after gypsum precipitation treatment. Therefore, gypsum precipitation by itself would not be sufficient to meet the 600 mg/L sulfate discharge limit at this mine.

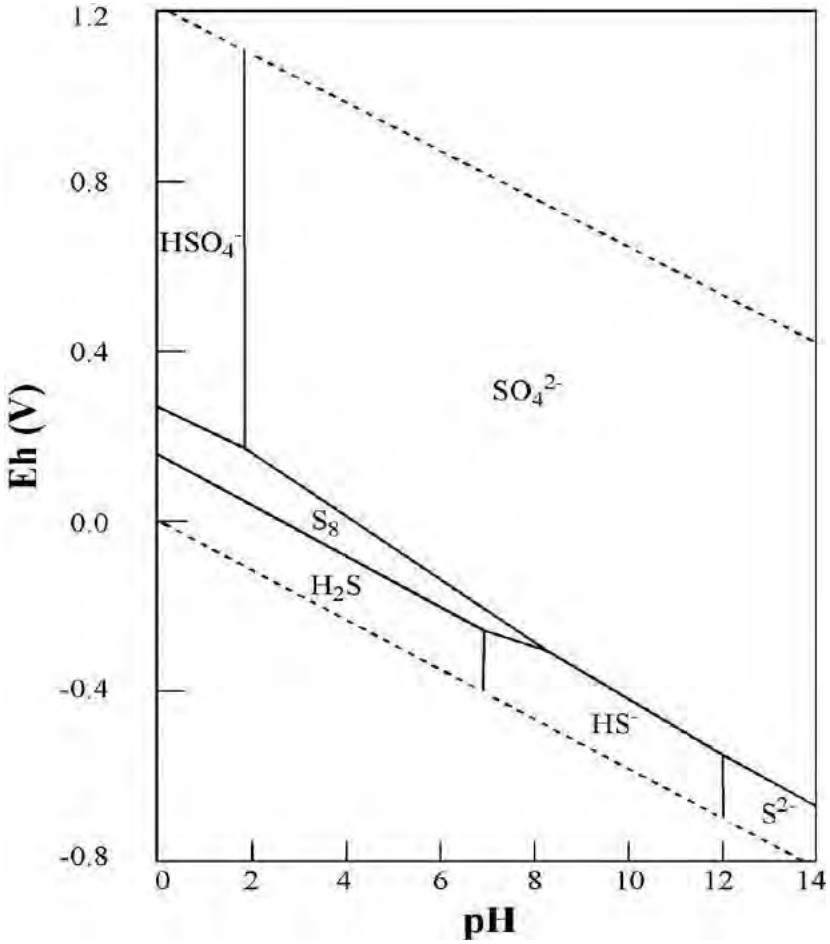

Figure 1 Stability diagram of sulfur showing the predominance of the sulfate anion in water. The dashed lines are the stability limits of water (Pourbaix, 1966)

Another chemical precipitation process, the formation of the insoluble mineral ettringite ($3CaO{\cdot}3CaSO_4{\cdot}Al_2O_3{\cdot}31H_2O$), was also explored (GARD Guide, 2014). Because ettringite is much more insoluble in water (K_{sp} = 2.8 x 10^{-45}) compared to gypsum, removal of sulfate by precipitating ettringite could consistently reduce the sulfate levels to below 600 mg/L (Equation 3):

$$6Ca^{2+}(aq) + 3SO_4^{2-}(aq) + 2Al(OH)_3(s) + 37H_2O(l) \rightarrow$$

$$3CaO{\cdot}3CaSO_4{\cdot}Al_2O_3{\cdot}31H_2O(s) + 6H_3O^{+}(aq) \quad (3)$$

One of the ettringite precipitation treatment processes that has been developed for sulfate removal is called the CESR process (Reinsel, 1999). In the CESR process, lime is first added to raise the pH and also to precipitate gypsum if the sulfate concentration is high enough and also to supply a calcium source to form the mineral ettringite. More lime and an aluminum reagent are then added in the next step, which results in the formation of the highly insoluble ettringite and the removal of most of the sulfate from solution (Figure 2).

Although bench scale testing showed that the CESR process can consistently remove sulfate down to < 200 mg/L, well below the 600 mg/L sulfate target (Reinsel, 1999), it was determined that CESR or similar ettringite–forming processes would not be suitable for several reasons. For example, careful examination of the stoichiometry of the ettringite formation reaction (Equation 3) shows that an exorbitant amount of sludge would be generated by the process, where more than four times the mass of sludge would be generated for every mass unit of sulfate removed. This compares to a mass ratio of less than two to one for the amount of gypsum sludge generated per mass unit of sulfate removed by the gypsum precipitation process (Equation 2).

Another reason for not considering further the CESR or related ettringite–formation processes for the full–scale mine water treatment plant to remove sulfate was because of the slow kinetics of the reaction to form ettringite using calcium aluminate as the reagent. Bench scale testing showed that it required long reaction times, up to 5 hours for completion (Liang et al., 2012). At a design flowrate of 5 MGD, a residence time of 5 hours would require more than one million gallons of capacity, which would be impractical for the full–scale water treatment system.

It should be pointed out that an ettringite–formation process using sodium aluminate as the aluminum source and hydrated lime as the calcium source to form ettringite has been developed and is reported to have much faster kinetics of ettringite formation (Outotec, 2014). Because of the large amounts of sludge generated by ettringite processes, the undesirable side effect of increasing sodium concentration in the treated water from using sodium aluminate, and the fact that the treated water sulfate concentration required at this site is not low enough to require ettringite formation, however, the ettringite process using sodium aluminate reagent was not considered either.

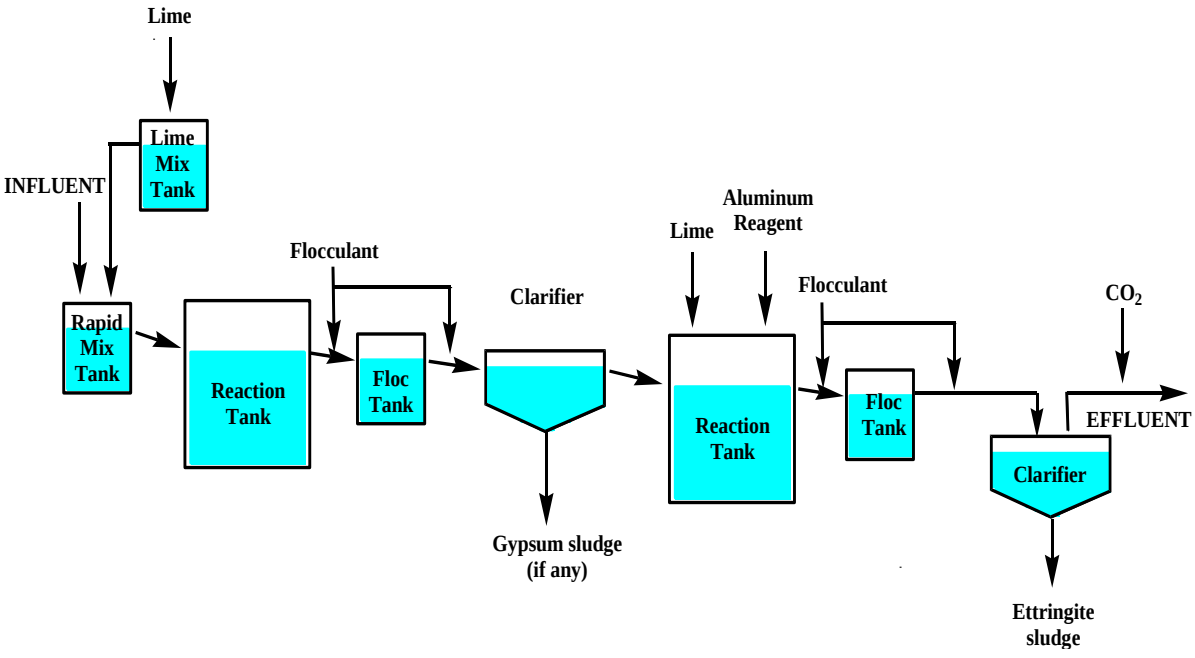

Figure 2 Schematic of CESR sulfate removal process

Membrane process for removing sulfate

Nanofiltration (NF) is also a potential option for sulfate removal for mine water treatment. NF can reject > 99% sulfate and would be able to consistently generate treated water with < 50 mg/L sulfate, much lower than the required 600 mg/L sulfate discharge target. Because of potential scaling issues on the NF membranes, especially for waters with high sulfate concentrations, pre–treatment for NF would need to be carefully considered. Another potential issue with using NF is that it would generate a lot of waste brine that would be expensive to manage. For example, at a 5 MGD flowrate and 70% recovery of the NF treatment process, 1.5 MGD of NF concentrate/brine waste would need to be managed and disposed (Figure 3).

Considering the issues of brine management and the fact that treating the water to < 50 mg/L sulfate would be an overkill at this mine site, it was determined that NF treatment in and of itself was not a viable option.

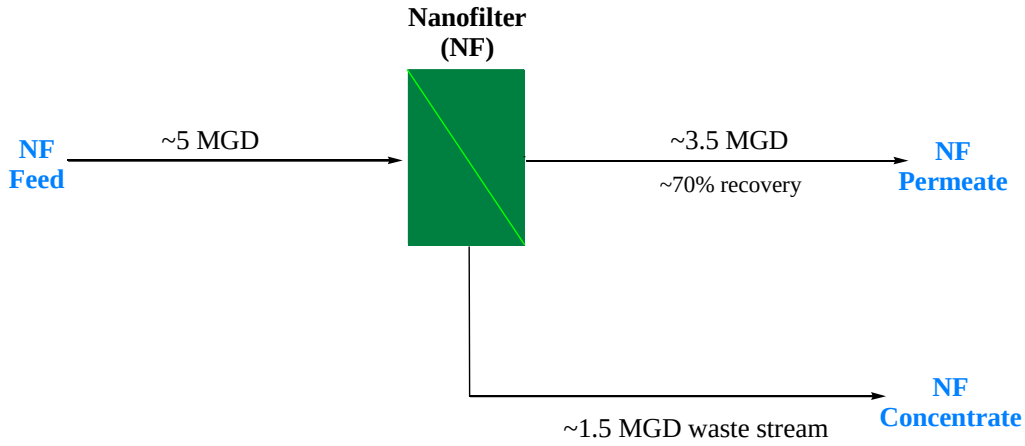

Figure 3 Schematic of NF treatment process showing need to manage large NF waste stream

RESULTS AND DISCUSSION

Hybrid membrane chemical precipitation sulfate removal process

Based on the issues with gypsum or ettringite precipitation and with NF membrane treatment discussed in the previous sections, preliminary evaluation of sulfate removal options for the mine water concluded that none of the options by themselves would be practical at the site.

Using the geochemical modeling software Phreeqc (USGS, 2014) to conduct chemical modeling suggested that a hybrid treatment process combining NF treatment with gypsum precipitation may be viable and meet the major criteria of consistently treating the water to < 600 mg/L sulfate and not generating as much waste sludge as the ettringite precipitation process. The concept was to use the NF to concentrate the stream so that more sulfate can be removed by gypsum precipitation in the NF concentrate stream compared to the more dilute full stream flow. And then the chemically treated NF concentrate stream can then be re–blended with the NF permeate stream so that no NF brine/concentrate stream will need to be managed or disposed separately; the re–blended stream will consistently meet the < 600 mg/L sulfate discharge limit due to the higher sulfate–removal

capacity of gypsum precipitation of the brine stream compared to gypsum precipitation of the full flow stream because of the higher concentration of sulfate in the NF brine stream. There would also be a recycle stream for the gypsum removal clarifier overflow that can be adjusted to fine–tune the blended discharge water quality.

The main components of the hybrid sulfate removal process are: 1) Pre–treatment using hydrated lime to decrease sulfate concentration to the gypsum saturation point. The pre–treatment process also precipitates and removes metals and silica to protect the nanofilter downstream in the process and increase the NF recovery; 2) Filtration upstream of the NF; 3) Nanofiltration process, which serves to concentrate the stream; 4) Hydrated lime treatment of NF concentrate stream to further remove sulfate as gypsum; 5) Re–blending of the chemically–treated NF concentrate stream with the NF permeate stream. The hybrid sulfate removal process is summarized and depicted in Figure 4.

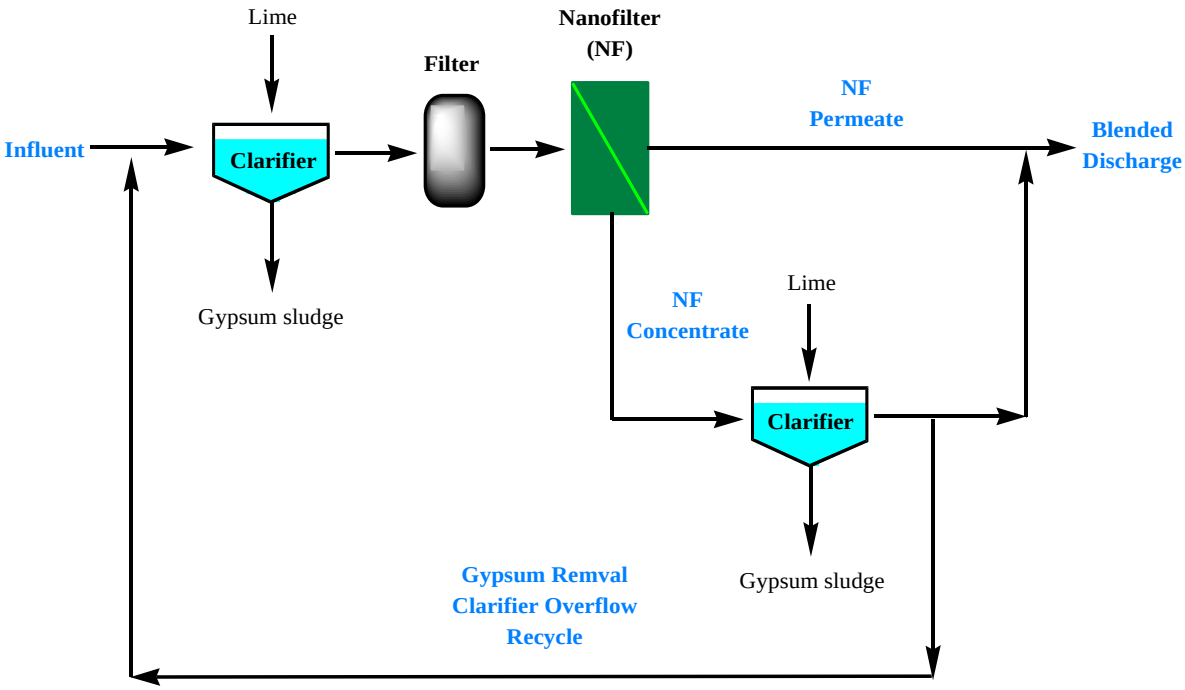

Figure 4 Schematic of hybrid gypsum precipitation and NF treatment processes

Pilot testing data

The hybrid treatment process depicted in Figure 4 and described above has been examined in a pilot test. The pilot testing was run for seven months at an average overall flowrate of approximately 20 gallons per minute (gpm), and the average NF recovery was approximately 70% with the use of a polyacrylate scale inhibitor and after iron, aluminum, and manganese were removed in the hydrated lime pre–treatment process. Data on the removal of these potentially scaling components in the lime pre–treatment process are shown in Table 1. It is of interest to note that aluminum was removed to low concentrations even at the pH of approximately 10. Data from major components of the pilot test are summarized in Table 2, which show data of the mass balance of sulfate removal across the hybrid treatment processes as determined from the pilot testing.

Table 1 Data from lime pre–treatment process to remove metals and increase NF recovery

	Al (Total, mg/L)	Fe (Total, mg/L)	Mn (Total, mg/L)
Raw Water	18	2.5	19
Lime Pre–Treated Water	0.15	0.02	0.01

Table 2 Data from pilot testing of hybrid gypsum precipitation and NF treatment processes (average values reported using two significant figures)

	pH	Sulfate (mg/L)	Total Dissolved Solids (TDS) (mg/L)
Raw Water	6.3	1,900	2,600
Lime Pre–Treated Water	10	1,400	2,200
NF Permeate	10	2.3	42
NF Concentrate	10	4,600	7,100
Lime–Treated NF Concentrate	11	1,800	2,400
Blended Discharge	7.5*	540	750
Treatment Goals	6.5–9	600	1,000

**After pH adjustment using CO_2*

As can be seen from the data presented in Table 2, the pilot study confirmed that it would be possible to use a hybrid treatment process to achieve the goal of treating sulfate down to 600 mg/L or less. Final design of the full-scale mine water treatment facility has been completed, and the mine water treatment plant is currently being constructed.

CONCLUSION

A full–scale mine water treatment facility has been designed and is currently under construction for treating up to approximately 5 MGD of water to remove sulfate to < 600 mg/L on a consistent basis. Assessment of chemical precipitation options showed that gypsum precipitation alone would not meet the 600 mg/L sulfate discharge target. So gypsum precipitation by itself was ruled out as a viable option. Although treating the water using ettringite precipitation would generate water that would meet the 600 mg/L sulfate discharge standard, it would also generate large amounts of waste sludge that would be difficult and expensive to manage. Additionally, bench scale testing showed that ettringite precipitation using calcium aluminate reagents were exceedingly slow and would require unrealistically large reaction tanks at a flowrate of 5 MGD, while using sodium aluminate, which is a potentially viable from a kinetics standpoint, would add too much sodium to the water as well as still generate exorbitant amounts of sludge. Therefore, chemical precipitation by itself, either using gypsum or ettringite precipitation, was ruled out as a practical option at the mine site. Evaluation of NF treatment also showed that while it would generate treated water that could easily meet the 600 mg/L sulfate discharge limit, the high flows of NF brine waste would be expensive to manage. Based on further evaluation of treatment options, a hybrid treatment process combining NF treatment and gypsum precipitation was developed first based on chemical modeling and then confirmed by pilot testing. The pilot testing confirmed that 600 mg/L sulfate in the treated water is achievable on a consistent basis.

The High Density Sludge (HDS) Process and Sulphate Control

Bernard Aubé and Douglas Lee
Amec Foster Wheeler Environment and Infrastructure,Canada

ABSTRACT

The high-density sludge (HDS) process has been the standard in the mining industry for treating metal-containing acid rock drainage (ARD), providing low metal levels in the final effluent, and reducing waste sludge volumes compared to other lime based processes. It has been applied for 40 years at mine sites all over the world to meet discharge limits for metals and pH. Recently, various jurisdictions have introduced low discharge limits for sulphate concentrations that are difficult to meet with conventional treatment systems. Also, when treated water is recycled, high sulphate concentrations can cause some undesired downstream impacts. To assist in reducing effluent sulphate concentrations, the recent trend shows that HDS plants have been constructed with considerably higher retentions times in the neutralisation reactors. The reason for this increase in retention time is due primarily to the slow gypsum-precipitation reactions that are the key to minimising sulphate concentrations. These reactions and their effects are explained in detail in this paper. Also discussed are the potential synergies between the HDS process and other processes that treat sulphate more directly. This includes the combination with membrane filtration (reverse osmosis or nanofiltration), with ettringite precipitation, with ion exchange, and even barium precipitation.

Keywords: acid mine drainage sulfate lime treatment

INTRODUCTION

Although many different biological and chemical technologies exist for treatment of acid rock drainage (ARD – or acid mine drainage, AMD), lime neutralisation remains by far the most widely applied treatment method. This is largely due to the high efficiency in removal of dissolved heavy metals combined with the fact that lime costs are low in comparison to alternatives. Lime treatment essentially consists in bringing the pH of the raw water to a point where the metals of concern are insoluble. These metals therefore precipitate to form minuscule particles. A separation of these precipitates is then required to produce a clear effluent which meets regional discharge criteria. The solid/liquid separation forms a sludge which, for a high-density sludge (HDS) process, can contain 10 to 30% solids by weight. This sludge can be further processed to increase the solid content and must be disposed of in an environmentally acceptable manner.

The HDS process has met requirements in the past as the focus for discharge limits has been on toxic metals and acidity. In recent years, there are more and more jurisdictions also including sulphate as a regulated parameter, including Chile and Peru. The specifically applied limits depend on the jurisdiction and often also on the receiver. The limits vary from approximately 2,000 mg/L (as sulphate, SO_4^{2-}) in the high end to as low as 10 mg/L in the receiver.

Lime treatment processes alone cannot meet the low effluent sulphate limits and even the higher limits in some cases. But there are modifications that can be brought to the HDS process which help minimise the final sulphate concentration either as a stand-alone treatment or in conjunction with other sulphate treatment systems. In this paper, the lime treatment of ARD is summarised and the associated minimisation of sulphate concentration is also explained.

THE BASIC CHEMISTRY OF LIME TREATMENT

The principle of lime neutralisation of ARD lies in the insolubility of heavy metals in alkaline conditions. By controlling pH to a typical setpoint of 9.5, metals such as iron (Fe), zinc (Zn), and copper (Cu) are precipitated (see Figure 1). Other metals such as nickel (Ni) and cadmium (Cd) require a higher pH, in the range of 10.5 to 11 to effectively precipitate the hydroxides. The precipitates can be formed individually as minuscule particles smaller than a single micron (1 μm). In a high-density sludge process, the precipitates are formed onto existing particles recycled within the process. This creates larger and denser particles that settle and compress better than the precipitates created with direct lime addition. This essentially defines the greatest difference between the HDS process and other lime treatment processes: the method of precipitating and separating the solids and the sludge that is formed.

It is important to note that the precipitation reactions and resulting precipitates are shown and discussed as per theory. In reality, almost all of the precipitates are amorphous mixtures of many metals, hydroxides, sulphates, and other ions present in solution, with several of the ions adsorbed and not truly precipitated in the presented form. The only actual crystals often identified in fresh sludge are calcite and gypsum. Aged sludges can contain other crystalline forms (Zinck, 2005).

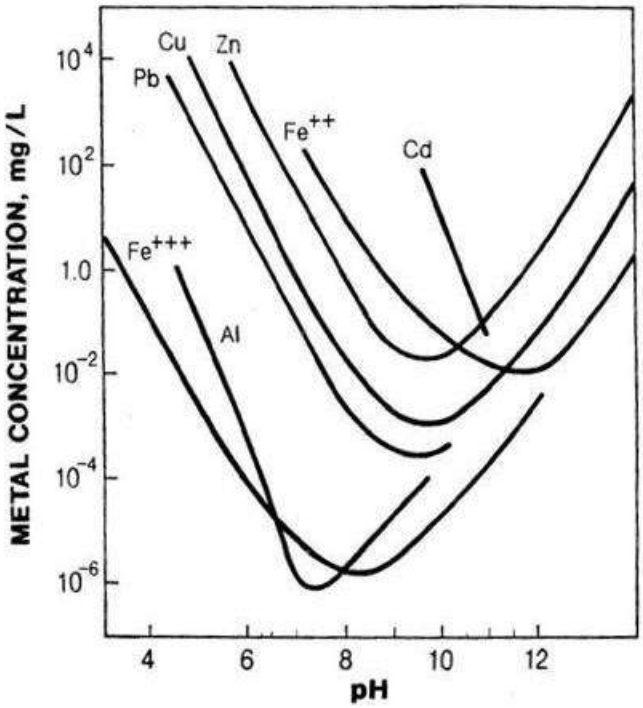

Figure 1 Metal Hydrolysis (from Aubé and Zinck, 2003)

Lime dissolution is the first step of the neutralisation process. For large treatment systems, quicklime is used. This lime must first be hydrated (slaked) and is normally fed to the process as a slurry. When fed to the process, the hydrated lime then dissolves to increase pH. The two following equations illustrate these reactions:

$$CaO + H_2O \Rightarrow Ca(OH)_2$$

$$Ca(OH)_2 \Rightarrow Ca^{2+} + 2OH^-$$

The increased pH then provides hydroxide ions which combine with the dissolved metals to produce precipitates. The following equations show the precipitation reactions with different metals:

$$Al^{3+} + 3OH^- \Rightarrow Al(OH)_3$$

$$Co^{2+} + 2OH^- \Rightarrow Co(OH)_2$$

$$Cu^{2+} + 2OH^- \Rightarrow Cu(OH)_2$$

$$Fe^{2+} + 2OH^- \Rightarrow Fe(OH)_2$$

$$Fe^{3+} + 3OH^- \Rightarrow Fe(OH)_3$$

$$Ni^{2+} + 2OH^- \Rightarrow Ni(OH)_2$$

$$Pb^{2+} + 2OH^- \Rightarrow Pb(OH)_2$$

$$Zn^{2+} + 2OH^- \Rightarrow Zn(OH)_2$$

The resulting water quality contains very low heavy metal concentrations due to this hydroxide precipitation. Proportional to the precipitation of these metals is the solubilisation of calcium from the lime. Effectively, for the dissolved ionic balance, Ca replaces the heavy metals in solution. This leads to the precipitation of gypsum as per the following equation:

$$Ca^{2+} + SO_4^{2-} \Rightarrow CaSO_4 \cdot 2H_2O$$

What differentiates gypsum from the metal hydroxides is that the metals precipitate very rapidly while gypsum precipitates slowly. Most lime treatment plant effluents are super-saturated for gypsum upon discharge. The reasons for this and the effects that are caused by this slow precipitation are discussed in greater detail in the following sections.

THE SULPHATE PROBLEM STATEMENT

In most sulphide mines, some precious metal mines, and some coal mines, the waste rock and tailings contain iron and other metal sulphides which oxidise to form AMD containing sulphuric acid and dissolved metals. This AMD problem is well documented in numerous other publications. Historically, AMD was either treated to remove toxicity and released to the environment or treated for recycle to the process (concentrator) with high sulphate concentrations.

Sulphate control has become a greater concern in recent years because it has been added as a regulated parameter in many jurisdictions. Sulphate concentrations can also present problems when the treated water is recycled. The gypsum formation discussed above also results in significant scaling issues, both within treatment plants and downstream. Within a conventional lime treatment plant there can be significant scaling on all surfaces, particularly in reactors where the lime is added when there is no sludge recirculation. Even with sludge recirculation, it is the clarifier overflow weir, effluent piping, flume, turbidimeters, and pH probes that sustain the greatest amount of scaling.

For some sites where the treated water is recycled as process water, the scaling caused by gypsum formation can be a critical cost issue. In one European underground mine, the recycled water used in the mine for cooling the drills (jumbos) via oil-water intercoolers results in significant scaling of these items and high maintenance costs. A gypsum-saturated solution also cannot be used as gland water for pumps due to the significant maintenance requirements. Scaling in process water piping and valves can also create issues with control and even safety concerns.

There are two main reasons for the scaling issues: 1) the gypsum precipitation reaction is slow and 2) gypsum is a crystal that preferentially forms on existing gypsum crystals.

While hydroxide reactions that cause the precipitation of metals are almost instantaneous, gypsum formation can take days to reach equilibrium. The comparatively slow precipitation is primarily a function of kinetics but can also be related to the solubility product constant (Ksp). The heavy metal hydroxide precipitates listed above have solubility constants in the order of 10^{-15} to 10^{-30}. Gypsum has a solubility product constant of 2.4×10^{-5} which is at least 10 orders of magnitude higher than that of the hydroxides. Kinetics can also be linked to size of the ions involved in the formation of the solid. In the case of the metal precipitates, all are related to the hydroxide ion, which is extremely mobile in an aqueous solution. For gypsum, the calcium mobility can be compared to that of the heavy metals, while the sulphate molecule, which is a much larger molecule than that of the hydroxide, is considerably less mobile.

Another important aspect of gypsum precipitation is that it occurs considerably more readily on existing gypsum crystals than by nucleation. Metal hydroxide particles readily nucleate in a solution that contains no solids, given the right pH conditions. Gypsum does not tend to nucleate but rather to form on a solid surface, preferably on existing gypsum. In clear water, without the presence of gypsum particles or other solids in suspension, the only existing surfaces are from the equipment and walls. An initial coating of gypsum forms on equipment surfaces, then these surfaces act as a seeding location for continued precipitation. This distinctiveness for gypsum explains why scaling on equipment surfaces occurs more readily in clear water, following solid-liquid separation.

THE HDS PROCESS

The high density sludge (HDS) process is the standard in the AMD treatment industry today (**Figure 2**). Instead of contacting lime directly to the AMD, this process first contacts recycled sludge with the lime slurry for neutralisation. To do this, the sludge from the clarifier bottom is pumped to a "Lime/Sludge Mix Tank" where sufficient lime to neutralise the AMD to the desired pH setpoint is also fed. This forces contact between the solids and promotes coagulation of lime particles onto the recycled precipitates. This mixture then overflows to the Lime Reactor (LR) where pH is controlled and the precipitation reactions are completed. Aeration is often added to this reactor to oxidise ferrous iron to ferric and form the more stable ferric hydroxide.

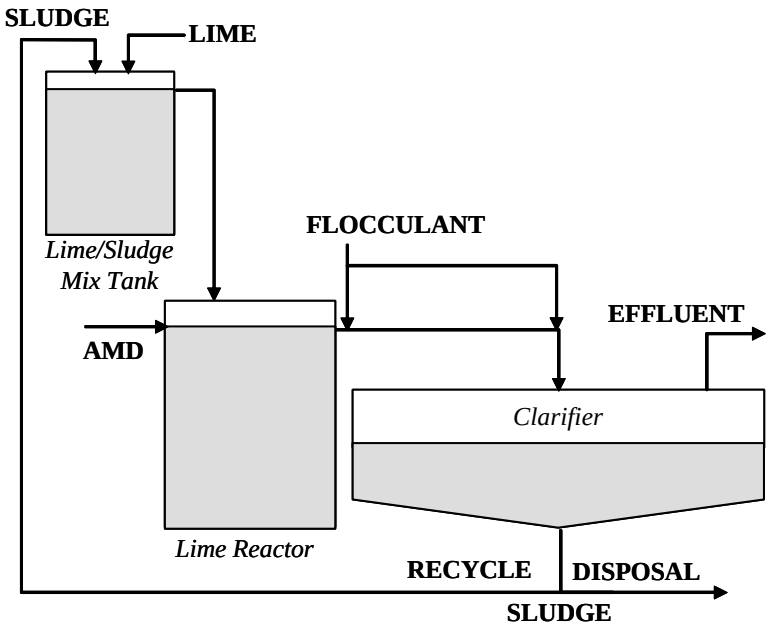

Figure 2 Simplified Representation of HDS Process

The slurry is then contacted to a flocculant solution either via a Flocculation Tank or by providing turbulence in the conduit leading from the Lime Reactor to the clarifier. A trough with baffles may be sufficient to ensure proper contact with the small particles. The flocculant serves to agglomerate

all precipitates and promote efficient settling in the clarifier. The clarifier overflow can either be discharged or recycled as process water as-is or polished prior to the next step. A simplified representation of the HDS process is shown in Figure 2.

The key to this process lies in the mixing of lime and sludge prior to neutralisation. The fact that the calcium hydroxide and recycled particles are combined causes the precipitation reactions to occur mostly on the surface of existing particles, thereby increasing their size and density. The precipitates from this process are therefore different from those where this lime/sludge mixture does not occur.

The HDS process presents significant advantages in operating costs over conventional lime addition, due the increased sludge density, decreased lime consumption, improved metal removal, and better solid/liquid separation (Aubé and Zinck, 1999). The higher sludge density means less waste is produced but also that more water is treated and released (or recycled).

Sulphate in the HDS Process

As discussed previously, a critical part of the HDS process is the Lime/Sludge Mix Tank, where recycled sludge is contacted with a concentrated lime slurry. The lime addition rate here is controlled by the desired setpoint in the Lime Reactor. Typically, the pH in this reactor is higher than 11 and can be as high as 12.5. As this high pH is due to lime dissolution, the calcium concentrations are very high. This promotes gypsum precipitation in this location and provides a high concentration of gypsum needles for the Lime Reactor. This is shown in Figure 3 in a scanning electron micrograph (SEM) of a freeze-dried slurry collected from an industrial Lime/Sludge Mix Tank. The needles in Figure 3 are gypsum crystals.

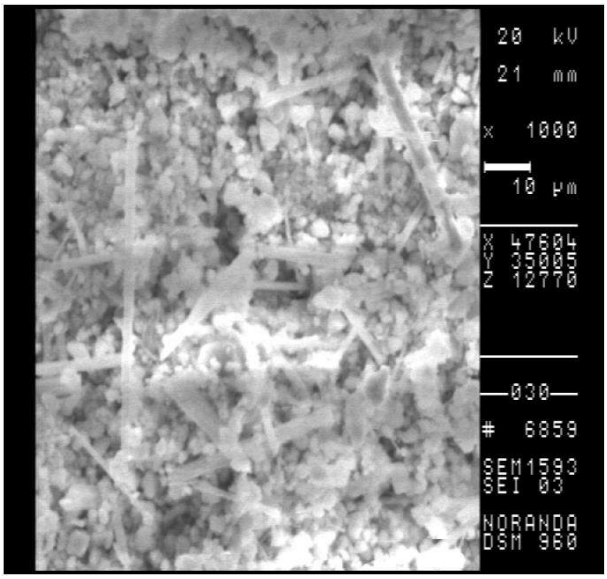

Figure 3 SEM Photograph of a Lime/Sludge Mixture

Modifications to the HDS Process for Improved Sulphate Removal

The major modification incorporated into the HDS process for improved sulphate control is to increase retention time in the reactors. This can be done by using multiple reactors in series. Table 1

shows a summary of HDS treatment plants built late in the past century (sites A to D), in comparison with more recent plants (sites 1 to 3) that were designed with a focus on sulphate concentrations. It is clear that the trend applied by process engineers in recent years is to add more reactors and greater retention time. In case of scaling issues, the reactors are often designed to be by-passed. This is true of the Geco plant (Site 1), for example, where either of the first two reactors can be by-passed. The other two examples can have any of the neutralisation reactors by-passed.

Table 1 Example HDS Plant Reactor Retention Times

Site	Start-up (year)	Treatment Flowrate (L/min)	Number of Reactors	Total Design Retention Time (minutes)
A	1984	3 000	2	40
B	1993	60 000	1	40
C	1993	10 000	1	40
D	1997	20 000	1	45
1	2005	15 500	3	150
2	2011	5 833	2	120
3	2014	30 000	3	120

A high sludge recycle rate also increases the concentration of gypsum crystals in the neutralising reactors to help promote additional gypsum precipitation. But the recycle rate can be limited by the efficiency of flocculant contact and solid/liquid separation; too high a recycle will lead to a high solid content in the slurry and can make flocculation difficult.

By applying these principles of increased retention time in the reactors where a continuous contact with existing gypsum crystals is provided by high sludge recycle, the resulting sulphate concentrations are lower as the slurry reaches the clarifier. There are limitations in the removal of sulphate in an HDS plant related not only to the kinetics of gypsum precipitation but also to the chemistry of the raw water. The gypsum precipitation occurs in large part due to Ca replacing heavy metals as the cation associated to sulphate. Some cations do not precipitate in HDS treatment, particularly alkali metals such as sodium (Na) and potassium (K). Magnesium may also remain in solution if the pH control point is less than 10. Sulphate concentrations will be higher in HDS-treated effluent if the AMD contains significant concentrations of these light metals. The final sulphate concentration therefore varies from site to site despite applying the same process, as the raw water chemistry varies significantly.

Some scaling is still likely to occur in HDS treatment plants, particularly in the effluent systems and reactor aeration systems. The more recent designs allow for maintenance to remove scaling where it may become problematic. Launders and flow-measuring devices are open or with removable covers for access to remove accumulated scaling. For the aeration systems in the reactors, the ability to by-pass a reactor can allow for maintenance while continuing treatment. Large man-doors are included in the design of the reactors for rapid access. Clarifiers can be equipped with larger access to facilitate using a small tractor (such as a Bobcat) to remove the accumulated scale. At mine sites

with high sulphate concentrations, it may be necessary to shut down on an annual basis for a week or two specifically for this clarifier cleaning.

Combination of HDS with Other Treatment Methods

In order to meet some effluent regulations for sulphate, HDS treatment cannot be applied alone. In these cases, other technologies can be used to treat for sulphate specifically. Four of these potential sulphate treatment technologies are discussed below, including membrane separation, ion exchange, ettringite precipitation, and barium precipitation.

The limitations inherent in the sulphate treatment technologies discussed below are the main reasons for their reduced applicability seen at the full scale. The following sections describe the opportunities to optimise these sulphate technologies through combination with the HDS process.

Membranes

The leading method of control for sulphate in the mining industry at this time is by membrane separation. These reverse osmosis (RO) or nano-filtration (NF) systems can produce a permeate capable of meeting any sulphate limit. The greatest disadvantage of this process is the formation of a concentrate (or brine) stream that often represents more than 30% of the initial raw water volume. The HDS process can be used to treat this high-sulphate concentrate to greatly reduce the final waste volume. Treatment of the brine with HDS can provide the required bleed of sulphate in the form of gypsum in the waste sludge, while the clarifier overflow can either be returned for re-treatment in the RO or mixed with the RO permeate depending on the target sulphate level in the final effluent.

The greatest challenge with membrane treatment for sulphate in the mining industry is the formation of gypsum in the membranes themselves, due to the super-concentration of the brine as it advances across the membrane. This gypsum precipitate is commonly due to the fact that the ARD contains sulfuric acid that has been neutralised with lime, thereby feeding a gypsum super-saturated solution to the membrane from the start. This scaling issue significantly reduces the service life of the membranes. Gypsum scaling can be reduced by decreasing recovery rates, backwashing, increasing tangential flow, and/or adding an anti-scalant. Each of these options increases treatment costs due to decreased discharge fractions (more recycled brine), increased pressures (higher energy costs), and/or high reagent costs.

Recent advances in membrane materials have resulted in NF membranes that can tolerate very low pH. In some applications, with a low pH stream containing high levels of metals and sulphate, it is possible to treat this stream with NF membranes with only particle filtration as a pre-treatment. At this low pH, prior to lime addition, the solubility level of gypsum is higher and the available calcium is lower, resulting in a decreased scaling potential in the NF membranes. This results in considerably higher recovery rates, with concentrate streams of less than 25% of the raw ARD feed. This can significantly reduce costs as the membranes last longer and the use of anti-scalants is reduced or even eliminated.

The NF permeate can then be combined with the balance of the AMD for further treatment in an HDS plant, but now the issues with gypsum scaling are reduced. The NF concentrate can be treated in an HDS process to further reduce the waste stream. If RO is required as a final treatment, the NF and RO concentrate streams can be combined and treated in the same HDS plant.

Essentially, membrane treatment alone would result in a significant waste stream and still require pH adjustment. To reduce waste, to present an outlet for sulphate (as gypsum), and increase overall water recovery in an economic manner, HDS is best used in conjunction with membrane treatment.

Ion Exchange

Another process offered by suppliers for sulphate treatment is ion exchange . In this process, two stages are applied with very specific ion exchange resins. One example of this process is the GYP-SIX process (Robertson and Rohrs, 1995). The cationic resin is specific for calcium and the anionic is specific for sulphate. The regeneration is performed with sulphuric acid on the cationic side and lime-saturated solution on the anionic side. The process produces gypsum as a by-product (or most likely as a waste). The proposed IX processes do not treat all contaminants to make the water compliant for discharge or recycle to a concentrator. One option is the application of the HDS process upstream of the IX process, and by minimising the concentrations of sulphate, it will be possible to reduce the overall costs of water treatment.

Ettringite

There are many suppliers presently proposing the ettringite process for sulphate control. This process has been proven to bring sulphate concentrations low but has the disadvantage of high costs due to the need for an aluminium (Al) reagent and the production of large volumes of low-density sludge. This is shown in the formula below.

$$6Ca^{2+} + 3SO_4^{2-} + 2Al(OH)_3 + 32\ H_2O \Rightarrow Ca_6Al_2(SO_4)_3(OH)_{12}{\cdot}26H_2O + 6H^+$$

In some cases, such as the CESR process (INAP, 2003), there is a metal precipitation step prior to ettringite formation. If the HDS process with an extended retention time in the neutralisation reactors were to be applied in this initial metal precipitation step, the initial sulphate concentrations for the ettringite step will be reduced. This would serve to decrease the consumption of the expensive Al reagent in the ettringite step. This will also significantly reduce the volume of sludge produced as the HDS process can form a sludge containing more than 20% solids with a significant sulphate (gypsum) content. The ettringite sludge is viscous and can contain less than 2% solids.

Barium Precipitation

Another well-known process for treatment of sulphate is precipitation using barium (Ba). It may be possible to integrate Ba into existing HDS treatment systems thereby reducing unnecessary and expensive capital investments. New systems could also incorporate Ba after lime addition. As a specific process for sulphate precipitation, Ba is not currently used in the full scale. This is due to high cost of the raw reagent, as Ba is not readily available in the quantities that would be required.

At a high pH, the addition of barium carbonate can be used to decrease sulphate concentrations via the following reaction:

$$Ca^{2+} + SO_4^{2-} + BaCO_3(s) \rightarrow BaSO_4(s) + CaCO_3(s)$$

It is also possible to use barium hydroxide directly, where the main process reaction would be the following:

$$Ba(OH)_2 + Me^{n+} + SO4 \rightarrow Me(OH)_n + BaSO_4(s)$$

Me represents the metal components of the effluent stream, typically iron, zinc, nickel, copper, cadmium, or cobalt. Barium chloride can also be used for sulphate precipitation but this process

will put into solution as much chloride as there is sulphate removed, thus exchanging one problem with another.

Prior treatment with the HDS process can help reduce the sulphate concentration and thus the operating costs of the sulphate treatment process as it decreases the consumption of barium.

CONCLUSION

Recent trends to improve the sulphate treatment in HDS plants involve longer retention time in neutralisation reactors as a primary modification. The process requires an optimised control of solids recirculation to provide sufficient gypsum seeding from sludge without negatively impacting the solid/liquid separation. The ability to access the equipment and by-pass reactors is also important for maintenance when treating high-sulphate waters.

The HDS process can be successfully combined with membrane filtration either before or after to control the effluent quality as required and minimise liquid waste from the concentrate. The HDS process is also uniquely suited to work with ettringite, barium, or ion exchange processes to reduce total treatment costs and waste management.

An Innovative Process to Reduce Sulfate in Membrane Concentrate Enhances Mine Water Recovery

Kashi Banerjee, Christopher Howell Charles Blumenschein and Herve Buisson
Veolia Water Technologies, USA

ABSTRACT

A treatment process was developed to reduce sulfate from nanofiltration (NF) concentrate to less than 100 mg/l. The treatment system is comprised of a two-stage chemical precipitation process. The impacts of sludge recirculation ratio, pH and chemical dosages were investigated. Calcium sulfate crystal growth kinetics was determined. Bench and two pilot-scale studies were conducted to evaluate the performance of the system. The studies also evaluated the performance of an NF system for removing sulfate from copper mine tailing pond water. Using the ion chromatography (IC) method, the concentration of sulfate in water was analyzed. Membrane performance was evaluated at various flux rates, water recovery rates and trans-membrane pressures. The process recovers more than 95% aluminum from the precipitated sludge for reuse. Based on the two pilot study results, a preliminary concept was developed. The innovative process increased overall water recovery significantly.

Keywords:

Sulfate; membrane concentrate; precipitation; calcium sulfoaluminate; water reuse

INTRODUCTION

The high solubility and stability of sulfate ions in aqueous solutions make processes for removal of this anion from water to low levels extremely complex. The application of nanofiltration (NF) for sulfate reduction is becoming popular with the promulgation of new regulations and increased interest in water reuse. However, handling of the NF concentrate with high sulfate is problematic. State-of-the-art sulfate treatment technology includes chemical precipitation, biological degradation, adsorption and/or ion-exchange, and membrane (nanofiltration and reverse osmosis) processes. Each of the processes is discussed in detail by Silva et al. (2010). Under favorable reaction conditions (water with low ionic strength), the desaturation process generates effluent containing about 1,800 mg/l of sulfate (as SO4). The major drawback of the biological reduction of sulfate is the generation of sulfide gas, a long residence time, and the metabolic waste products, which are difficult to handle. Evaporation/crystallization is an energy-intensive process. Ion exchange produces regenerants containing extremely high concentrations of sulfate, which are also difficult to handle. Therefore, a sulfate removal technology that can reduce the sulfate concentration in the treated effluent of the desaturation process down to a low level (say <100 mg/L) is needed.

The primary objectives of this project were to determine and validate an appropriate membrane (NF) process to reduce the sulfate concentration in the water as well as to establish an innovative sulfate treatment technology for the membrane reject. The treated effluent then could be blended with the NF permeate to achieve a higher water recovery for reuse.

METHODOLOGY

Initially, a treatability study was conducted to validate the proposed sulfate treatment system and to generate data that were used as baseline information for the on-site pilot-scale experiment.

Wastewater Sampling and Characterization

Samples were collected from the tailings pond of a copper mine site. The analytical results of the "as-received" sample are presented in Table 1. All metals were analyzed using the Inductively Coupled Plasma – Mass Spectroscopy (ICP-MS) method, and sulfate was analyzed using the Ion Chromatography (IC) method.

Table 1 Characteristics of Untreated Pond Water

Parameters	Concentrations
pH, S.U.	7.4
Total Alkalinity , mg/l $CaCO_3$	28
TDS, mg/l	3070
Turbidity, NTU	1.41
TOC, mg/l	2.4
Chlorides, mg/l	66.8
Sulfate, mg/l	1,830

Calcium, mg/l	692
Iron, mg/l	0.01
Magnesium, mg/l	21.1
Manganese, mg/l	0.17
Molybdenum, mg/l	0.25
Potassium, mg/l	124
Sodium, mg/l	104

Laboratory-Scale Study

Using the actual pond water sample from the mine site, a laboratory study was conducted, including molybdenum removal, SDI reduction followed by NF for sulfate reduction, and treatment of the NF concentrate.

Molybdenum Removal and SDI Reduction

To ensure a molybdenum concentration below 0.05 mg/l, iron (as Fe^{3+}) was added under slightly acidic condition (pH between 6.0 and 6.5), and SDI was reduced to <3 by adding a polymeric flocculent.

Sulfate Removal with NF

After pretreatment, the pH of the NF feed water was adjusted to about 7.5. The membrane was operated at a 60% water recovery rate. An antiscalant was used to protect the membrane from scaling. Samples were collected from the permeate and the reject line, and the trans-membrane pressure (TMP) was noted. The treated samples were analyzed for sulfate, calcium, conductivity, total dissolved solids (TDS), and other pertinent cations and anions. The detailed laboratory study procedures are presented elsewhere (Banerjee et al., 2012).

NF Reject Treatment

Sulfate present in the NF reject at a high concentration was removed as a precipitate of calcium sulfate by the desaturation process. The study was conducted in a continuous system for two weeks using Veolia Water's proprietary Turbomix® reactor (a draft-tube, high-speed reactor). A detailed description of the Turbomix reactor is provided elsewhere (Banerjee et al., 2010). The reactor was equipped with a sludge recirculation system. NF reject was pumped into the reactor where calcium ion was added. Lime or a combination of lime and calcium chloride was used as the source of calcium ions. The precipitation reaction was performed in the presence of a seed material. After precipitation, solids were separated from the liquid in a clarifier. A portion of the sludge was recycled back to the reactor, and the other portion was dewatered. Samples of the clarified effluent were filtered through 0.45-μ paper and analyzed for calcium and sulfate.

The effluent from the above process was further treated with aluminum-based salt to precipitate sulfate as a highly insoluble calcium sulfoaluminate mineral. A high-speed Turbomix® reactor was also used in this case. At a specified sludge recirculation ratio, a sulfate removal kinetic study was conducted. Calcium sulfoaluminate mineral was separated from the clear water, and aluminum ion was regenerated from the sludge, after pH adjustment, and recycled back to the process.

Pilot-Scale Study

Based on the laboratory study results, a 1.3 l/s (4.5 m^3/hour) pilot unit was designed and constructed. Pilot studies were conducted for about two months. The general process flow diagram of pilot study is included in Figure 1. The pretreatment included iron coagulation, gravity separation, and a Multimedia Filter (MMF). The NF system was comprised of three 200-mm-diameter elements (two DOW 90 – 400 elements and one DOW 270 – 400 element). The unit was run at three different flux rates ranging between 22 and 30 lmh, and was operated continuously (24 hours/7 days a week) at 350 percent $CaSO_4$ saturation. Using lime and calcium chloride in the presence of a seed material, sulfate from the NF reject was desaturated in the first-stage high-speed Turbomix® reactor. Under the same process condition, about 80% of the samples were collected and analyzed three times to check the reproducibility of the results. Using a HACH kit, sulfate was analyzed at the site, and Ion chromatography method was used to determine sulfate concentration in the laboratory. Using water from a coal mine site, the 2nd set of pilot study was conducted. A similar sampling, analytical, and replication procedures were followed as described above.

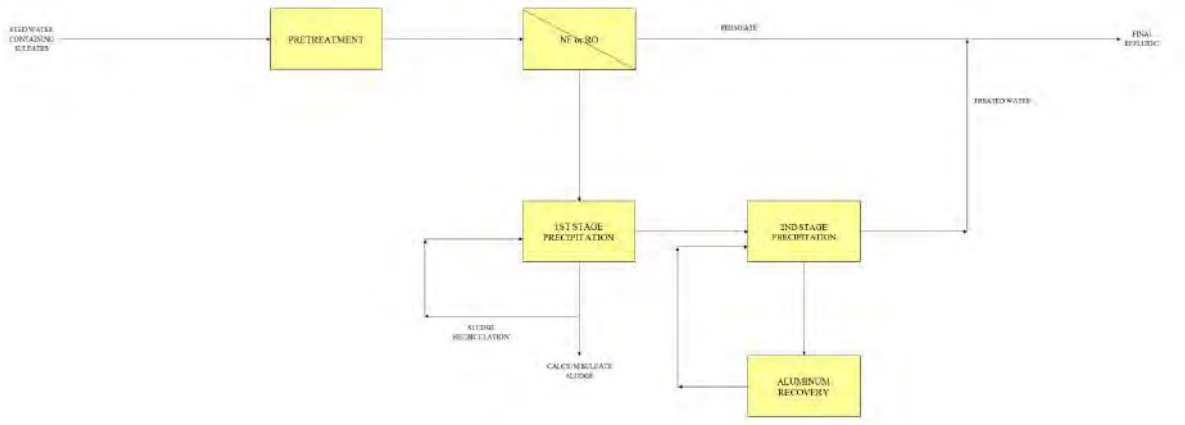

Figure 1 Pilot Flow Diagram

RESULTS AND DISCUSSION

Laboratory-Scale Study

The average calcium and sulfate concentrations in the NF feed water were 640 (as Ca^{2+}) and 1,600 mg/l (as SO_4^{2-}), respectively. More than 98% of the sulfate was rejected at the 60% water recovery rate. The average concentration of sulfate in the permeate was about 25 mg/l. Increasing the membrane flux rate did not affect the permeate quality significantly. The concentration of calcium in the NF reject at the 60% water recovery rate varied between 1535 and 1550 mg/l, and that of sulfate ranged between 3,500 and 4,100 mg/l. Results of the laboratory-scale membrane performance are shown elsewhere (Banerjee et al., 2012).

The results of calcium sulfate desaturation kinetics in the presence of seed material with sludge recirculation are shown in Table 2. As the table illustrates, sulfate in the treated water was reduced from 4,000 (average concentration) to 1,300 mg/l, which is less than the theoretical solubility limit of

1,800 mg/l as dissolved sulfate. The results also reveal that without the sludge recirculation, sulfate was reduced to about 2,000 mg/L. The seed material was added only once (during the process start-up). Detailed laboratory study results are presented elsewhere (Banerjee et al., 2012).

Table 2 Sulfate Removal after Calcium Sulfate Precipitation/Adsorption using Lime and Calcium Chloride, or Lime only, with Seed Material in a Sludge Recirculation System

Sludge Recirculation Ratio	20:1	15:1	10:1	15:1*	0*
pH	9.3	9.3	9.2	12.0*	12.0*
Dissolved Sulfate, mg/L	1,350	1,100	1,200	1,100*	2,000*

*This experiment was conducted only with lime.

The data show that sludge recirculation and seeding have a significant impact on the calcium sulfate desaturation process. The seed material used in this process has a highly reactive surface, which increases the reaction driving force and the available free energy of the system. It is anticipated that besides chemical precipitation, sulfate ions present in the NF reject are adsorbed onto the reactive surface of the seed material as well as onto the freshly precipitated calcium sulfate solids. Additionally, increased crystal growth of the precipitated solids takes place in the presence of the seed material.

Pilot-Scale Study

The sulfate concentration in the raw water ranged between 1,800 and 2,900 mg/l (average 2,300 mg/l). During the study, the sulfate concentration in the raw water increased by about 30%. The calcium concentration in the raw water did not change significantly, and the average turbidity in the water was about 25 NTU. After pretreatment, iron, manganese, molybdenum, and SDI were reduced to <0.3mg/l, <0.05mg/l, <0.05mg/l, and <3, respectively. Since the raw water contained a higher sulfate concentration, initially the NF was run at 50% water recovery to avoid scaling; after that, it was operated for two weeks at a 60% water recovery rate with an increased antiscalant dosage.

Sulfate and calcium rejection data are presented in Figures 2 and 3. As Figure 2 shows, about 98.5% of the sulfate was rejected, and sulfate in the NF permeate ranged between 25 and 55 mg/l. The average sulfate concentration in the permeate was 35 mg/l. The percent rejection of calcium ranged between 90 and 99% (see Figure 3). Calcium in the NF permeate ranged between 10 and 60 mg/l. Sulfate rejection showed a very stable line in the high 90's (Figure 1) in comparison to calcium rejection (Figure 2). Since the membrane surface is negatively charged, the membrane primarily rejects sulfate, and because of ion pairing, the sulfate holds back the positively charged calcium and magnesium ions from passing through the membrane.

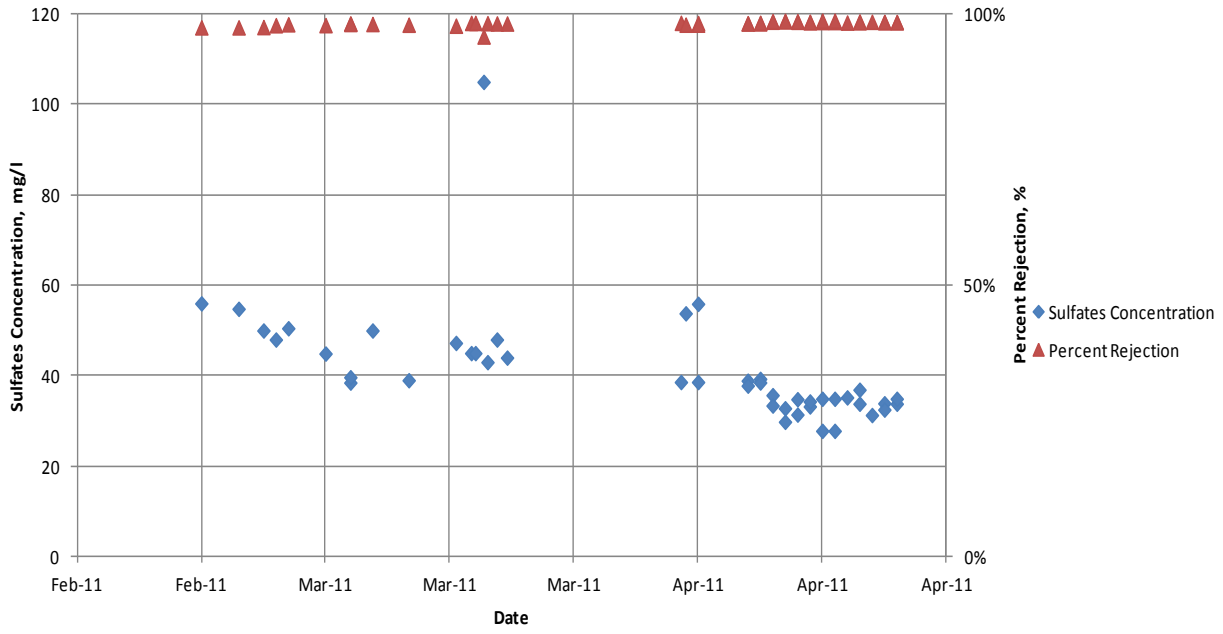

Figure 2 NF Permeate – Sulfate Concentrations and Percent Rejection

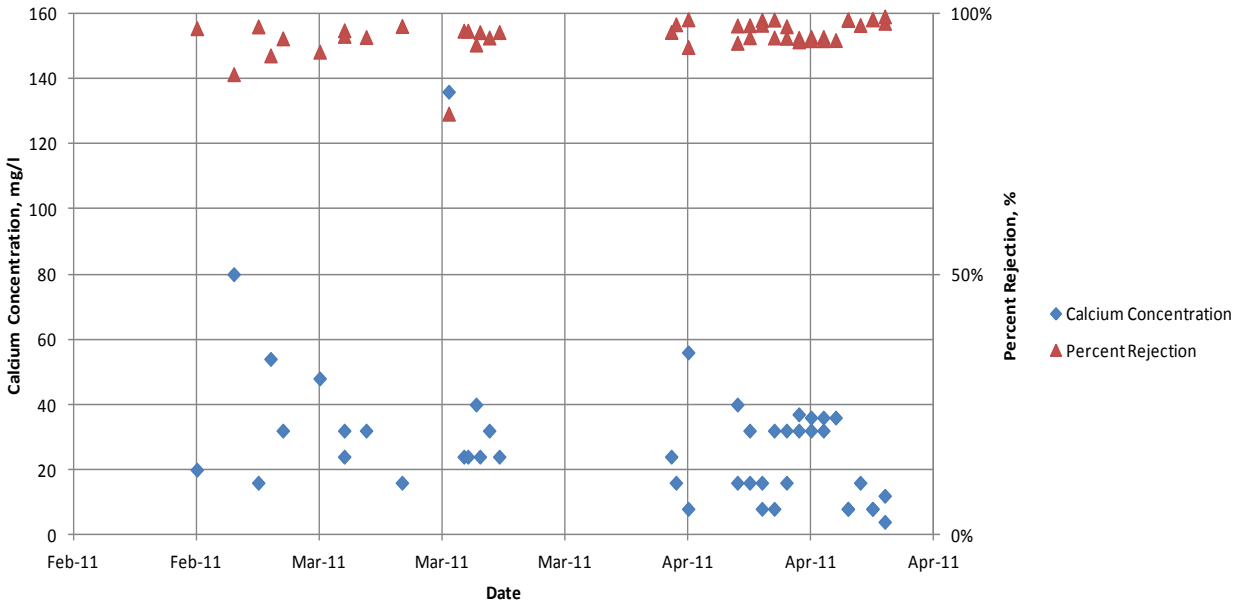

Figure 3 NF Permeate – Calcium Concentrations and Percent Rejection

The sulfate concentration in the NF reject ranged between 2,500 and 4,000 mg/l, and calcium in the reject varied between 800 and 1,800 mg/l. TMP across the membrane never exceeded 0.7 bar because of the low SDI values in the feed water and periodic flushing of the membrane with NF permeate. The membranes were flushed once every twelve hours.

Sulfate treatment results for NF concentrate by the desaturation process are presented in Figure 4. In this process, sulfate was removed through gypsum ($CaSO_4 \cdot 2H_2O$) precipitation using a combination of lime and calcium chloride under a controlled pH at a specified sludge recirculation ratio within 30 minutes of reaction in the presence of seed material, which was added one time during the study. During the desaturation process, utilizing a Turbomix™ reactor and MULTIFLO™ technology, sulfate was reduced to less than 1,500 mg/l.

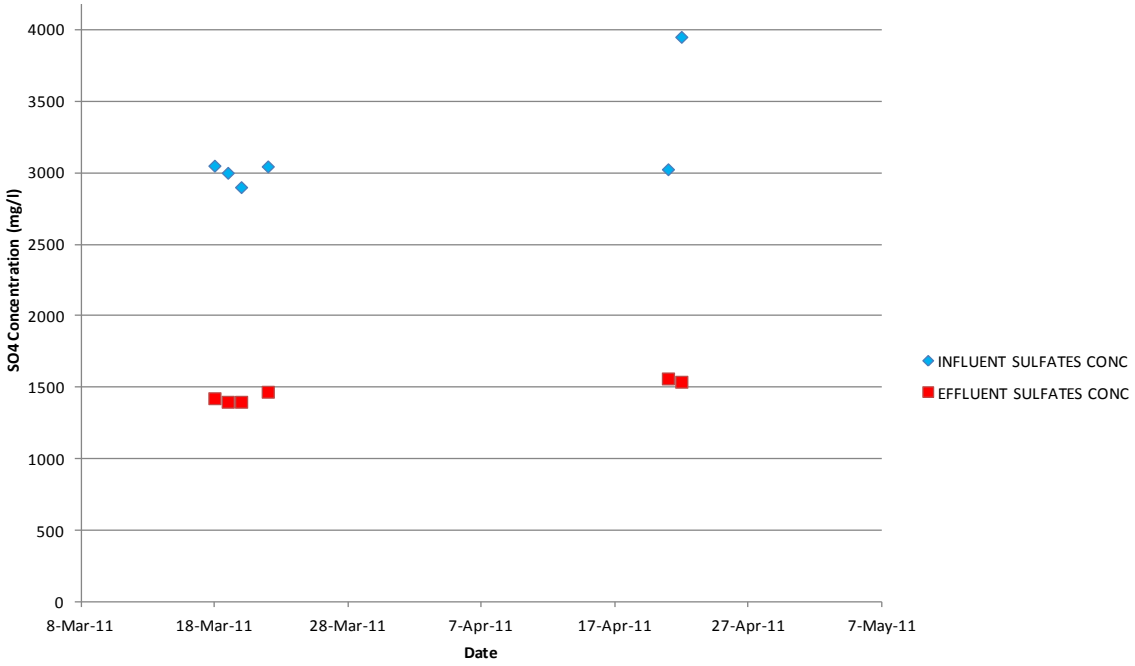

Figure 4 CaSO4 Desaturation with Sludge Recirculation and with Seed Material

Further Reduction of Sulfate by Calcium Sulfate Complexation

Dissolved sulfate from the desaturated calcium sulfate effluent was further reduced by forming an insoluble complex known as calcium sulfoaluminate mineral. The associated chemical dosages and sludge recirculation ratios were determined from the preliminary laboratory study results. Sulfate reduction kinetics results for the most efficient recirculation ratio are shown in Figure 5.

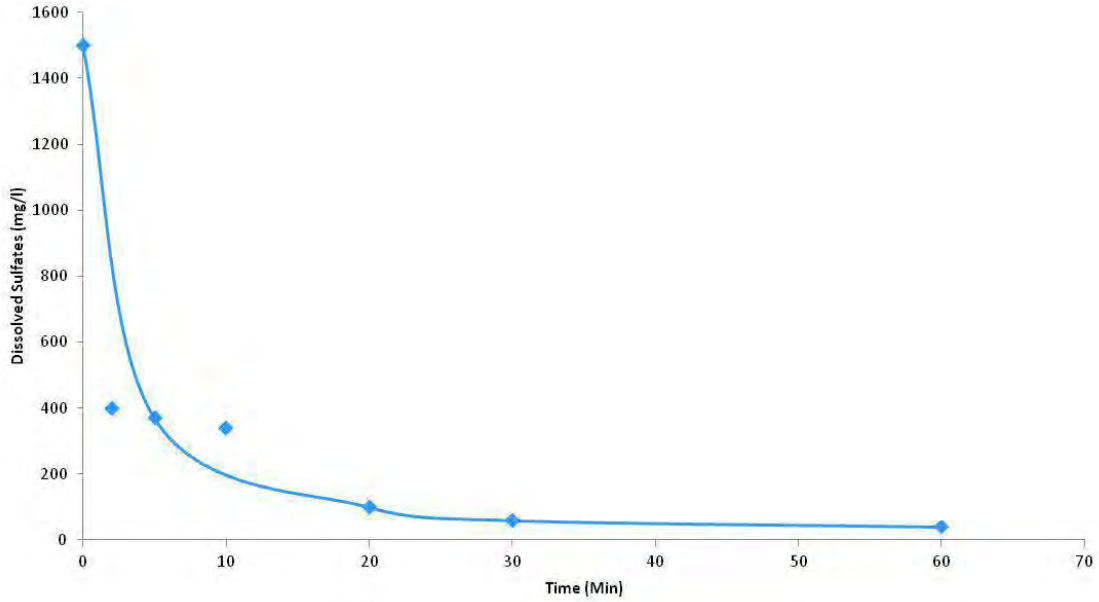

Figure 5 Sulfate Precipitations Kinetics as Calcium Sulfoaluminate Mineral

As the figure illustrates, increasing the reaction time decreased the sulfate concentration, and the reaction was completed within 20 minutes. During that period, dissolved sulfate was reduced to <100 mg/l.

As indicated earlier, using the water from a coal mine site, the 2nd set of pilot study was conducted. The primary objective was to recover aluminum from calcium sulfoaluminate (Ettringite) sludge, and reuse that in the process. The study was conducted for a period of 16 weeks. Freshly prepared tri hydroxide of aluminum (Gibbsite) was used for the first two weeks of the study to precipitate sulfate as the Ettringite mineral. Once the system reached to the steady state condition, regenerated tri hydroxide of aluminum was used for Ettringite precipitation.

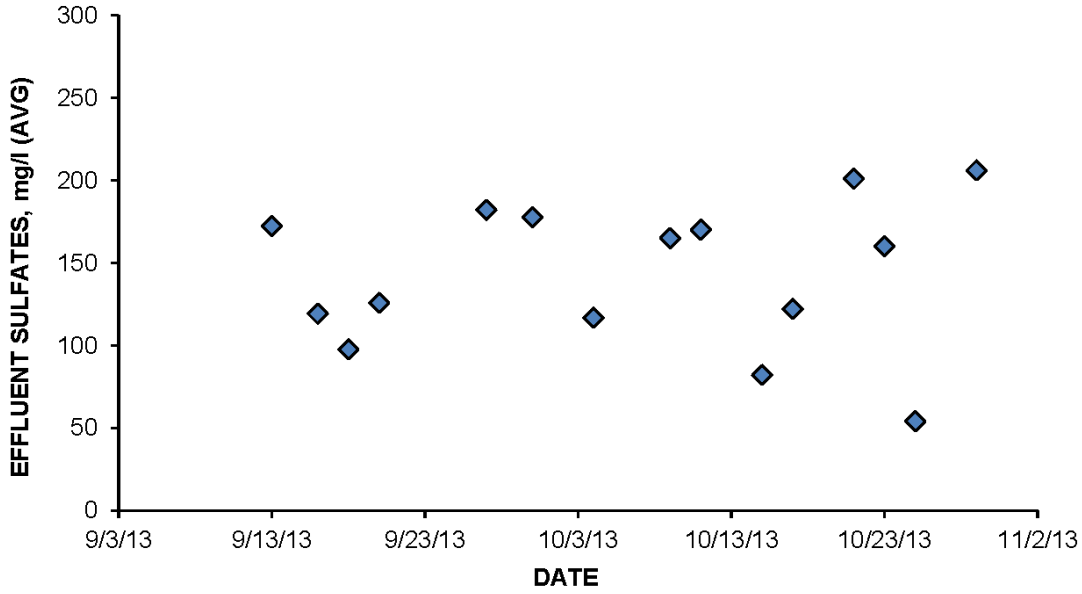

Figure 6 Effluent Sulfate with Regenerated Gibbsite

As indicated in Figure 6, after solid/liquid separation, sulfate was reduced to <100 mg/L The particle size distribution results (not shown in the paper; will be included in the presentation) revealed that the average particle diameter of the Ettringite solids is 20μ, and more than 1% of the particles have the diameter less than 1μ. Consequently, carry-over of the fine colloids of Ettringite has contributed to elevate the sulfate results. It is anticipated that with adequate sludge recirculation, the solids carry-over problem would be under control. Dissolved aluminum in the treated effluent ranged between 0.1 and 0.35 mg/L (see Figure 7).

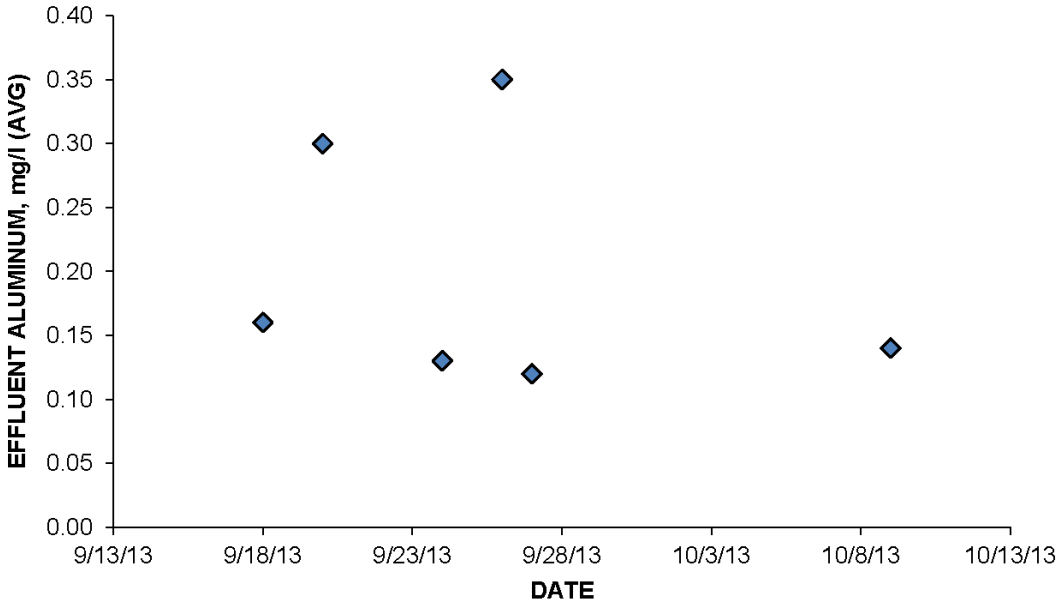

Figure 7 Aluminum in the Treated Effluent

Aluminum from the calcium sulfoaluminate precipitate was recovered by dissolving this mineral in acid. After solid/liquid separation, more than 95% of the aluminum-based salt was recovered and reused to precipitate calcium sulfoaluminate for sulfate reduction.

Based on the pilot-scale results, a flow and mass balance calculation was performed, and a conceptual process was proposed (see Figure 8). The process includes pretreatment for iron, manganese, molybdenum, total suspended solids (TSS), and other pertinent contaminants followed by NF for sulfate removal and sulfate reduction from NF reject by a two-stage chemical precipitation process. The flow and mass balance calculation for this specific site revealed that after blending the treated NF reject with the permeate, the overall water recovery increased from 60 to 90%.

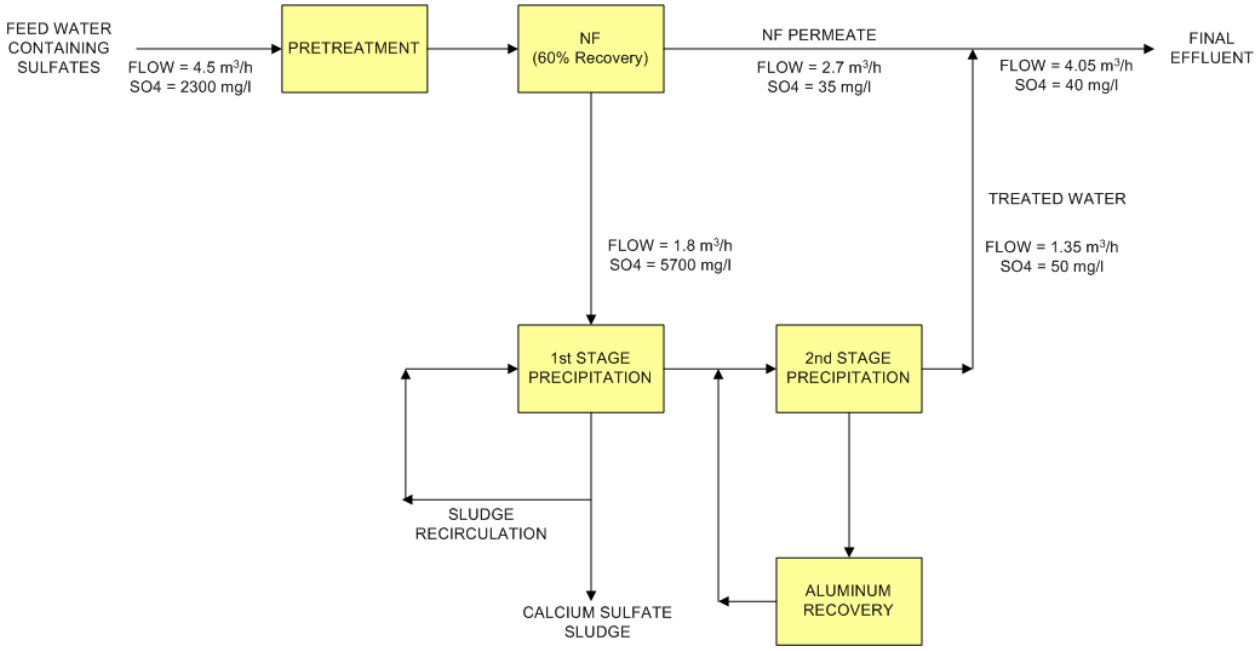

Figure 8 Process Flow Diagram

CONCLUSION

Sulfate from the NF reject can be reduced to less than 1,500 mg/l by a chemical precipitation and/or adsorption process in the presence of a seed material with sludge recirculation. Calcium sulfate crystal growth can be accomplished in a continuous system with a specified reaction time and sludge recirculation ratio. The sulfate concentration can be further reduced to less than 100 mg/l by a calcium sulfoaluminate precipitation process. The crystal growth and precipitation reaction kinetics of this process are fast and can be accomplished within 20 minutes of reaction. More than 95% of the aluminum was recovered and reused. This innovative concept increased overall water recovery significantly.

ABSTRACT

Two different kinds of agglomerated and filter stable adsorbents were developed based on bio-technologically synthesized schwertmannite (SHM) from iron and sulfate containing lignite mine water. The adsorbents were obtained by compaction and by mixing SHM with an organic polymer without impairing its adsorption capacity regarding arsenic, respectively.

At first, both types of SHM adsorbents were tested in comparison to the commercially available iron hydroxide adsorbent (Ferrosorp®Plus, HeGoBiotec GmbH) in two batch test series with (1) tap water stocked with 20 mg/L As(V) and As(III), respectively and (2) drainage water from an abandoned uranium mine of the ore mountains (Eastern Germany) which contained about 1 mg As/L. Both types of SHM adsorbents showed higher maximum As(III) and As(V) adsorption capacities (28.0 to 31.1 mg/g adsorbent) than Ferrosorp®Plus (22.7 and 18.0 mg/g adsorbent, respectively).

Thereafter, two column test series were performed directly at the abandoned uranium mine site with the drainage water and a filter bed residence time of 11 to 34 minutes. Due to its slow adsorption kinetic, the effluent limit value of 0.1 mg As/L was exceeded significantly earlier in the Ferrosorp®Plus column than in the columns filled with SHM-adsorbents. The compacted product SHM-sorpP showed a better long time effect due to its 40% higher bulk density.

In dumping experiments with the As loaded SHM adsorbents and alternating rain water (pH 5) and continuous groundwater elution (pH 7), only 0.13 – 0.6% and 0.03% of the adsorbed As were desorbed within 285 days, respectively. Currently, further pilot scale trials are being prepared for testing the SHM agglomerates with various kinds of mine and industrial wastewaters.

INTRODUCTION

The Vattenfall Europe Mining AG and the G.E.O.S. company are operating in close collaboration a pilot plant for microbial-mediated ferrous iron oxidation in the open pit lignite mine near Nochten (Lusatia, Germany) where schwertmannite (SHM) is synthesized as a byproduct of a worldwide unique water treatment process (Janneck et al, 2010 ; DE 102 21 756 B4). The pilot plant (Figure 1) is operated with iron and sulfate rich mine water from the Nochten pit. In the framework of a recently finished research project founded by the German Ministry of Education and Research (Peiffer et.al., 2012), two methods for the production of an agglomerated adsorbent based on SHM were developed for utilization of water stable agglomerates in passive treatment systems for Arsenic-contaminated mine waters.

MATERIALS AND METHODS

Adsorbents

The SHM-based adsorbents were fabricated a) by compaction (called SHM-sorpP thereafter) and b) by mixing SHM with an organic polymer (called SHM-sorpX thereafter), respectively. The latter was produced by using filter-moist SHM (approximately 48 wt-% water content), a binder amount of 8 wt% (in order to obtain a stable product), a drying step of 6 hours at 85°C and a curing step of 1 hour at 120°C thereafter. The binder-free adsorbent was produced by high-pressure compaction in a briquette press with controllable pressure gradient at the Höcker Polytechnik GmbH, Hilter, Germany (Figure 2). For this purpose, the SHM was dried at 60°C in order to obtain a water content of 10 to 20 wt-%. The moisture of the raw material SHM has an important influence on the briquette quality. SHM does not adhere and will still remain as a dusty powder if the water content is too low, even at sufficient pressure conditions. If the water content is too high, the substance exhibits thixotropic behavior. Details of the briquette fabrication are given in EU patent application EP 2664376A1.

The new SHM-based adsorbents (Figure 3) for the treatment of arsenic contaminated mine water should be compared to that of a commercially available iron-hydroxide adsorbent like Ferrosorp®Pus (HeGo Biotec GmbH). Table 1 summarizes the characteristic parameters of all three adsorbents.

Filter bed porosity	[%]	75	69	80
Specific surface area (SSA)	[m^2/g]	143.9	64.7	320.8
Micropore surf. area	[m^2/g]	8.7	25	276.6
Micropore volume	[cm^3/g]	0.0031	0.0044	0.0983
Intraparticle porosity*	[%]	0.75	1.29	29.7

*intraparticle porosity = grain density * micropore volume

Table 2 Selected parameters of the As(III) or As(V) enriched tap water used in batch tests and the drainage water of an abandoned uranium mine (Ore Mountains, Germany) used in pilot scale column tests

parameter	pH [-]	TIC	SO_4	Ca	Mg	Fe	Si	As
					[mg/L]			
Tap water	8.15	18.2	31.0	40.2	3.4	<0.1	1.9	(+10/ +20)
Drainage water	7.05	63.1	0.49	49.7	11.8	<0.1	10.0	0.85-1.8

Water

Two kinds of water were used in the study. For the investigation of the principal As adsorption behavior (adsorption capacities and kinetics), batch test series with As-enriched tap water were performed. The suitability of the new SHM adsorbents for practical water mine treatment was studied in two field site column test series at an abandoned uranium mining site (Ore Mountains, Eastern Germany) using drainage water. Table 2 summarizes the parameters of these waters.

Test methods

Batch tests In order to investigate the principal As adsorption behavior (adsorption capacities and kinetics) of the new SHM adsorbents, samples of SHM-SorpX and SHM-SorpP were prewashed to remove residual, superficially-adhered sulfate. The As uptake behavior was investigated in 250 mL glass bottles with screw caps at an initial As(III) and As(V) concentration of 10 and 20 mg/L tap water (quality mentioned in the pre-selection test section) as $Na_2HAsO_4*7H_2O$ p.a. and $NaAsO_2$ p.a., and an adsorbent mass of 0.5 g/L for an overall time of 24 days. Prior to the beginning of the experiments, the solution pH was adjusted to a value of 7.4 +/- 0.1 with diluted HCl. The bottles were gently shaken on a horizontal shaker at T= 22 ± 2°C. During the experiments, no pH buffering was done in order to simulate conditions of water treatment plants. Sampling of pH and As concentration was performed after 1, 3, 6, 11 hours and 1, 2, 4, 6, 10, 14 and 24 days. In order to compare the As(III) and As(V) adsorption capacities of both SHM-adsorbents with the iron hydroxide adsorbent Ferrosorp®Plus, parallel tests with 10 and 20 mg/L As(III) or As(V) and dose of 0,5 g/L of these adsorbents were performed and sampled after 1 hour and 14 days. As(III) experiments were carried out under nitrogen atmosphere in a glove box and the tap water used for the As(III) stock solution was degassed under vacuum.

Field site column tests Thanks to the support of WISMUT GmbH, two column test series could be performed directly at an abandoned uranium mining site. From these tests, the suitability of the new SHM adsorbents for passive mine water treatment systems could be investigated. Table 3 contains important data including trial periods, column dimensions and filter bed residence times. In the 1st column series, the column plant was placed directly at the outlet of the abandoned uranium mine (shaft G1), where the drainage contained about two-thirds arsenite (As(III)). Thereafter, the drainage flows through an aeration cascade and two sedimentation ponds and is decontaminated in a passive water treatment system subsequently (operated by the WISMUT GmbH). The residence time of the drainage water between the mine outlet and this treatment system is approximately 7 days, along the way As(III) is completely oxidized to As(V). Based on the results of the previous batch tests, where the SHM adsorbents offered better adsorption properties

for As(V), the column plant was placed directly at the inlet of the passive water treatment system (shaft G4B) for the 2nd column test series. Figure 4 shows the column set-up.

Table 3 Test parameters of the field site column test series

Test series	Location	Trial period	Dimension of the columns	C(As, influent)	Filter bed residence time
1	shaft G1	2012, sept.-dec. & 2013, may –sept.	D = 4 cm, L = 20 cm V_{column} = 251 cm^3	**ca. 1.8 mg/L:** 65% As(III), 28% As(V)	28 - 34 min
2	shaft G4B	2013, oct.- dec.	D = 3 cm, L = 14.5 cm V_{column}= 102 cm^3	**ca. 0.85 mg/L:** 100% As(V)	11 – 16 min

Sampling of each column influent and effluent were done three times a week, and ferrous iron and pH were estimated by a test kit. Arsenic was analysed by AAS (Perkin Elmer) after membrane filtration (0.2 µm Cellulose Acetate) and conservation by 1% HNO_3(c). The development of As-Species from shaft G1 to shaft G4B was investigated during a field campaign according to the method of (Le et al., 2000).

Figure 4 Field site column test design with a prefilter (sand column) and an admission pressure pump (left), the column test plant with effluent containers (middle) and the Plexiglas columns filled with adsorbents (right)

Dumping tests Dumping tests were performed to verify the long-term binding stability of SHM-sorpX and SHM-sorpP for arsenic. Therefore, the As-loaded SHM-adsorbents from the batch tests were tested under two "worst case" scenarios. (1) A rainwater elution scenario should represent a dumping site with an insufficient surface cover and (2) a groundwater elution scenario should simulate a dumping site without basic sealing. For the rainwater scenario, the SHM adsorbents were wetted by synthetic rainwater (pH 5, Ca: 0.6 mg/L, K, Na, NH_4, Mg: 0.3 mg/L, NO_3, SO_4: 2 mg/L, Cl: 0.5 mg/L) for 24 hours every 2 to 4 weeks. A non-contaminated mine water from Ehrenfriedersdorf (Ore Mountains, Eastern Germany) with pH 7.9, EC 445 µS/cm, SO_4: 102 mg/L, HCO_3^-: 47.3 mg/L, Si: 6,5 mg/L, Fe: < 0.1 mg/L and Mn: <0.1 mg/L was used for the groundwater

elution scenario respectively. In all tests, the water to adsorbent ratio was 1:10. The change of the equilibrium water phase and the subsequent As analysis (sample preparation and analytical method as mentioned above) were done every 2-4 weeks (in a total of 15 cycles) for an overall test time of 9.5 month (285 days).

RESULTS

Batch tests

Figure 5 shows the adsorption kinetic of As(III) and As(V) for both SHM-sorpX and SHM-sorpP. The amount of adsorbed As (q_t in mg/g adsorbent) was plotted against the square-root of the shaking time t (in days$^{0.5}$) in order to visualize different adsorption kinetic behaviours. According to (Weber & Morris, 1963), theses q_t-$t^{0.5}$-plots (with $q_t = k*t^{0.5}$ and the slope/equilibrium rate constant k) show multi-linearity, if not only an external diffusion of the adsorbate (As(III) or As(V)) to the surface of the adsorbents, but also intraparticle diffusion controls the adsorption behaviour. The main part of As adsorption was controlled by external diffusion of As to the adsorbent surfaces and appears within the first two days of the experiments, Intra-particle diffusion of superficially adsorbed As into the meso- or micropores of the SHM adsorbents could be evidenced in minor parts by a second, significantly lower slope of each q_t-$t^{0.5}$ plot. SHM-sorpX shows a faster 'short-time' adsorption behavior for As(III) and As(V) (steeper slopes of the first parts of the q_t-$t^{0.5}$-plots), whereas SHM-sorpP takes over thereafter (during the 'long-time' adsorption, steeper slopes of the second parts of the q_t-$t^{0.5}$-plots), especially in the experiments with As(V). During the contact with water in the batch test, SHM-sorpP seems to form higher intraparticle porosity than SHM-sorpX, which could be very advantageous for a longtime use in filter bed systems. This can be attributed to the curing of the SHM-sorpX product by the binder addition.

Table 4 contains the As(III) and As(V) adsorption capacities for SHM-sorpX, SHM-sorpP and Ferrosorp®Plus after 1 hour and 14 days, respectively. Whereas the As(III) adsorption to both SHM adsorbents was slightly lower than that of Ferrosorp®Plus after 1 hour, SHM-sorpP and SHM-sorpX had adsorbed more As(III) than the iron hydroxide adsorbent after 14 days. In contrast to this, the As(V) adsorption to SHM-sorpP and SHM-sorpX was always significantly higher than that of the iron hydroxide adsorbent, even after 1 hour. This could be referred to a more positive surface charge of the SHM because of a proton release during its hydrolysis.

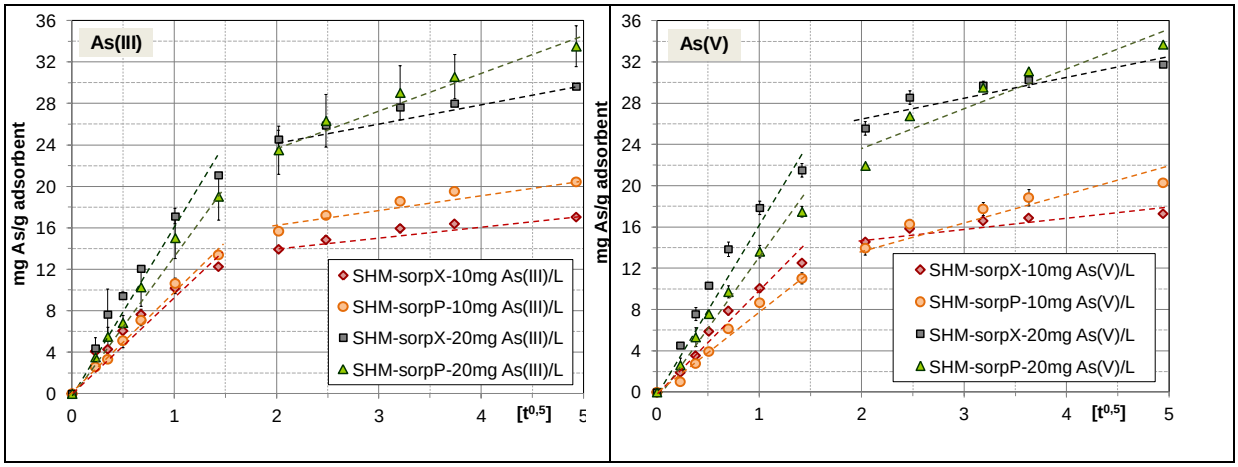

Figure 5 As adsorption kinetics of SHM-adsorbents, 0.5 g ads./L, pH_{start}: 7.4±0.1, no pH buffering during the tests

Field site column tests

In both test series, a significantly better performance could be demonstrated for the newly developed SHM adsorbents compared to Ferrosorp®Plus (Figure 6). Thereby, the higher bulk density of SHM-sorpP proved to be a major advantage. This allows 40% higher amounts of adsorbent in the filter beds and so their lifetimes can be increased greatly. In addition, it seems that the 'open' (in contrast to product SHM-sorpX not glued) surface structure allows a slight kinetic sorption (intraparticle diffusion), whereby initially superficial adsorbed arsenic is carried deeper into the granule structure and the surface adsorption area can receive new arsenic. The second series of experiments has been shown that the new SHM-adsorbents due to their, already in the laboratory tests (Tab.1) proven, better As (V) – adsorption kinetics have another big advantage compared to the adsorbent Ferrosorp®Plus. This enables much shorter residence times in the filter bed and the water flow rate could be increased significantly. Due to the beginning of the frost period, the test series 2 was completed by December 2013.

Table 4 As(III)- and As(V)- capacities estimated in batch tests with 0.5 g adsorbent/L and 20 mg As/L, pH_{Start}= 7,4±0,1 after 1 hour and 14 days (rather maximal adsorption capacities)

Adsorbent	after 1 hour		after 14 days	
	mg As(III)/g ($pH_{equilibrium}$)	mg As(V)/g ($pH_{equilibrium}$)	mg AsIII)/g ($pH_{equilibrium}$)	mg As(V)/g ($pH_{equilibrium}$)
SHM-sorpX	**4.4**±1.0 (pH 6.8)	**4.5**±0.7 (pH 6.9)	**28.0**±0.7 (pH 6.8)	**30.3**±0.2 (pH 6.8)
SHM-sorpP	**3.5**±0.4 (pH 7.0)	**2.6**±0.01 (pH 7.0)	**30.6**±2,1 (pH 6.6)	**31.1**±0.7 (pH 6.9)
Ferrosorp®Plus	**4.8**±0.1 (pH 7.6)	**1.6**±0.3 (pH 7.3)	**22.7**±0.4 (pH 8.2)	**18.0**±0.2 (pH 7.9)

Table 5 and 6 contain a summary of the characteristic parameters and the filter-bed volumes which could be exchanged up to the exceedance of the effluent limit concentration of 0.1 mg As/L. Because of the higher residence time in the 1st test series, the calculated, integral As loading of the adsorbents were in the same range. However, it should be considered, that the filter bed system with SHM-sorpP contained a 40% higher adsorbent mass. In the 2nd test series, the As loading of Ferrosorp®Plus was remarkably lower, and demonstrated its worse adsorption kinetic again.

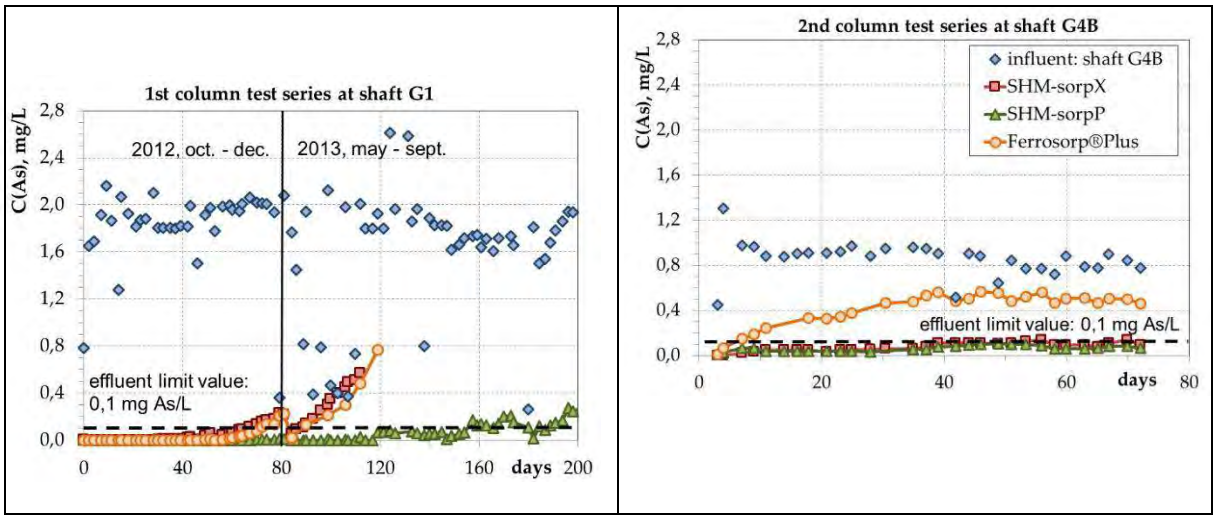

Figure 6 Development of As-concentrations in the column effluents of the 1st (left) and 2nd test series

Table 5 Summary of the 1st column test series at shaft G1

Adsorbent (mass)	**Filter bed residence time**	**Filter bed volumes treated $C(As)_{effl}$ >0.1 mg/L**	**Total through put / test time at $C(As)_{effl}$ >0.1 mg/L**	**Calculated As adsorp. capacity at $C(As)_{effl}$ >0.1 mg/L**
Ferrosorp®Plus (153 g)	34 min	2,784	501 L/ 72 d	6.1 mg As/g Ads.
SHM-sorpX (177 g)	32 min	3,633	654 L/ 90 d	6.1 mg As/g Ads.
SHM-sorpP (304 g)	28 min	6,389	1214 L/ 157 d	6.9 mg As/g Ads.

Table 6 Summary of the 2nd column test series at shaft G4B

Adsorbent (mass)	**Filter bed residence time**	**Filter bed volumes treated $C(As)_{effl}$ >0.1 mg/L**	**Total through put / test time at $C(As)_{effl}$ >0.1 mg/L**	**Calculated As adsorp. capacity at $C(As)_{effl}$ >0.1 mg/L**
Ferrosorp®Plus (73 g)	15.6 min	549	44 L/ 7 d	0.5 mg As/g Ads.
SHM-sorpX (66 g)	13.2 min	4,418	353 L/ 39 d	4.7 mg As/g Ads.
SHM-sorpP (118 g)	11.4 min	5,966	418 L/ 49 d	2.9 mg As/g Ads.

After the end of both column test series, the As-loaded SHM adsorbents were also analyzed by aqua regia digestion for their arsenic content in the inlet and outlet areas of the columns (Table 7). The results show, that the As adsorption capacities of the SHM adsorbents have not been fully exhausted compared to the values reached in the batch tests. If a series connection of two columns

will be used, As adsorption capacity up to 20 mg As/g should be achievable in the entire first column.

Table 7 As content of the SHM adsorbents after the end of the column tests

Column	SHM-sorpP		SHM-sorpX	
	inlet area	outlet area	inlet area	outlet area
Series 1	20.3 mg As /g	5.1 mg As/g	16.4 mg As/g	4.2 mg As/g
Series 2	8.4 mg As/g	1.7 mg As/g	13.4 mg As/g	2.8 mg As/g

Dumping tests

Sequential elution tests with groundwater and synthetic rainwater were performed with As loaded SHM adsorbents from the As(III) adsorption kinetic tests. Between 0.13% and 0.6% of the adsorbed As were desorbed by a total of 15 cycles of alternating wetting with rainwater and subsequent drying (Table 8). Leaching of As by continuous elution with groundwater for 285 days was not significant (0.03 % of the initial value). After one elution cycle, the concentration limit of 2.5 mg/L of dumping class DKIII (German DepVerwV, 2005) was not exceeded in any case of dumping. This assessment demonstrates that dumping of As-contaminated SHM adsorbents would be tolerable according to German dumping classes even under worst case conditions like a dumping site without an intact surface or bottom sealing and no additional treatment of the SHM adsorbents for immobilisation purpose is necessary.

Table 8 Desorption of As from SHM-adsorbents

Adsorbent	SHM-sorpX	SHM-sorpP	SHM-sorpX	SHM-sorpP
C(As, adsorbed)	32.8 mg/g	31.5 mg/g	32.8 mg/g	31.5 mg/g
Elution procedure	**Alternating rainwater elution (pH 5)**		**Continuous groundwater elution (pH 7)**	
Total As eluated (15 cycles)	0.13 %	0.60%	0.03 %	0.03%
C(As, eluated, 1st cycle)	1.41 mg/L	1.87 mg/L	1.57 mg/L	0.72 mg/L

CONCLUSION

Schwertmannite, biotechnologically synthesized in a pilot plant for lignite mine water treatment, was used for the production of two filter stable adsorbents (grain size 1-2mm) in order to use them in passive treatment systems for As contaminated mine waters. The adsorbents were obtained by compaction and by mixing SHM with an organic polymer, respectively.

In batch tests series with both SHM-adsorbents and a commercially-available iron hydroxide adsorbent (Ferrosorp®Plus, HeGo Biotec GmbH) as well as tap water enriched with 20 mg/L As(III) or As(V), 28.0 to 31.1 mg As/g SHM-adsorbents and 22.7 to 18.0 mg As/g Ferrosorp®Plus were estimated after 24 days equilibrium time, respectively. Thereafter, two column test series were performed directly at an abandoned uranium mining site with drainage water. Because of its worse adsorption kinetic, the effluent limit value of 0.1 mg As/L was exceeded in the Ferrosorp®Plus column significantly earlier than in the columns filled with SHM-adsorbents. Thereby, the

compacted product SHM-sorpP showed a better long time effect due to its 40% higher bulk density. In dumping tests with As loaded SHM adsorbents and alternating rain water (pH 5) and continuous groundwater elution (pH 7) elution, only 0.13 – 0.6% and 0.03% of the adsorbed As were desorbed into 285 days, respectively.

Investigation and Strategy on Iron Removal from Water Courses in Mining Induced Areas

Friedrich Carl Benthaus[1], Wilfried Uhlmann[2], and Oliver Totsche[1]

1. *LMBV, Germany*
2. *IWB, Germany*

ABSTRACT

The ground water table has been lowered for lignite mining purposes at Lausitz area between Cottbus and Dresden (Germany) for a long period of time. Pyrite contained in unconsolidated rocks as well as overburden oxidized intensively at up to 30 or 50 m depth. High quantities of soluble ferrous iron as well as insoluble ferric iron were generated.

While mining on large scale closed in this area, the ground water table rose in recent years. Water courses again are predominated by groundwater inflow. The iron input into the river Spree and into adjunct water creeks can be observed as a cloudy, reddish brown substance.

Large scale investigations have been carried out in order to detect the most important sources of iron contamination along the river Spree. Measuring the flow at different seasons and measuring pH, alkalinity, iron and sulfate along the river course at one day gives a perfect impression of the river status.

A high concentrated groundwater inflow in rivers had been detected not only in connection with dump areas. Increased ferrous iron concentrations have been detected for example at highly permeable aquifers and the outflow of former bog areas.

In order to remove iron from the Spree river water, various treatment units were designed and implemented. The concept for removing the iron followed the principles of simplicity in process, low cost design and minimal chemical additions. Former water treatment plants are reused as sedimentation ponds. Wetlands are constructed for settling of ferric oxyhydroxide solids. Even microbial treatment of groundwater is in test scale with encouraging results.

INTRODUCTION

Lignite mining makes an important contribution to the supply of electrical energy in Germany. In Lusatian district, the area between Dresden and Cottbus, nearly 65 million tonnes of lignite were extracted in 2013, about a third of Germany total production

The lignite seams are embedded in horizontal strata of soft rock sand and silt of Tertiary and Pleistocene age. In order to extract this coal from depths of 30 to 50 metres, the water in the overlying strata has to be lowered by draining. In the past a depression cone of approximately 2,100 square kilometres occurred (Fig.1), extending well over the borders of the opencast mining area.

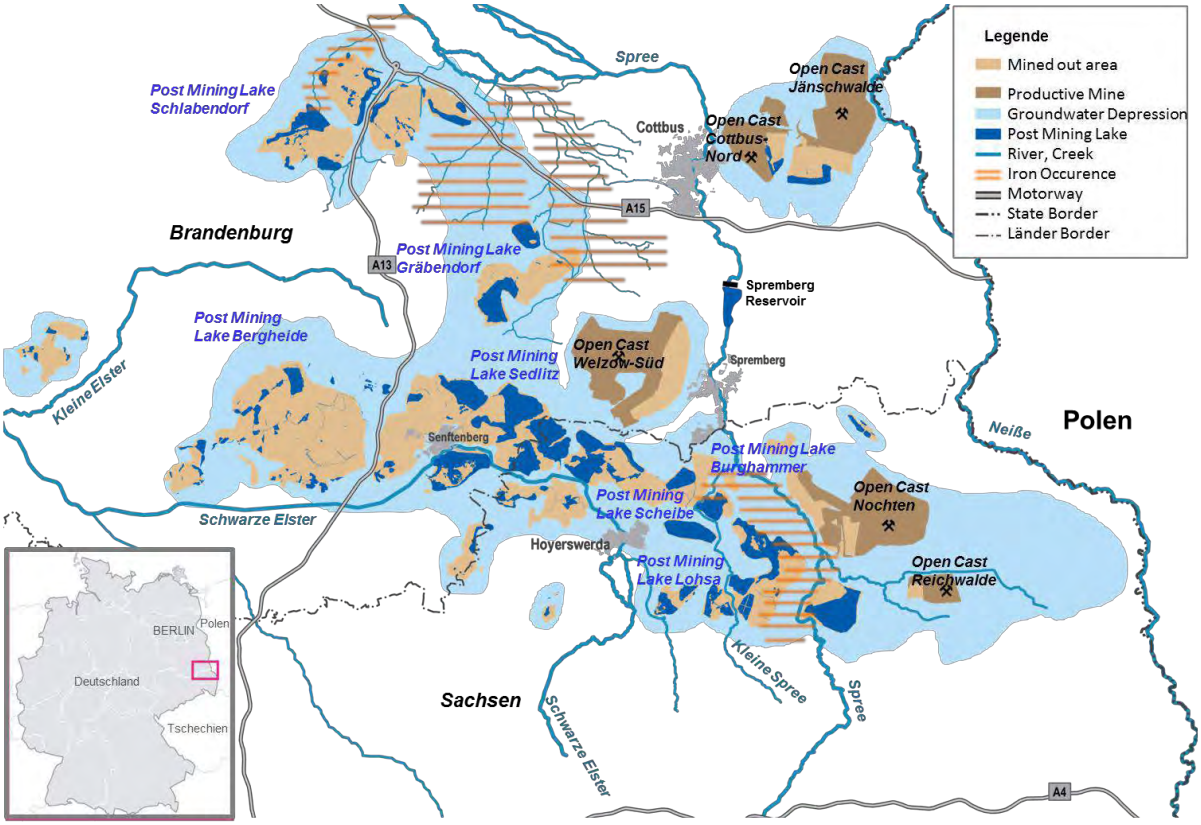

Figure 1 The Lusatian lignite mining district in Germany

Since 1990 a total of 32 lignite mines have had to be closed down. Either deposits have been depleted or the economic and competitive conditions have changed dramatically. The German mining legislation requires that all mines to be rehabilitated. The rehabilitation Lausitzer und Mitteldeutsche Bergbauverwaltungs GmbH (LMBV) has taken charge of. It comprises the removal of all installations, stabilisation of slopes, flooding the opencast mining areas and the restoring the natural water resources.

PROBLEMS OCCURRING WHILE GROUND WATER RISE

Pyrite layers accompanying the seams had previously been under the exclusion of air. While lowering ground water, the oxidation of the drained strata in the depression cone has resulted in soluble iron and sulphate compounds. As the groundwater level rises, these substances are now carried into the water courses.

While sulphate remains in solution in these waters, iron oxidises further, forming iron precipitate. Heavy loads of the resultant iron ochre represent a serious burden for the water course ecosystems affected (see Fig. 2). As a consequence, for example, water plants lack light because of suspended solids. Mussels are smothered by the fine silt and the turbidity deprives fishes of their spawning grounds through the accumulation of mud.

Figure 2 Iron burden in the "Kleine Spree" river (Photo: Theiss)

Investigations by IBW (2010b) and IWB (2013) have shown that there are various sources for the accumulation of iron ochre in water courses (Fig.3). Lignite mining in Lusatia has resulted in large disturbance of the catchment. Besides this, agricultural improvements such as surface draining (1) or turf cutting (6) or even bog iron ore extraction in the last century causes an "initial load" (Fig.3).

The aeration of aquifers following the groundwater depression, takes place even far outside the immediate opencast mining area (2). Oxidation in these aquifers is relatively weak compared with that in material that was relocated in inner dumps (3) or in outer dumps (4) during mining operations. The inner dumps will be submerged again once the water table has been restored. This will result in the cessation of the oxidation process, at least in the long run. The outer dumps will slowly become completely oxidised, and these substances will be carried into the groundwater as well as surface water bodies by precipitation. Groundwater outflows from acid post-mining lakes (5) partly are loaded with iron. In Lusatia the numerous moorlands are a very significant source of

iron (6) because large quantities of iron sulphide minerals have formed as they developed. As the ground water rises the oxidised iron compounds are washed out.

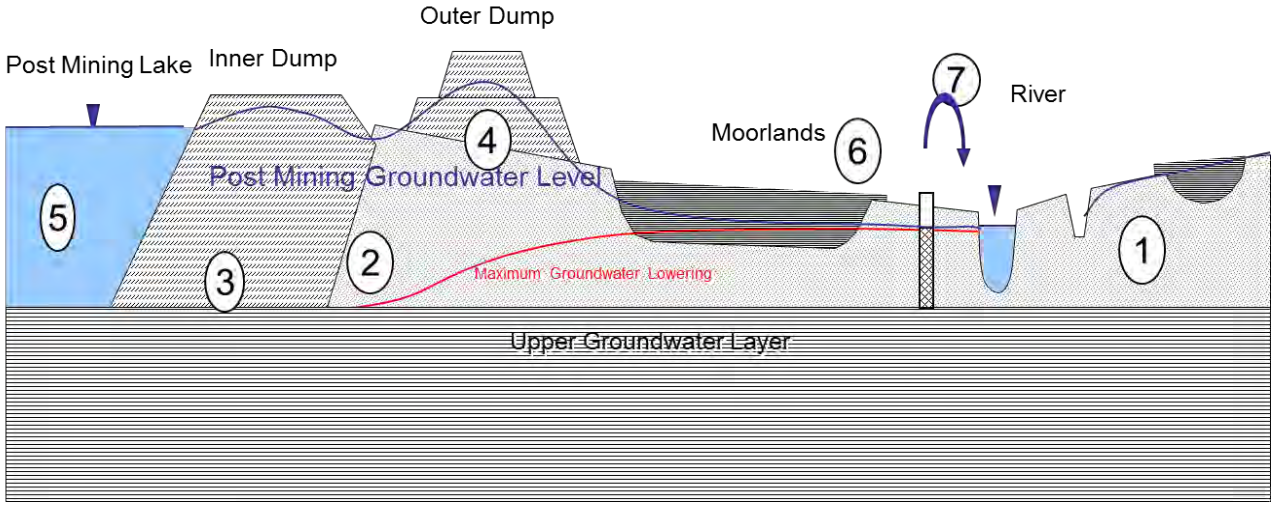

Figure 3 Sources of iron contamination in watercourses in Lusatian district (IWB 2013)

The following article deals with problems on aerated aquifers (2), inner dumps (3), and outer dumps (4).

IRON LOADS AND HOT SPOT AREAS

Initially an elevated concentration of iron was identified from 2003 onwards in a River Spree tributary, called "Kleine Spree" that is fed with ground water inflow. In the "Kleine Spree" river the concentration of iron rose continuously till 2010 up to approximately 10 mg/L while mean low water level in summer time. After a period of heavy precipitation in 2010 and 2011, high concentrations of iron could be seen and measured along some 20 kilometres of the River Spree.

This iron originates from the Pleistocene aquifer in the depression cone of the former Lohsa and Burghammer lignite opencast mines (Fig.4). The ground water level in the Pleistocene aquifer had been lowered by as much as 50 metres, and as a result the sediments had been aerated for many decades. There are no aquitards in the upper level of the aquifer. The clastic Pleistocene sediments show between 0.01 % and, at most, 0.05 % of pyrite by mass, while they do not contain any carbonate minerals whatsoever.

The pyrite weathered significantly because of the good permeability of the coarse, dewatered aquifer. Because of this, groundwater locally contains up to 400 mg/L of iron and 1,400 mg/L of sulphate. Groundwater that is so severely contaminated had previously only been encountered in well-aerated lignite opencast mine dumps. Following the raising of the ground water level, this groundwater now flows into watercourses (Fig. 4).

The historic level of iron in Lusatian water courses is approximately 1 mg/L. The iron comprises of differing proportions of dissolved iron(II), iron(II, III) humic acids and iron(III) hydroxide in suspension. The light adsorption is so strong that even relatively low concentrations of iron(III) hydroxide result in high degrees of turbidity. Above concentrations of about 2 mg/L, the iron(III)

hydroxide can be seen colouring bodies of water and water courses ochre and making them turbid (Fig. 2).

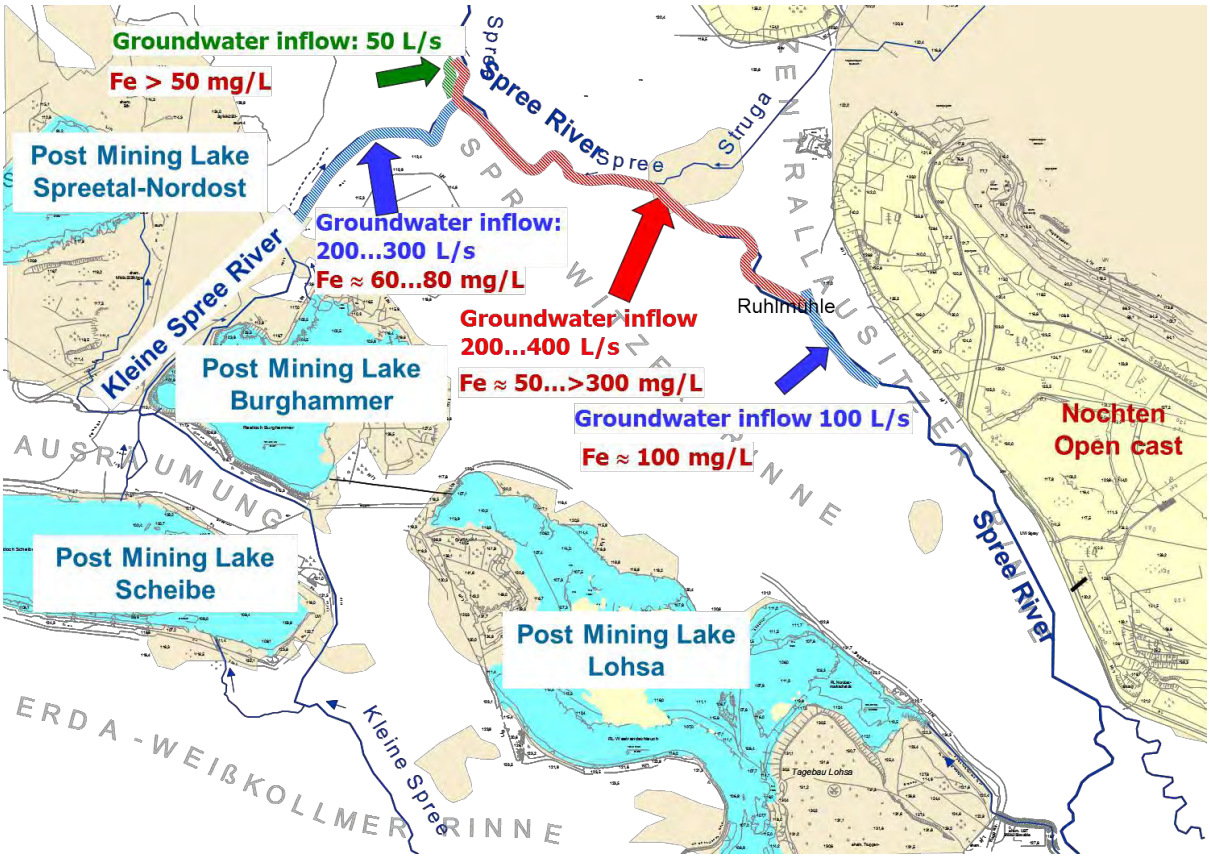

Figure 4 Iron loaded groundwater inflow into the River Spree and the River Kleine Spree

Because of the high quantity of groundwater inflow (1,0 m³/s) along the River "Kleine Spree", the concentration of iron has risen up to 20 and 30 mg/L. The iron is transferred from the groundwater as iron(II). The oxidation of iron(II) in the watercourses is dependant on temperature and pH value. The hydrolysis of iron(III) lowers the pH value so that conditions for iron oxidation in the watercourses deteriorate further. As a result, particularly in winter time when through flows are higher, the dissolved iron(II) is transported over considerable distances. At present iron(II) at a pH value ranging from 5 to 6 is being found in the River Kleine Spree because of the pH-limited oxidation.

Currently between 4 and 8 mg/L of total iron are measured in the River Spree (14 m³/s). The majority of the iron occurs as iron(III) hydroxide. During the winter months as much as 50% of the iron is found as dissolved iron(II).

The iron oxide sludge is deposited along the banks and stagnant water zones of the affected watercourses. It is re-suspended during high water periods and carried further by the flow. Consequently the total concentration of iron in the River Spree can reach 10 to 20 mg/L. Iron can currently be identified along Spree River as far as the Spremberg reservoir (fig. 5). This reservoir contains more than 20 million cubic metres. At average flow rates into the River Spree the retention period varies from 2 to 4 weeks. At present the Spremberg reservoir is providing reliable protection to downstream stretches of the River Spree. This includes the Spreewald biosphere reserve and tourism destination.

Figure 5 Iron load carried into the Spremberg reservoir (photo Rauhut)

Currently investigations are being carried out to determine whether the Spremberg Reservoir will retain its protective capacity. The reservoir had been erected for water management purposes, as increasing the flows during low water episodes and for flood control while high water. The high iron load of the River Spree is harmful to its ecology. European and German water legislation do not permit the deterioration of a body of water or of a water course. It requires to localise the sources of contamination precisely so that targeted preventive measures can be planned and implemented.

MONITORING

The localisation and quantification of inflow presents a challenge to hydrogeological monitoring. The diffuse iron-loaded inflows can be measured directly at very few sites. Depending on the local and hydrological conditions there are various methods that are suitable for measuring diffuse material discharges:

- hydrochemical groundwater exploration
- flow monitorings in the entire watercourses on particular days

Hydro chemical groundwater surveys in the immediate neighbourhood of the river allow the inflow area to be delimited. This requires a close-meshed network of groundwater wells. The Pleistocene aquifer is geohydraulically and hydro chemically very heterogeneous. In the entire River Kleine Spree, monitoring of flows and water quality on particular days are promising. When a section of the watercourse is closely covered with flow monitoring and sampling points, the volume and material inflows can be spatially defined with a high level of resolution. Errors had been minimised by multiple repetitions of targeted monitoring. To determine the loads of dissolved substances the monitoring was made on a particular day at low outflow rates and under stable hydraulic and geohydraulically conditions. To determine the hydraulic conditions, the water levels in the watercourses and the groundwater level near the river are measured with load cells and

continuously logged. With knowledge of the process dynamics along the river, the results of monitoring can be interpreted reliably. The sensitivity of the monitoring can be assessed using associated geohydraulic modelling.

A diffuse ground water inflow of between 200 and 300 L/s was identified along a stretch of the river "Kleine Spree" approximately 4 kilometres long (fig. 4). The emerging groundwater had a mean iron concentration of between 70 and 80 mg/L. An iron concentration ranging from 3 to 450 mg/L was measured at about 20 monitoring points in the groundwater surrounding the river "Kleine Spree". The median for iron concentration in the groundwater is between 50 and 60 mg/L.

In the Spree with comparatively high flow rates, the water quality has been successfully monitored at short intervals. The hydro chemical results have been associated with flow rates at continuously monitored wells. This allows a reliable determination of iron loads over a longer monitoring period. Drawing up an overall balance involves a number of specific problems. At low rates of flow, there is a relatively high proportion of diffuse inflows from ground water. Some of the iron remains in the riverbed as iron sludge. That iron is not registered by discrete monitoring. Usually the sedimented iron sludge is remobilised during a high water event. On the other hand, during such event the diffuse inflow of groundwater is pushed back. Consequently during high waters, in spite of the short flow times, mainly iron(III) hydroxide and hardly any dissolved iron(II) are found. In the Spremberg Reservoir three monitoring campaigns were set up: upstream of the auxiliary dam, downstream of it, and downstream of the main dam (Fig. 6).

As the flows at these positions are known, it was possible to assess the transformation and the retention of iron in the reservoir (5 to 20 million m^3). Using the results from the monitoring point above the Spremberg Rervoir the seasonal and hydrological influences on iron transport can be identified

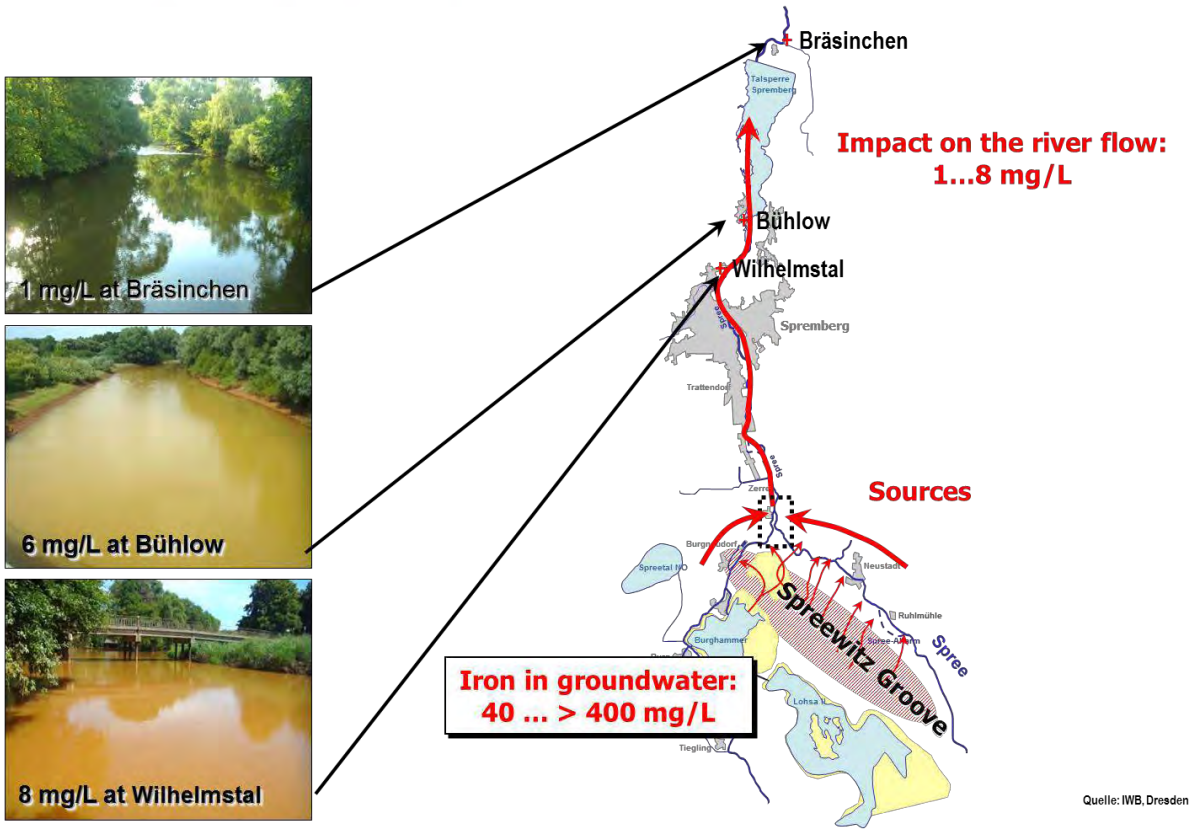

Figure 6 Iron sources and impact along the river Spree

In the "Kleine Spree" river, the volumetric flows of the diffuse groundwater inflow into the River Spree cannot be measured directly. Taking the regional water balance into account, and applying the values of a geohydraulic groundwater and runoff model, the volume of flow is estimated to be between 300 and 700 L/s (Fig. 4). The concentration of iron can be captured here at a few selected locations where groundwater monitoring wells have been installed.

A few local surface tributaries to the River Spree can be reliably measured. An oxbow parallel to the River Spree drains groundwater over a stretch of about one kilometer. The groundwater inflow into the oxbow is most stable during low and medium water periods. At an inflow between 100 and 130 L/s; here the iron concentration is about 150 mg/L. Another 600-metre long ditch for lowering local groundwater draws off about 20 L/s of groundwater containing over 350 mg/L of iron.

Planning preventive measures it is important to know the diffuse groundwater peak inflows into watercourses. This issue has both a hydraulic and a hydrochemical aspect. The maximal groundwater inflow into watercourses is expected when the groundwater rise will be completed in some years. Groundwater hydrographs show that the increase in groundwater levels has progressed far, but is not yet complete in all parts of the area under investigation.

In most places where groundwater is monitored the iron concentration has been stable for a long time. In some monitoring wells near the river the concentration of iron increases as the groundwater level rises. Reverse trends of a diminishing concentration of iron have not yet been observed. Consequently it can be assumed that the iron load in watercourses will continue to increase for some years.

At present, about 600 to 1,200 L/s of iron-loaded groundwater flows into the river "Kleine Spree". Only about 150 L/s of which stems from newly-formed aquifers in the catchment area. The remainder is produced by permeation losses from the Lohsa and Burghammer post-mining lakes. The volume of iron-loaded groundwater in the Spreewitz groove is estimated to be between 600 and 800 million m^3. The balance also shows that flows of iron-loaded groundwater into the watercourses must be expected to continue at least for the next 15 to 40 years.

REMEDIATION APPROACHES

To reduce the iron loading in the River Spree different approaches are followed:

- water treatment in or near the river
- water retention, drainage, and treatment

A water treatment plant and a natural wetland area in or near the river are being examined as potential solutions. Such treatment plant on the River Spree would have to be dimensioned for a volume flow of 12 m^3/s at initial inflow values of between 4 and 8 mg/L of iron. An appropriately dimensioned technical plant of this size and for these inputs would be very expensive to build and operate. A natural retention wetland on the other hand would require an area of between 30 and 60 hectares for treatment by sedimentation. Such areas at the end are not available in the intensively used landscape of the River Spree.

Nevertheless the technical effort is considerable. The technology includes four stages: extraction, raising the ground water, transfer it to a treatment plant, cleaning the iron-loaded groundwater, and finally treating the iron sludge.

Cleaning the iron-loaded groundwater is ideally carried out in a water treatment facility using alkaline and polymer flocculants. As an alternative to a treatment plant, the iron-rich groundwater can be pumped (no. 6) into the deep, anoxic area of a nearby post-mining lake. Because the surrounding post-mining lakes are acidified and therefore require long-term chemical treatment anyway, the sludge treatment can be dealt with in the process.

A remediation of the entire Pleistocene aquifer contaminated with iron is out of question because of its enormous costs. Quite apart from the fact, there is no state-of-the-art groundwater treatment technology for dealing with the iron load mentioned. It is acknowledged that there are possibilities for developing subsurface water treatment using heterotrophic sulphate reduction (no. 1). The significantly greater expense characteristic of this process is partly made up for by the absence of drainage, water treatment, and iron sludge treatment. Large-scale field trials in this context are being undertaken at present.

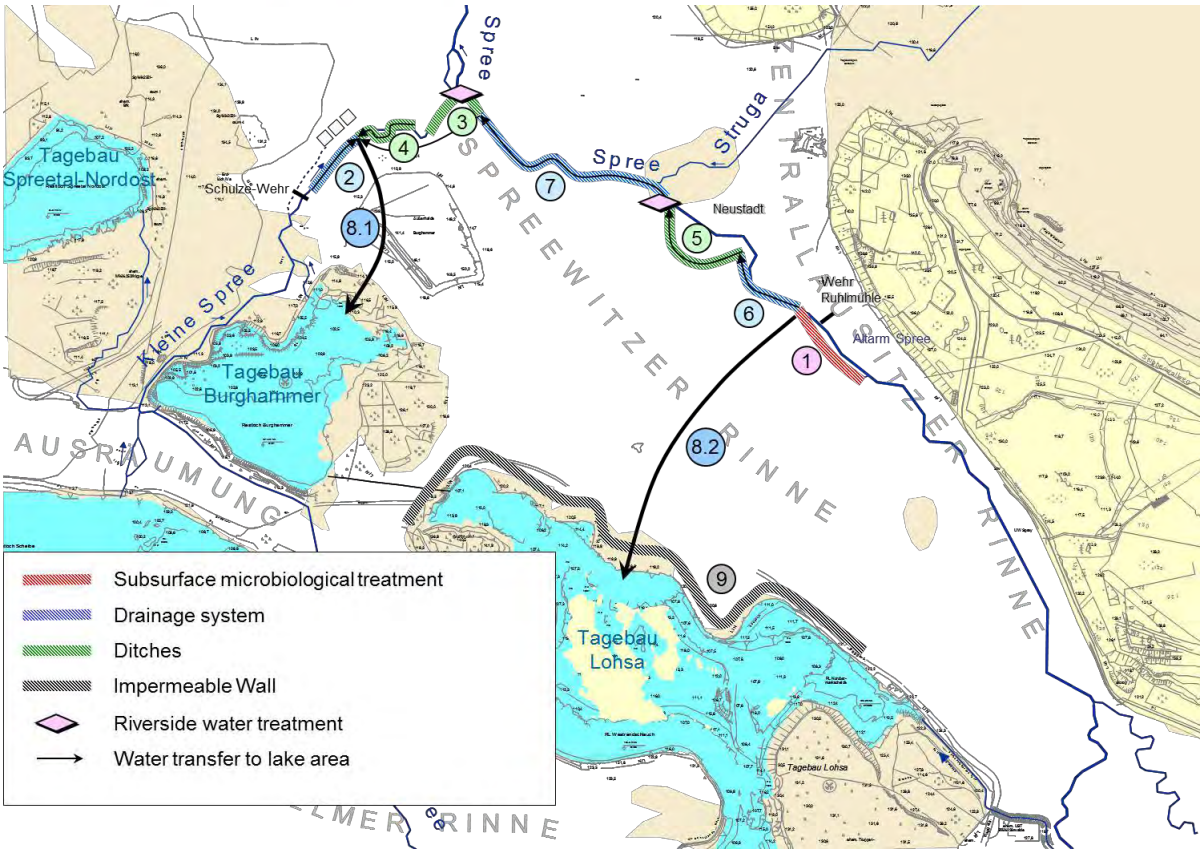

Figure 7 Measures to reduce iron discharge into the River Spree

As an hydraulic alternative the installation of a barrier wall on the northern border of the Lohsa post-mining lake (no. 9) is being examined. The intention would be to achieve a substantial reduction of the groundwater outflow, and thus of the iron loads being carried to the River Spree. A barrier solution could reduce measures near the river in the medium term.

SUMMARY

The Tertiary and Pleistocene strata in the Lusatian soil contain Pyrite which oxidised following the groundwater lowering in previous decades. This has resulted in the formation of groundwater that contains up to 400 mg/L of iron in places. This groundwater is now diffusely flowing into the watercourses of Spree river. A specific exploration scheme has been implemented to determine the loads along the river flow. Hydrochemical surveying of the groundwater at numerous monitoring well near to the river permits local differences in load levels to be determined. Varying loads were identified by repeating monitorings in summer and winter on specific days.

Depending on the varying loads along the course of the river flow a barrier concept had been developed to reduce the diffuse inflow. A substantial reduction of these discharges can be achieved economically over the medium term.

2. *Department of Geology, University of the Free State, South Africa*

ABSTRACT

An experimental lab scale reactor that treats alkaline mine drainage has been developed based on hydrogeochemical characteristics of most of the South African coal mines leachates, which generally have high concentrations of sulfates, TDS (total dissolve solid), salinity and heavy metals (mainly Fe^{3+} and Al^{3+}).

The experiment development was based on the DAS system (disperse alkaline substrate). In this case, barium carbonate ($BaCO_3$) was used as alkaline reactive, fixed to a non-toxic inert matrix (wood chips). The experiment was carried out with 3 different proportions of wood:$BaCO_3$ (w/w); 1:2, 1:3 and 1:4 with a residence time of 24 hours. SO_4^{2-} and Ca^{2+} contained in AMD precipitate as $BaSO_4$ and $CaCO_3$, respectively, according to (1) thermodynamic modelling by PHREEQC, (2) geochemical and (3) mineralogical characterization. The pH increased up to 9-10, which allowed the removal of divalent metals. Reactors were maintained for 6 months and the results that were acquired from all of them demonstrated their reactivity, without saturation or clogging in any of the columns, towards the total removal of nitrates (100%), 93% of sulfates, 50% hardness (Ca^{2+}, Mg^{2+} and Na^{2+}), as well as 68-93% of metal removal (Fe^{3+}, Al^{3+}, Cu^{2+}, Zn^{2+} and Mn^{2+}, in moderate concentrations). Therefore, parameters such as salinity, TDS and conductivity decreased throughout the experiment. Water volume treated was approx. 764 L during 26 weeks in the lab scale reactors and the physicochemical parameters of the water after treatment are within the allowable limits for drinking water, according to SANS 241 class 1 for Drinking Water (South African national standard, 2006; 2011).

INTRODUCTION

Coal mine drainage

South Africa has 95% of Africa's known coal reserves and the 9th biggest recoverable coal reserves (61 000 Mt) in the world where 27 400 Mt were proven coal reserves in 2012 (Energy Information Administration, 2014).

These coal deposits have about 4% of pyrite (Snyman & Botha, 1993; van Dyk, 2006) which is the cause for the coal mine drainage to contain sulphur. However the typical acidity produced by the oxidation of pyrite (equations 1 and 2) and by the subsequent oxidation and precipitation of Fe (equation 3 to 5) is neutralized by the CO_3^{-2} released from the calcite ($CaCO_3$) and dolomite ($CaMg(CO_3)_2$) that is contained in South African's coal; about 6.7% and 10.1% respectively (van Dyk, 2006). Therefore, coal mines in South Africa can generate acid, neutral or alkaline mine drainage (AMD) (Kirby, Dennis & Kahler, 2009). When pyrite and other sulfide minerals associated with coal deposits are exposed to water and oxygen, several chemical and biochemical reactions take place. These reactions can be seen in the Singer & Stumm (1970).

Oxidation of pyrite can be produced by oxygen (eq. 1) or ferric iron (eq. 2) in the presence of water. Further oxidation of Fe^{2+} to Fe^{3+} occurs when sufficient oxygen is dissolved in the water or when water is exposed to atmospheric oxygen (eq. 3). This reaction is also accelerated by the presence of oxidizing bacteria such as *Acidithiobacillus ferrooxidans*. Ferric iron can either precipitate as $Fe(OH)_3$, (eq. 4) or it can react directly with pyrite to produce more ferrous iron and acidity as shown by eq. 5. The presence of alkaline compounds such as calcite and dolomite decreases the acidity of the AMD by consuming protons (H^+) and releasing bicarbonate anion (HCO_3^-) as shows the eq. 6 and 7 (Pokrovsky, Golubev & Schott, 2005).

$$FeS_2 + 3.5\ O_2 + H_2O \rightarrow Fe^{2+} + 2SO_4^{2-} + 2H^+ \quad (1)$$

$$FeS_2 + 14Fe^{3+} + 8H_2O \rightarrow 15Fe^{2+} + 2SO_4^{2-} + 16H^+ \quad (2)$$

$$Fe^{2+} + 0.25\ O_2 + H^+ \xrightarrow{Acidithiobacillus\ ferrooxidans} Fe^{3+} + 0.5H_2O \quad (3)$$

$$Fe^{3+} + 3H_2O \leftrightarrow Fe(OH)_{3(S)} + 3H^+ \quad (4)$$

$$14Fe^{3+} + FeS_2 + 8H_2O \rightarrow 2SO_4^{2-} + 15Fe^{2+} + 16H^+ \quad (5)$$

$$CaCO_3 + H^+ \rightarrow Ca + HCO_3^- \quad (6)$$

$$CaMg(CO_3)_2 + 2H^+ \rightarrow Ca + Mg + 2(HCO_3^-) \quad (7)$$

Therefore the alkalinity of the coal mine drainage depends, among others, on the ratio between acidic and alkaline minerals of each specific coal deposit and surroundings.

Case study

The case study was done on the alkaline drainage generated by a coal mine situated at (25°42'23.2"S, 29°59'32.7"E), that is mining the coal from the north eastern coalfield of the Karoo basin, located in Mpumalanga province. The AMD generated is collected in the evaporation dam located SW within the facility area (25°42'20.4"S 29°59'28.4"E). This AMD has a pH of 7.45 and, in contrast, the electrical conductivity (EC), salinity (Sal) and total dissolved solids (TDS) are fairly high (2090 µS/cm, 980 mg/L and 100mg/L, respectively). The AMD has high concentrations of sulfates and nitrates (1 253 mg/L and 3 032 mg/L respectively) as well as dissolved Ca and Mg (262.41 mg/L and 132.60 mg/L respectively).

State of the art AMD treatments

Many passive and semi-passive treatments have been developed over the past three decades to remediate AMD, such as aerobic and anaerobic wetlands, Anoxic Limestone Drains (ALD), limestone sands, beds, ponds and open channels, diversion wells, reducing and alkalinity producing systems (RAPS), ReRAPS, water-powered devices, windmills, sodium carbonate briquettes, sodium hydroxide, hydrated lime and quick lime (e.g. Watzlaf et al., 2004). Recently, a new system has been developed with the aim to solve the clogging problem caused by the Al^{3+} and Fe^{3+} precipitation that has been documented in many of these systems (Robbins et al., 1996; Cravotta and Trahan, 1999; Watzlaf et al., 2000; 2002; Rees et al., 2001; Ziemkiewicz et al., 2003; Rose et al., 2004). This new system called Dispersed Alkaline Substrate (DAS) consists of an inert matrix of wood chips, which provide high permeability and reduce clogging problems, mixed with a fine-grained alkaline material such as limestone sand (Rotting et al., 2008).

The reactor system that the authors have developed on a laboratory scale is based on a modified DAS system. The modification includes the substitution of limestone ($CaCO_3$) with barium carbonate ($BaCO_3$) powder. This system, called B-DAS, has been designed with the aim to improve the removal of sulfates by precipitating it as $BaSO_4$ as well as improving the salinity (see reactions below). The aim is extended to find a system that is able to remediate not only acid mine drainage but neutral and alkaline mine drainages as well. $BaCO_3$ easily dissolves at a pH above 4 which makes it ideal to treat these drainages. The AMD used in this study has a pH of 7.45 which undergoes the dissolution process as follow; $BaCO_3$ is dissolved (eq. 8). Dissolved sulfates can precipitate as barium sulfates (eq. 9). The pH is increased to 10 by consuming protons and releasing hydroxide anion (eq. 8) and bicarbonate anion (eq. 10). The high pH and the presence of bicarbonate anions promote metal precipitation as carbonates (e.g. Ca and Mg):

$$BaCO_3 + H_2O \rightarrow Ba + HCO_3^- + OH^- \quad (8)$$

$$BaCO_3 + H_2SO_4 \rightarrow BaSO_4 + H_2CO_3^- \quad (9)$$

$$BaCO_3 + H^+ \rightarrow Ba + HCO_3^- \quad (10)$$

$$Me + HCO_3^- \rightarrow MeCO_3 + H^+ \quad (11)$$

METHODOLOGY

Column experiment

Three down-flow columns were constructed from PVC pipes (10 cm inner diameter, height 50 cm) and equipped with four additional lateral sampling ports. Each port had a small perforated pipe in the column matrix to promote homogeneous samplings and allow homogeneous flow within the columns by increasing the area of sampling while, avoiding, as far as possible, preferential flow.

Each column contained a layer of quartz gravel (particle size about 5-8 mm) at the bottom (2.5 cm). This layer was covered with a 40 cm reactive material layer, which consisted of $BaCO_3$ and wood shaving mixture. Each column had different ratios of wood: $BaCO_3$ (w/w); these were columns (A) 1:2 (260g:520g) , (B) 1:3 (240g:720g) and (C) 1:4 (220g:960g).

During the six months of the experiment the down-flow reactors, with supernatant open to the atmosphere, were fed with the AMD, as input water from the top using a peristaltic pump and flowed down gravitationally. The outflow was collected in a container that also functioned as an aeration and sedimentation tank. The flow rate was 1.09 mL / min with a residence time of 24 hours for each B-DAS columns. The porosity of the systems was 70% (volumetrically calculated).

Sampling

During the first week of the columns running, samples were taken daily from the outlet of each column (A, B and C) and after that sampling was done weekly for the next six. Another set of samples were taken monthly from the four sampling ports of each column, to evaluate the spatial evolution of each column during the experiment.

Finally, the columns were drained and column C was cut with an angle grinder to have access to the precipitates formed on the wood shavings (see left of figure 4). Three samples of precipitates were collected at the top, middle and bottom of the column for further analysis .

Analytical techniques

Water analysis

Source water was collected from the evaporation dam in 25L carboys, transported to the laboratory and stored at 4°C. pH, EC, Sal, TDS, redox potential (ORP) and temperature (T) was measured on site. These physicochemical parameters were also analysed from the columns weekly and monthly. The measures were done with the ExStix®II multi-probe and ExStix®II ORP probe. ORP measures were corrected to the Eh standard hydrogen electrode (SHE). Samples were analysed by ICP at the Institute for Groundwater Studies at UFS, filtered and acidified to pH < 2 with HNO_3 2% (v/v), to compare influent and effluent chemistry of the columns. Sulfate (SO_4^{2-}), Fe^{2+} and Fe^{Total} concentrations were analysed by a HACH spectrophotometer (model DR/900 colorimeter) according to the colorimetric methods described in the HACH Procedures Manual (Method Sulfate 608, Method Ferrous iron 255 and FerroVer 265, respectively).

Geochemical modeling

The precipitation of newly formed solid phases by the $BaCO_3$ was confirmed by using a thermodynamic model (PHREEQC) as well as by characterizing the final solid products. These saturated mineral phases in the system were estimated, assuming that the initial solution in contact with an alkaline material (in our case $BaCO_3$) reaches equilibrium with that material. The PHREEQC-2 geochemical speciation model (Parkhurst & Appelo, 2005) in conjunction with the MINTEQ thermodynamic database (Allison et al., 1991) was used to determine the aqueous speciation of solutions and saturation indices (SI) of solid phases that could control the concentration of dissolved species in the simulation SI=log(IAP/KS) where IAP is the ion activity product and KS is the solubility constant. Zero, negative or positive SI values indicate that the solutions are saturated, undersaturated and supersaturated respectively, with regards to a solid phase.

Mineralogical characterization

The Panalytical Empyrean x-ray diffractometer (XRD) was used under the following conditions: slit fixed at 10mm, Cu / Kα monochromatic radiation, 40mA and 45 kV. Samples were run at a speed of 2°θ /min (5-70°) to analyse the precipitates formed. Interpretation of data was done by the Highscore program. Samples were milled previously to a particle size less than 10 micron. Due to the small quantity of sample, a zero-background wafer sample holder was used.

The scanning electron microscope Jeol GSM 6610 equipped with energy dispersive system (SEM-EDS) was used for the analysis, along with Astimex 53 Minerals Mount MINM25-53 standards. The accelerating voltage of the beam during analysis was 20.0 kV with a spot size of 50 and working distance of 10 mm. Sample preparation for this method involves a strip of double-sided carbon tape attached to a glass section. The samples were coated with a thin layer of carbon (± 15-100nm) to prevent charging.

RESULTS AND DISCUSSION

Water analysis

Temporal evolution

Figure 1 indicates that the data of the three columns are similar; the pH increased from 7.5 to 9.8 and the rest of the parameters (TDS, Sal, Cond, Eh, sulfates and iron) decreased from the first sampling performed after 24 hours. Fe^{2+} and Fe^{Total} concentrations were always below detection limit (BDL). The sulfate concentration decreased from 1400 mg/L to BDL after one week. However Sal, TDS and Cond reached the lowest values after four months (from 980 mg/L, 1000 mg/L and 2090 µS/cm to 283 mg/L, 209 mg/L and 576 µS/cm, respectively). The Eh decreased from 296 to 150 mV within the first 24 hours and continued to decrease for two month to -21 mV, thereafter stabilized at about -35 ± 15 mV.

The ICP analysis (Table 1) shows that the concentration of the Ba in the water increased in the first sampling, this is probably because the $BaCO_3$ powder that is not attached to the wood shavings is released into the water, however the Ba concentration decreased and stabilized around 0.7 mg/L thereafter. Most of the compounds started to decrease within 24 hours such as Ca, Mg, Cl, NO_3, SO_4

and Zn; from 262.4, 132.6, 9.2, 3032, 1253, 0.007 mg/L to 36.8, 97.8, 4.1, 1766, 147 and 0.003 mg/L, respectively (calculated as the average of the three columns). The rest of the compounds, such as Na, K, Al, Fe and Mn clearly started to be removed from the second sampling (5th week) from 4.9, 5.9, 0.044, 0.057 and 0.03 mg/L to 3.1, 5.3, 0.03, 0.008 and 0.002 mg/L, respectively (calculated as the average of the three columns). At the end of the experiment all the compounds were within the limits allowable for drinking water according to SANS 241 (South African national standard 2006; 2011), except for the Mg that exceed the limit by 15mg/L. The final removal of each compound is shown in Table 2. The similar evolution of the three columns, allowed for the spatial evolution analysis to be performed in column B and the geochemical characterization of the precipitates in column C.

Spatial evolution

Two sets of samples from the four sampling ports, named from top to bottom: one, two, three and four, were collected from column B and analysed. The residence time of the AMD in the column was 24 h, therefore the contact time with the reactive material of the samples from each port was approximately 6, 12, 18 and 24 h, respectively. The results (Figure 2) show that the removal of every compound analysed occurred mainly at port one. The composition of the water at port two, three and four had no significant differences. Therefore, the fast dissolution of the $BaCO_3$ in contact with the AMD is displayed. This is also demonstrated by the analysis of precipitates.

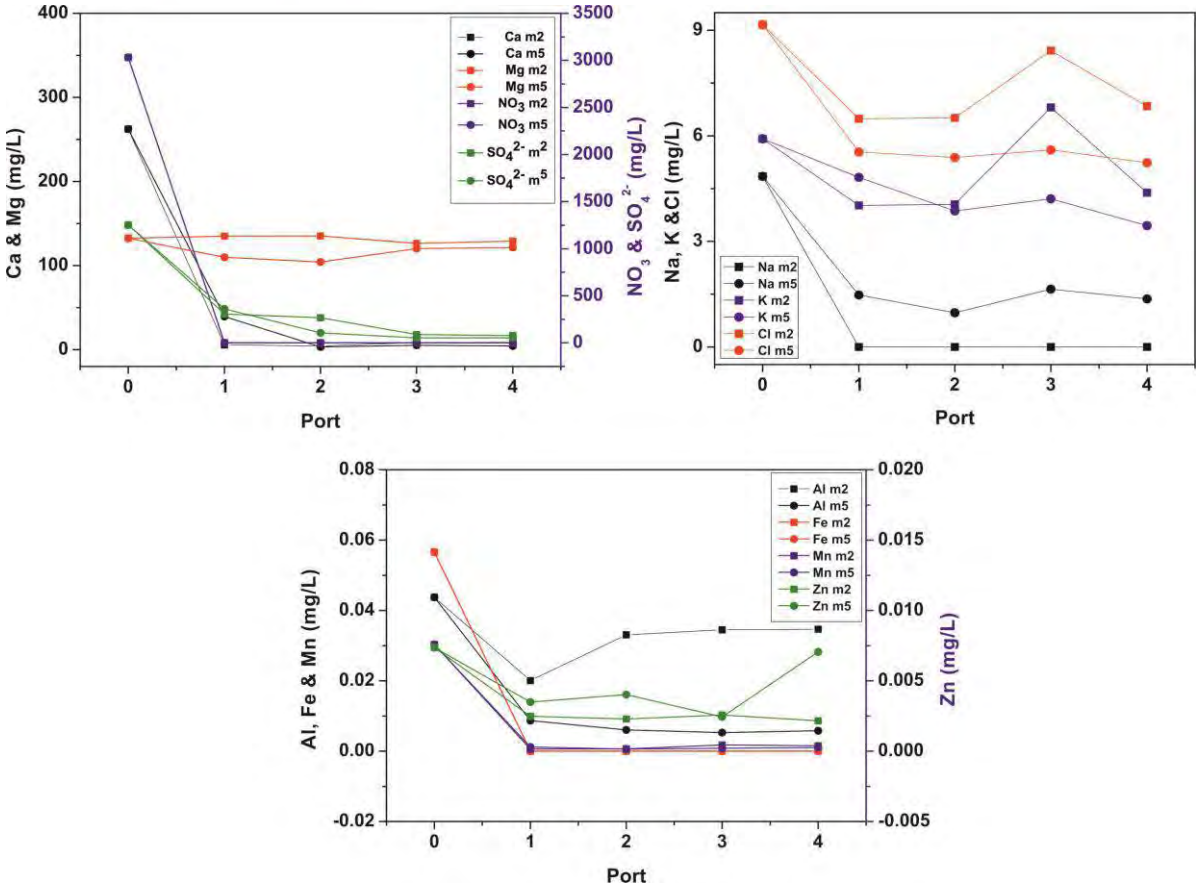

Figure 2 Spatial evolution of the main chemical compounds of the water throughout column C, from top (inlet) to bottom (port 4)

Geochemical modelling

The simulation was based on the physicochemical characteristics of the AMD used as the solution in this experiment. Witherite was assumed as equilibrium phase 0, since total dissolution was expected. The predicted precipitates were barite ($BaSO_4$; SI~3.49), calcite ($CaCO_3$; SI~1.25), dolomite ($CaMg(CO_3)_2$; SI~2.50), $Fe(OH)_{3(a)}$ (SI~1.75), hausmannite (Mn_3O_4: SI~15.34) and pyrolusite (MnO_2; SI~9.85). However, due the low concentration of Fe and Mn, those precipitates could be masked in the XRD analysis.

Mineralogical characterization

According to the SEM-EDS analysis of the bottom sample, the composition of most of the crystals were mainly Ba (79 - 95%), O (4 - 21%) and some of them also had trace amounts of sulfur (0.5 - 4%) in the form of clear needles smaller than 5µm. The XRD analyses determined that those crystals were 95.1% witherite ($BaCO_3$) and 4.9% barite ($BaSO_4$) (red diffractogram in Figure 4). In the middle

sample the concentration of witherite was lower (24.4%); the precipitation of barite increased (56.4%); the precipitation of Ca detected in SEM analysis (Figure 3c & d) was confirmed by the XRD analysis where calcite and aragonite where detected (6.4 and 12.8% respectively). However, the precipitation of Mg and K detected by SEM were masked in the XRD analysis, mainly due to the high concentration of barite (green diffractogram in Figure 4). In the top sample the concentration of witherite (Figure 3b) and barite were slightly lower (23.4 and 46.7%, respectively), but calcite and aragonite concentrations were higher (7.6 and 22.3%, respectively) (Figure 3a). In this section of the column precipitates with Al, Fe, Mg, Na, Si, Cl and K were also found (Figure 3b).

According to the analyses, the AMD dissolves the $BaCO_3$ in the top of the column and releases Ba^{2+} and HCO_3^-, both precipitate mainly as $BaSO_4$ and $CaCO_3$. Thereafter, the AMD was already remediated and did not continue to react with the $BaCO_3$ in the column. This is confirmed by the neoformed minerals found at the top and the middle, whereas the bottom sample still had reactive $BaCO_3$ and no neoformed mineral phase was found. Furthermore, in the picture of Figure 4 it can be observed that the bottom of the column is still white due the $BaCO_3$ that remained on it.

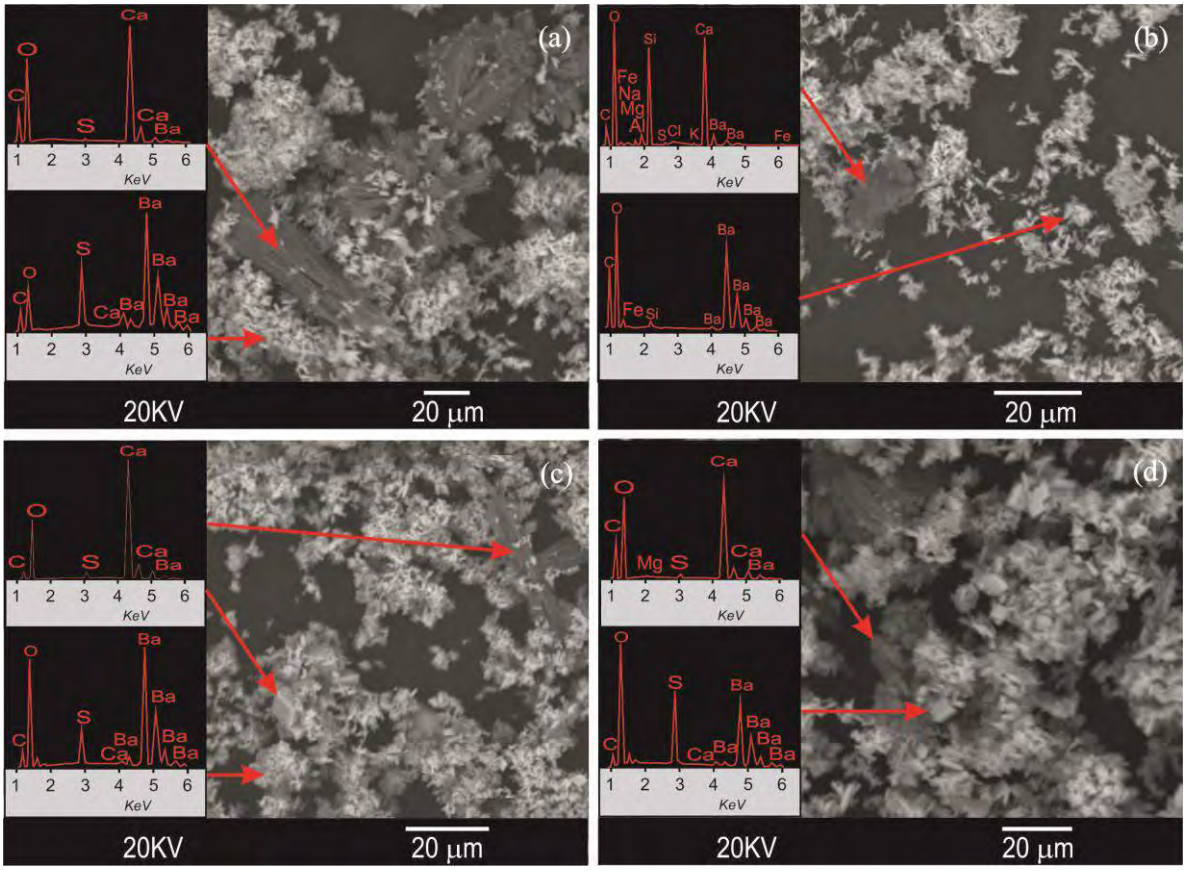

Figure 3 SEM images of (a) top sample: fibrous aggregates of $CaCO_3$, acicular $BaSO_4$, (b) amorphous precipitation and $BaCO_3$;(c) middle sample: fibrous and rhombohedral crystals of $CaCO_3$ and acicular $BaSO_4$ (d) globular $CaCO_3$ and orthorhombic $BaSO_4$.

CONCLUSIONS

764 L of alkaline coal mine drainage from the site was treated by the B-DAS (Barium carbonate - disperse alkaline substrate) system in lab scale reactors. The aim to remove the high cations and anions concentration as well as the Sal and TDS from this drainage was achieved. According to the water analysis and the mineralogical characterization, the B-DAS system has demonstrated the capacity to remove 93% of sulfates through the precipitation of barite ($BaSO_4$); 98% of Ca by precipitation of calcite and aragonite ($CaCO_3$); remove Mn, Na, Fe, Al, Zn, Mg (93, 91, 90, 82, 68 and 13%, respectively). K and Si were also found in the neoformed precipitates. NO_3 was also removed (99.9%) from the AMD, but the absence of N in the precipitates and the extremely reductive condition in the reactor (Eh about -35 mV) could have promoted the denitrification process. The EC, Sal and TDS decreased about 50 – 70%.

According to the XRD analysis, after 6 months, column C had about 22 % of the $BaCO_3$ at the top and 95 % at the bottom of the column. Therefore, the reactive capacity of the $BaCO_3$ could be extended. Neoformed crystals were found in the top and middle samples, but not in the bottom sample, indicating that the dissolution of the $BaCO_3$ and the consequent precipitations took place in less than six hours (estimated residence time of the water in the top section of the column), demonstrating the effective treatment and the capacity of this system.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge funding from the Technology Innovation Agency (TIA, South Africa). We thank Exxaro for site and sample access to the mining company's facilities, as well as the University of the Free State, in particular the Institute for Groundwater Studies and Department of Geology for the assistance in sample analysis.

Low-Cost Carbon-Based Materials for Selective Removal of As(III) from Waste Waters

Yiannis Deligiannakis, Yiannis Georgiou, Eleftherios Mouzourakis and Ioannis Konstantinou
Lab of Physical Chemistry of Materials & Environment, Dept. of Environmental & Natural Resources Management, University of Patras, Greece

ABSTRACT

A low-cost carbon-based material from pyrolytic carbon from recycled tyres (PCrt) has been developed for selective removal of lead or arsenite from waste waters. The PCrt material has been characterized with X-Ray Fluorescence, XRD, And FTIR spectroscopies. Arsenite and Pb uptake was studied at the ppb level by Cathodic and Anodic Stripping Voltammetry (CSV). Adsorption isotherms, kinetic and pH-edge data show that PCrt can bind arsenite at a wide pH range from 4 to 9. More specifically, PCrt after mild treatment with HNO_3 and calcination at 500°C can adsorb 8.8 mg of As (III) and 27,7 mg Pb(II) per gram of material. PCrt can selectively uptake arsenite vs. lead when the two metals are present simultaneously in the aqueous solution. Importantly, when Pb is first adsorbed by PCrt, this forms PbS sites that act as additional arsenite binding sites. This is a unique example where one toxic metal, Pb(II), acts synergistically for adsorption of another toxic, As(III) on the appropriate matrix.

Keywords: low-cost, pyrolytic carbon, selective, Pb(II), As(III), metal uptake

INTRODUCTION

Disposal of waste tyres has become a serious source of environmental pollution [1]. More of 330 million waste tyres are discarded each year [2]. Tyre rubbers consist mainly of synthetic and natural rubber, tyre rubber additives i.e. like carbon black, sulphur and zinc oxide [1, 3]. A feasible solution for an environmentally friendly treatment of waste tyres would be to recycle them to valuable products that can be used in various applications.

Pyrolysis is an established process, which involves thermal decomposition of waste tyres at high temperatures (450-900 ^{o}C) under oxygen-free atmosphere, transforming them into useful products [3-4]. Tyre rubber pyrolysis results in the production of an oil- and a gas- fraction, plus the carbonized solid residue, the Pyrolytic Char from recycled tyres (PCrt) [3]. Pyrolytic oil and gas can be used as a source of chemical feedstock or a fuel with high calorific value for in-process, on-site or off-side applications [5]. PCrt may be used as carbon black filler for the tyre and printing-ink industries or as a precursor to manufacture low-cost adsorbent materials because of its high carbon content [4].

Arsenic may present in two main redox states Arsenites (As $^{3+}$) and Arsenate (As $^{5+}$) in natural waters, changes in solubility and mobility therefore occur as a function of redox potential and pH conditions in the environment and also are common in natural waters.[6] The World Health Organization (WHO) provisional guideline of 10 ppb (0.01 mg L^{-1}) have be adopted as the drinking water standard also U.S. Environmental Protection Agency (U.S EPA) required public drinking water to 10 ppb (0.01 mg L^{-1}). Arsenic is mobilized by natural weathering reactions, biological activity, geochemical reactions, volcanic emissions and other anthropogenic activities. Most environmental arsenic problems are the result of mobilization under natural conditions. However, mining activities, combustion of fossil fuels, use of arsenic pesticides, herbicides, and crop desiccants and use of arsenic additives to livestock feed create additional impacts.[7]. Pb (II) dominates in acid while $PbOH^{+}$ predominates in most environment pHs. The drinking water guideline recommended by WHO is 0.05 mg L^{-1}. The maximum allowable lead in drinking water has been set at a concentration of 15 ppb by U.S. EPA. Lead is widely used in processing industries such as electroplating, paint and dyes, explosive manufacturing, and lead batteries and in lakes and streams by acid. Also leads emitted into the atmosphere by combustion of fossil fuels and the smelting of sulfide ores.[8]. Also historic mining and industrial have produced numerous sites containing high concentration levels of As, Pb, Zn and Cd. Remediation of the contaminated sites is necessary because unthreaded effluent may have an adverse impact for the protection of the environment and public health.[9]. In the present study, priority heavy metal Pb (II) and metalloid As (III) were used as representative adsorbates which were removed from aqueous solutions by PCrt. Batch experiments were conducted to investigated kinetics and isotherms characteristic of arsenite and lead adsorption onto Pc. Finally we test the competitive adsorption of arsenite and lead onto PCrt.

METHODOLOGY

Preparation of tyre rubber pyrolytic char: The char was derived from the pyrolysis of used rubber tyres at 450^{o}C in oxygen-free atmosphere under vacuum for 4 hours. For the purification of as-received pyrolytic tyre char 2 gr of as received pyrolytic char suspended onto 2M HNO_3 for 2 hr . At the end of 2 hr suspension the material was collect and washed with deionized water for 6 times

to final pH =7 and solid was finally dried at room temperature. After room temperature drying, solid was calcinated at 500 °C under inert condition (N_2) for 1 hr.

Chemicals: Sodium meta-arsenite $NaAsO_2$ was obtained from Sigma-Aldrich, while HCl, NaOH and KNO_3. $Cu(NO_3)\cdot 3H_2O$, $Pb(NO_3)_2$ and HNO_3 were obtain from Merck. 2-(N-Morpholino) ethanesulfonic acid hydrate, 4-Morpholineethanesulfonic acid MES hydrate & 4-(2-Hydroxyethyl) piperazine-1-ethanesulfonic acid, N-(2-Hydroxyethyl) piperazine-N-(2-ethanesulfonic acid) HEPES used for pH buffering were obtained from Sigma-Aldrich. Ultrapure water was produced by a Milli-Q Academic system, Millipore. All solutions were prepared with analytical grade chemicals and ultrapure Milli-Q water with a conductivity of 18.2 μS cm^{-1}

Characterization of pyrolytic chars: The X-Ray powder Diffraction (XRD) patterns for the as received PCrt, char purified and $char_{500}$, were recorded by a Brüker Advance D8 instrument using Cu K_a radiation (λ = 1.5418 Å) in the 2θ range from 10° to 80°with a 2θ resolution of 0.02°. N_2 adsorption–desorption isotherms were obtained at 77 K using a Tristar Micrometrics Instruments and the specific surface area (S_{BET}) of the $Char_{500}$ was calculated using the Brünauer–Emmett–Teller (BET) method based on the adsorption data. The carbon, hydrogen, nitrogen and oxygen (CHNO) contents of the tyre - derived chars were determined using an elemental analyzer Perkin Elmer (2400 Series II) at 1.100 °C. Oxygen content was determined by mass difference. The ash content was determined by calcination of 1g of chars in a muffle furnace (800 °C, 4 h).

Analytical determination of As (III) and Pb (II): The concentration of metals in the aqueous solution was determined by Cathodic Stripping Voltammetry (CSV) using a Trace Master5-MD150 polarograph by Radiometer Analytica. An Ag/AgCl electrode with a double liquid junction was used as the reference electrode whilst a Pt electrode. Importantly, samples were not purged with N_2 gas in order to avoid loss of As(III) [10]. During the stripping step the solution was stirred at 525 rpm. For the measurements we used aliquots of 8.3 mL adjusted at pH 0.5 by HCl [11]. Then 8 ppm Cu^{2+} was added and the pH was readjusted if necessary to pH 0.5. In the following, As (III) was determined by square-wave CSV (SW-CSV) with accumulation potential E = -400 mV and accumulation time 60 s. As (III) was quantified by its signal at $E_{1/2}$ = -670 mV. The concentrations of Lead in the aqueous phase were determined by Anodic Stripping Voltammetry (ASV) .[12]

As (III) and Pb (II) sorption experiments: As (III) and Pb (II) uptake from aqueous solutions were studied in batch experiments. Adsorption kinetics of arsenite and lead onto PCrt, were screened for contact times ranging between 0 and 240 min at pH 7, $NaAsO_2$ = 3 mg L^{-1}, PCrt = 0.1 g L^{-1} and $Pb(NO)_3$=3 mg L^{-1} , PCrt= 0.1 g L^{-1} . In each experiment the supernatant was collected by centrifugation and then analyzed for arsenite and lead. Adsorption isotherms were recorded at pH 7 in the presence of $NaAsO_2$ and $Pb(NO)_3$ at concentrations between 10 to 50 mg gr^{-1} and 10 to 60 mg gr^{-1} respectively for 0.1 g L^{-1} of PCrt suspended in 50 mL buffer solution in polypropylene tubes.

Comparative adsorption were recorded at pH 7 in presence $NaAsO_2$ = 3 mg L^{-1} $Pb(NO)_3$=3 mg L^{-1} , PCrt = 0.1 g L^{-1} in 50 mL buffer for 120 min equilibrium time. Control experiments (without PCrt) showed no loss of initial As (III). The initial pH values of buffers were adjusted using small volumes of 2.5 M HCl or 2.5 M NaOH to the desired value. After metals addition, the suspension was allowed to equilibrate for 120 min at room temperature (25 °C ± 0.2) for arsenite and lead respectively while agitated in a magnetic stirrer. After completion of the equilibration, the suspension was centrifuged at 5000 rpm for 10 min the As (III) concentration of the supernatant solution was analyzed by Cathodic Stripping Voltammetry (CSV) and the Pb (II) concentration of

the supernatant solution was analyzed by Square Wave Anodic Stripping Voltammetry (SW-ASV) as described above.

RESULTS AND DISCUSSION

Characterization of the materials: The X-Ray Diffraction patterns of as receive PCrt, acid- treated PCrt, PCrt calcinated at 500 °C after acid- treatment, are presented in Figure 1. The XRD patterns show a typical peak of graphitic carbon 25° [13](Fig. 1). The peaks at 27°, 47° and 57° are characteristic of zinc sulfide (ZnS) [14]. On the other hand, the peak at 43° relates to iron carbides (Fe_3C).[14-15]

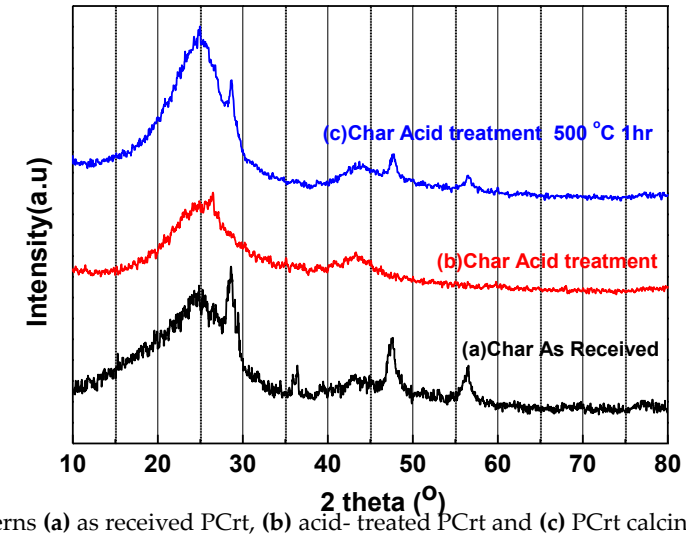

Figure 1 XRDs patterns **(a)** as received PCrt, **(b)** acid- treated PCrt and **(c)** PCrt calcinated at 500 °C after acid- treatment.

The IR spectra of the materials are shown in Fig. 2. The absorption peaks at 3400, 2380, 1600 cm^{-1} can be assigned to the =C-H, C-H and C=C stretching modes and shown in all materials [16]. The band at 1060 cm^{-1} is due to S=O stretching and appears in all materials [16]. The weak peak at 500 cm^{-1} indicates the existence S-S bonds and appears to as received char and char calcinated at 500 °C for 1 hour [16]. The band at 722 cm^{-1} is due to ZnS and shows up only at char calcinated at 500 °C for 1 hour[17]

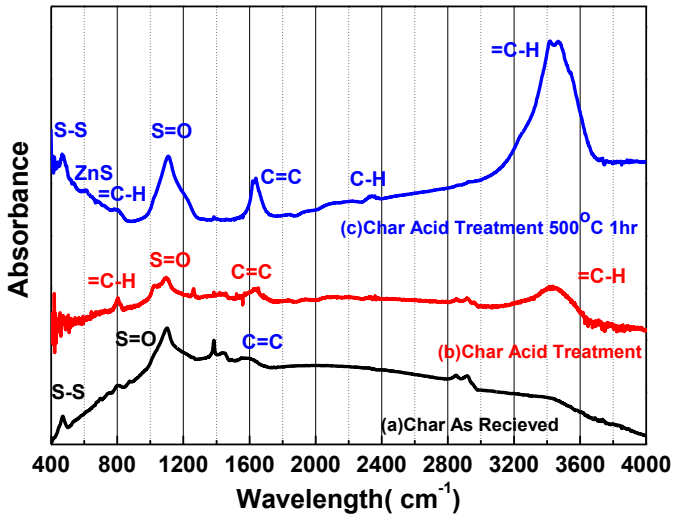

Figure 2 FTIR patterns **(a)** as received PCrt, **(b)** acid- treated PCrt and **(c)** PCrt calcinated at 500 °C after acid- treatment.

Arsenite and Lead adsorption: Adsorption kinetic data of arsenite onto PCrt in contact times ranging between 0 and 240 min (4 h). Arsenite uptake is accomplished after 120 min (data not shown). The maximum As (III) uptake capacity for the PCrt was evaluated at room temperature by fitting the experimental data with the Langmuir adsorption isotherm

$$q_e = \frac{q_m * K * C_e}{1 + K * C_e} \qquad \text{(Eq.1)}$$

Where q_e is the surface concentration or the surface density in mg g^{-1}. C_e has units of either mol L^{-1} or mg L^{-1}. The maximum q_m adsorption derived from the fit, listed in Table 1 is found 8,8 mg gr^{-1} of As(III) per gram at pH=7 (Fig. 3a).

Adsorption kinetic data of lead onto PCrt in contact times ranging between 0 and 240 min (4 h). Lead uptake is accomplished in the first 120 min (data not shown). The maximum Pb(II) uptake capacity for the PCrt was evaluated at room temperature by fitting the experimental data (see Table 1) with the Langmuir adsorption isotherm with equation 1 as describe above and was found 27.7 mg gr^{-1} of Pb(II) per gram at pH=7 (Fig. 3b)

Table 1 Langmuir Isotherm Constants at pH 7.0

Materials	Adsorbed	q_m (mg gr^{-1})	K_l	R^2
PCrt _acid_500^{0}C	As(III)	8,8	0,084	0,991
PCrt _acid_500^{0}C	Pb(II)	27,7	0,087	0,979
[[PCrt _acid_500^{0}C]- Pb(II)]	As(III)	31	0,69	0,989

For comparison, adsorption experiments with as received char and wash and char calcinated at 500 °C without acid-treatment show 1.8 mg gr^{-1} of arsenite at pH 7. This demonstrates that acid-treatment before the calcination step is essential for optimizing the PCrt surface for metal uptake.

(red line) Theoretical Langmuir isotherm calculated using the parameters listed in Table 1. Open symbls: As(III) uptake isotherms in the presence of 100mM NaCl, or 3mg/L Zn(II). **(b)** (symbols) Adsorption Isotherm of Pb (II) onto PCrt calcinated at 500 °C after acid- treatment. Open symbls: Pb(II) uptake isotherms in the presence of 100mM NaCl, or 3mg/L Zn(II) (red line) Theoretical Langmuir isotherm calculated using the parameters listed in Table 1, **(c)** (symbols) Adsorption Isotherm of As (III) onto [[PCrt _acid_500^{0}C]-Pb(II)]. (red line) Theoretical Langmuir isotherm calculated using the parameters listed in Table 1.

Selectivity of As(III) Uptake:

(a) Pb(II) enhances As(III) Uptake: Comparative adsorption Pb (II) and As (III) onto PCrt reveal an interesting phenomenon. When simultaneously present in the initial solution, 3 mg L^{-1} $NaAsO_2$ and 3 mg L^{-1} $Pb(NO)_3$ with 0.1 g L^{-1} PCrt, the adsorption of arsenite is strongly increased to 22.5 mg gr^{-1} and adsorption of lead show decrease to 16.9 mg gr^{-1}. This indicates that Pb (II) results in an –at first glance unexpected- enhancement of As (III) uptake. To further prove this we have performed an adsorption experiment where [i] first 27,7 mg gr^{-1} Pb (II) was allowed to be adsorbed on PCrt

_acid_500^{0}C for 2 hours, [ii] then As(III) adsorption was studied on the so-formed [[PCrt _acid_500^{0}C]- Pb(II)] material. The data reveal a significant boost of the As (III) uptake to 31 mg gr^{-1} after 30 min equilibrium time (Fig. 3c).This clearly demonstrates a novel phenomenon that can be explained if we consider the formation of PbS sites i.e. from adsorbed Pb (II) ions on S-sites that exist in the PCrt structure. In crystalline form, PbS has strong affinity for As (III) Bostick et al. [18] and Piquette et al. [19] that show arsenites adsorption onto PbS (galena). In the present case we consider that PbS sites are formed during lead adsorption, and these act as additional As (III) adsorption sites.

(b) Effect of electrolyte ions Na^+, Cl^-: Common electrolyte ions i.e. such as Na^+ and Cl^- have different effect on As(III) vs. Pb(II) uptake (compare open circles in Fig 3(a) vs. 3(b)). In the case of As(III) electrolyte ions at 100mM concentration have practically no effect, while Pb(II) uptake is inhbited by ~15%. This phenomenon can be explained as follows: at any pH<9 As(III) is in its neutral form H_3AsO_3 [6, 18] thus it is adsorbed preferentially on neutral sites of the adsorbing materials [6, 12,13b 18]. In contrast, Pb(II) cations are preferentially uptaken by anionic surface sites [12, 13b]. Thus electrolyte ions –which act via electrostatic forces in the electrostatic double layer at the interface- have no effect on the <H_3AsO_2-[neutral surface sites]> interaction whilst they do affect the <Pd(2+)-[surface anionic sites]> interaction.

(c) Effect of Zn(II): analogously, the presence of 3mg/L Zn(II) ions has negligible effect on As(III) uptake, see Figure 3a, while they severely compete for Pb(II) binding i.e. since both Pb(II) and Zn(II) cations compete for binding at the same anionic surface sites of PCrt.

Thus the present data reveal a selective As(III) uptake by the PCrt metarial that is not impaired by other common cations or anions.

Comparison with analogous As(III) sorbents: Low-cost Granular Activated Carbon, (GAC) and Fe-loaded GAC were reported to achieve an uptake of 0.4 mg As/g (GAC) and 3 mg/gr (GAC)-Fe respectively [20]. Other methods such as co-precipitation e.g. with Al or Fe hydroxides require significantly longer timescales i.e. days [6], *vs.* a max time of 120 minutes in the present systems. Moreover, the so formed precipitates have to be deposited on a low-cost substrate such as sand, Al_2O_3 or a carbon matrix [6, 21] in order to be usable in leaching-free column applications. For example Fe-hydroxide coated Al_2O_3 was shown to achieve As(III) uptake 7.6mg/g [6]. Our present approach suggests that PCrt-Pb outperforms these materials. When compared with more expensive materials prepared in our lab [12, 13d] the low-cost PCrt can be considered as a promising material on a performance/ cost basis.

Functionalized Pyrolytic Carbon from Recycled Tyres: A Hybrid Material for Selective Removal of Pb, Cd from Waste Waters

Alexandra Mavrogiorgou and Maria Louloudi
Laboratory of Inorganic Chemistry, University of Ioannina, Greece

ABSTRACT

Carbon-based materials from recycled tyres (**PCox)** have been functionalized by covalently grafting organisilanised functionalities (**Si-L)** bearing ligating groups **L** [where **L**=4-imidazoledithiocarboxylic acid or 4-imidazolcarboxaldehyde]. These ligands **L** bear with high affinity for heavy metals. Here Pb^{2+}, Cd^{2+} uptake was studied by Adsorption isotherms and pH-edge data using Anodic Stripping Voltammetry (ASV). The maximum metal-uptake capacity of **L@PCox** material is 32.3 mg of Cd^{2+} per gram of **L@PCox** when L=4-Imid-ald (47.4 mg/gr when **L**=4-Imid-dithio) at pH 7.0. For Pb^{2+}, the max uptake is 17.1mg/g (for L=4-Imid-ald) and 34.2mg/g when **L**=4-Imid-dithio at pH 7. In the presence of competitive Zn^{2+} or Cu^{2+} ions, the **L@PCox** matrerials show a strong selectively for the Pb^{2+} or Cd^{2+} ions. This is attributed to the selectivity of the ligands **L** to the bigger lead or cadmium ions. When compared with the no functionalized pyrolytic carbon, the functionalised materials **L@PCox** show > 400% improvement for Cd and Pd uptake.

Keywords: pyrolytic carbon, fuctionalisation, Cd, Pb, metal uptake

INTRODUCTION

Pyrolytic char is one of the main products obtained after the pyrolysis process for disposing of waste tyres. It has contiguous structure with carbon black and this confers on it the general properties of carbonaceous materials such as thermal stability, high corrosion resistance in acid/base and low cost [1]. Concerning different technologies applied to the removal of heavy metal ions from aqueous bodies, metal adsorption onto solid supports such as activated carbon, zeolites, clays and metal oxides has been used so far [2]. However, the efficiency and selectivity of these solid supports are quite low, and improved metal absorbents have been prepared by coupling chelating ligands to support matrixes. The organic functionalities typically serve to form complexes with heavy metal ions, and the solid support allows easy removal from the liquid waste e.g. by filtration for example [3]. Various functionalized adsorbents with heavy metal complexing ligands have been reported [4,5] based mainly on polymers [6,7], clays [8,9], silica gel [3,10] and mesoporous silica [11,12].
Here, we report the functionalization of carbon-based materials from recycled tyres (**PC=Pyrolytic arbon)** *via* covalently grafting of organisilane-functionalities (**Si-L)** which bear ligating groups (**L)** with high affinity for heavy metals such as Pb^{2+}, Cd^{2+}. The so-prepared **L@PCox** hybrids contained functional groups **L**=4-imidazoledithiocarboxylic acid and 4-Imidazolcarboxaldehyde that are known to have specific ligation affinity for the heavy metals tested. Heavy-meta uptake was studied in aqueous solutions at pH 4-9 i.e. pertinent for industrial or surface waste waters.

METHODOLOGY

Oxidation of pyrolytic carbon. 5 gr of pyrolytic carbon (**PC**) were refluxed with 90 ml 65% v/v HNO_3 for 6h. The oxidized pyrolytic carbon (**PCox**) obtained was separated by filtration, washed exhaustively with distilled water until pH~7 and dried under reduced pressure at 40 °C for 12 h. DRIFTS-IR (cm^{-1}, selected peaks): 2919, 2855: ν(C-H); 1701: ν(C=O); 1542: ν(C=C); 1162: ν(C-O). Thermal analysis: the derivative thermogram of **PCox** shows a broad peak in the range of 130-420 °C assigned to the decomposition of –COOH surface groups with a 10.0 % weight loss and an intense peak at 600 °C assigned to the combustion of carbon support. The –COOH groups formed are *ca.* 2.2 mmol g^{-1} determined by thermogravimetric and elemental analysis. The **PCox** had an average surface area of *ca.* 687 m^2 g^{-1}.

Synthesis of Organosilane-ligands. *(a) Synthesis of organo-silanes* ***4-Imid-dithio-OS*** *and* ***4-Imid-ald-OS****.* 1.5 mmol of 4-imidazoledithiocarboxylic acid or 4-imidazolcarboxaldehyde and 1.0 mmol of (3-glycidyloxypropyl)-trimethoxysilane or (3-aminopropyl)-trimethoxysilane respectively were stirred for 24 h in 10 ml of MeOH under N_2 at 60°C in order to generate **L1-OS** and **L2-OS** silane-precursors. *(b) Formation of modified carbon materials.* The **L1@PCox** and **L2@PCox** materials were prepared through co-condensation of **4-Imid-dithio-OS** or **4-Imid-ald-OS** precursors with the –OH functional groups of oxidised carbon **PCox**. Accordingly, 0.5 g oxidised carbon **PCox** and 5 ml EtOH were added to the precursor **L1-OS** or **L2-OS** solution, and the resulting slurry was stirred at 60 °C for 24 h. The obtained solids, **4-Imid-dithio@PCox** and **4-Imid-ald@PCox,** were washed several times with MeOH and EtOH and dried under vacuum at 60 °C for 12 h.

4-Imid-dithio@PCox: DRIFTS-IR (cm^{-1}, selected peaks): 2918, 2853: ν(C-H); 1702: ν(C=O); 1652: ν(C=N); 1561: ν(N-H); 1542: ν(C=C); 1159: ν(C-S); 901: ν(C-O-Si). Thermal analysis provides a weight

loss of 14.1 % assigned to the decomposition of the surface –COOH groups and the anchored organic ligand. This material showed an average surface area of *ca.* 45 m^2 g^{-1}.

4-Imid-ald@PCox: DRIFTS-IR (cm^{-1}, selected peaks): 2923, 2855: ν(C-H); 1702: ν(C=O); 1597: ν(C=N); 1542: ν(C=C); 1107: ν(C-O); 799: ν(C-O-Si). Thermal analysis shows a weight loss of 15.1 % corresponds to the decomposition of the surface –COOH groups and the anchored organic ligand. This material had an average surface area of *ca.* 75 m^2 g^{-1}.

Analytical determination of Cd^{2+} and Pb2+: Determination of metal concentrations in aqueous phase was carried out by Anodic Stripping Voltammetry using a Trace Master5-MD150 polarograph by Radiometer Analytica as described earlier [3]. The measuring cells were borosilicate glass cell from Radiometer. The working electrode was a hanging mercury drop electrode (HMDE), with an Hg drop with 0.4mm diameter generated by a 70μm capillary. The reference electrode was an Ag/AgCl electrode with a double liquid junction. The counter electrode was a Pt electrode. Initially, before the stripping step N_2 gas (99.999% purity) was passed from the measuring solutions to remove any trace O_2. During this step the solution was under continuous stirring at 525rpm. During the stripping step the solution was not stirred. Square Wave (SW) measurements were performed in the anodic direction i.e. Square Wave Anodic Stripping Voltammetry (SW-ASV), to quantify metal ions. Typically under our experimental conditions, 1.05 10^{-6}M $Pb(NO_3)_2$ in 0.01M KNO_3 resulted in a current of Ip=0.851μA, Ep=-340mV at pH 6.5 and 1.05 10^{-6}M $Cd(NO_3)_2$ in 0.01M KNO_3 resulted in a current of Ip=0.820μA, Ep=-460mV at pH 6.5. Adsorption kinetics of cadmium and lead onto L@PCox , were performed for contact times ranging between 0 and 120 min at pH 7, L@PCox = 0.1 g L^{-1} and $Cd(NO)_3$ or $Pb(NO)_3$=3 mg L^{-1}. In each experiment the supernatant was collected by centrifugation and then analyzed for cadmium and lead. Adsorption isotherms were recorded at pH 7 in the presence of $Cd(NO_3)_2$ and $Pb(NO_3)_2$ at concentrations between 10- 50 mg g^{-1} , and 10- 60 mg g^{-1} respectively for 0.1 g L^{-1} of L@PCox suspended in 50 mL buffer solution in polypropylene tubes. The initial pH values of buffers were adjusted using small volumes of 2.5 M HNO_3 or 2.5 M NaOH to the desired value. After metals addition, the suspension was allowed to equilibrate for 120 min at room temperature (25 °C ± 0.2) for cadmium and lead, while agitated in a magnetic stirrer. After completion of the equilibration, the suspension was centrifuged at 5000 rpm for 10 min. The Cd^{2+} or Pb^{2+} concentration of the supernatant solution was analyzed by Square Wave Anodic Stripping Voltammetry (SW-ASV) as described above. In the competition experiments, $Cu(NO_3)_2$ or $Zn(NO_3)_2$ where added in the same reaction mixture together with lead or cadmium and determined using SW-ASV.

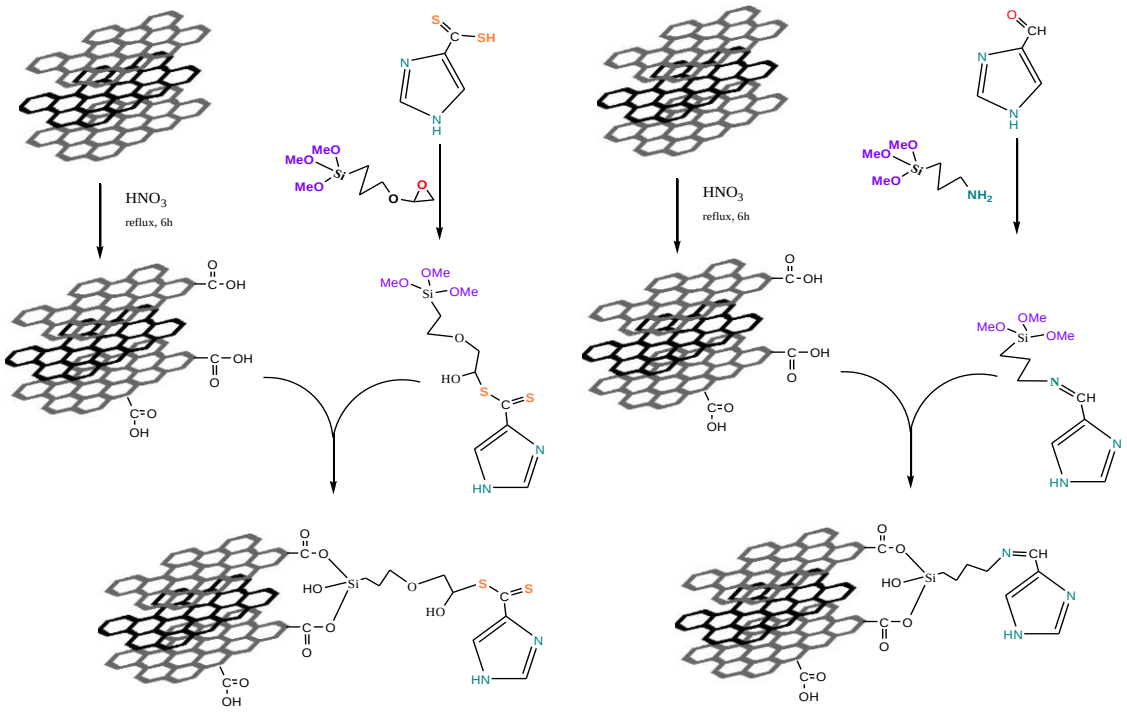
RESULTS AND DISCUSSION

Synthesis of the adsorbents

The methodology applied here for anchoring of chelating ligands onto pyrolytic carbon uses silylation reaction of silane-precursors, depicted in Figure 1. The key concept of the present method is, first, a reaction of bifunctional, commercially available, alkoxy-silanes with 4-imidazoledithiocarboxylic acid or 4-imidazolcarboxaldehyde producing **4-Imid-dithio-OS** and **4-**

Imid-ald-OS precursors which has the alkoxy-moiety intact, and, second, silylation reaction of the so obtained silane-precursors with the surfacial –OH groups of the oxidized pyrolytic carbon.

Overall, the present synthetic procedure involves: (i) oxidation of the pyrolytic carbon **PC** with concentrated HNO_3; (ii) derivatization of the 4-imidazoledithiocarboxylic acid or 4-imidazolcarboxaldehyde to form silane-compounds; and (iii) anchoring of the silane-precursors to the oxidised pyrolytic carbon **PCox**. Derivatization occurs *via* reaction of 4-imidazoledithiocarboxylic acid and 4-Imidazolcarboxaldehyde with (3-glycidyloxypropyl)- or (3-aminopropyl)-trimethoxysilane to generate **4-Imid-dithio-OS** and **4-Imid-ald-OS** silane-precursors respectively. The propyl-trimethoxysilane moieties of **4-Imid-dithio-OS** and **4-Imid-ald-OS** allows their covalent attachment on the oxidized pyrolytic carbon **PCox** surface via hydrolysis and co-condensation with the –OH functionalities of the **PCox** leading to the formation of **4-Imid-dithio@PCox** and **4-Imid-ald@PCox** hybrid materials respectively.



4-Imid-dithio@PCox **4-Imid-ald@PCox**

Figure 1 Grafting of 4-imidazoledithiocarboxylic acid and 4-Imidazolcarboxaldehyde on the surface of **PCox**

The DRIFTS-IR spectra of the **4-Imid-dithio@PCox** and **4-Imid-ald@PCox** show several bands corresponding to various structural units of the solid support as well as from the chelating ligands 4-imidazoledithiocarboxylic acid or 4-imidazolcarboxaldehyde. More specifically, the modified materials display the characteristic $-CH_2$ stretching bands in the region 2950–2850 cm^{-1} and $-CH_2-$ aliphatic deformation vibrations in the region 1500–1300 cm^{-1}, as weak intensity bands. The bands at 1702 cm^{-1} are attributed to ν(C=O) stretching vibrations. The C=N and C=C stretching vibrations of **4-Imid-dithio@PCox** were observed at 1652 and 1542 cm^{-1}, respectively. The same vibrations were also observed at 1597 and 1542 cm^{-1} attributed to imidazole ring in the **4-Imid-ald@PCox** material.
The derivative thermograms for **4-Imid-dithio@PCox** and **4-Imid-ald@PCox** show 14.1 and 15.1% weight loss respectively, in the range 130-400 °C, which corresponds to a loss of anchored organic moieties and surface oxidised functionalities. Taking into account that the parent **PCox** material bears 10.0 % [w:w] –COOH surface groups which are decomposed in the same temperature region, the additional weight loss of 4.1 and 5.1% is assigned to the decomposition of the anchored organic ligand 4-imidazoledithiocarboxylic acid and 4-imidazolcarboxaldehyde respectively**.** The loading of 4-imidazoledithiocarboxylic acid and 4-imidazolcarboxaldehyde is *ca.* 0.3 and 0.5 mmol g^{-1} respectively.

Heavy Metal Uptake

Pb^{2+} uptake: Figure 2 presents the uptake of Pb^{2+} ions by 4-imid-ald@PCox (2A) or 4-imid-dithio@PCox (2B). The functionalised materials have significantly i.e. at least fourfold, improved Pd-uptake compared to the untreated pyrolytic carbon material (PC). Then pH-egde profiles in Figure 2 indicate that 4-imid-ald@PCox binds Pb via the imidazole group which deprotonates at alkaline pH. In contrast or 4-imid-dithio@PCox can bind metal cations at all the pH values tested. This is attributed to Sulfur atoms that have strong affinity for Cd and Pb. The S atoms act synergistically with the imidazole, thus achieving a higher Pd-uptake than imidazole alone.

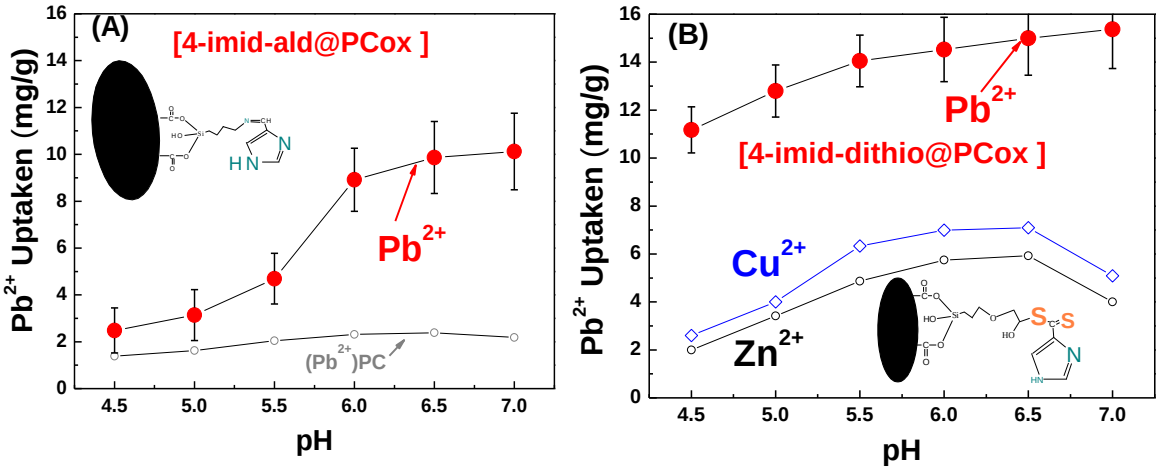


Figure 2 (A) Adsorption pH-edge for Pb^{2+} onto or 4-imid-ald@PCox (•) or untreated Pyrolytic Carbon (PC) (◦). (B) onto 4-imid-dithio@PCox (♦). In 2B, the pH-edge adsorprion of Cu^{2+} (◊) or Zn^{2+} (◦) ions is shown.

Cd^{2+} uptake: Figure 3 presents the uptake of Cd^{2+} ions by 4-imid-ald@PCox (A) or 4-imid-dithio@PCox (B). As in the case of Pb, the functionalised materials have significantly better Cd-uptake ability, than the untreated pyrolytic carbon material (PC). The beneficial role of the S-atoms in or 4-imid-dithio@PCox is also seen in Figure 3B e.g. *vs.* imidazole alone, in 4-imid-ald@PCox Figure 3B.

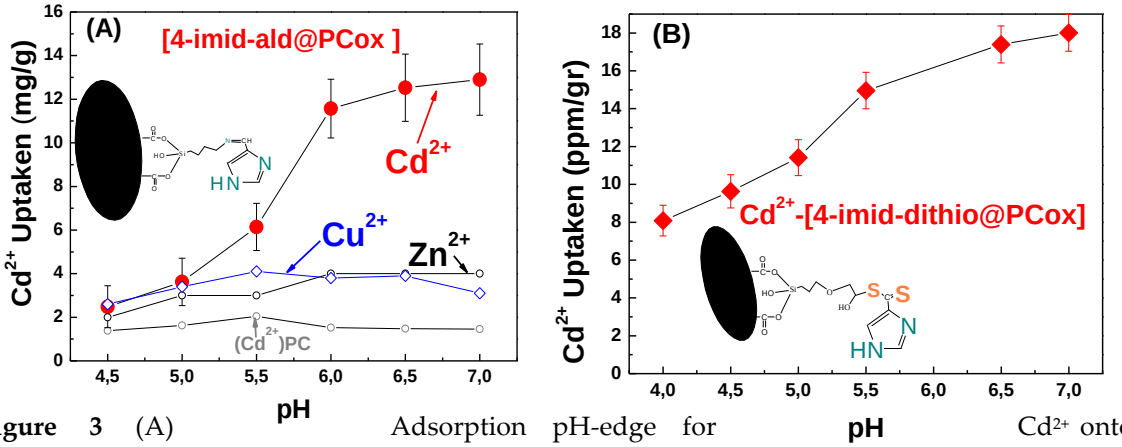

Figure 3 (A) Adsorption pH-edge for Cd^{2+} onto 4-imid-ald@PCox (•) or untreated Pyrolytic Carbon (PC) (◦). (B) onto 4-imid-dithio@PCox (♦).(♦). In 3A, the pH-edge adsorprion of Cu^{2+} (◊) or Zn^{2+} (◦) ions is shown.

As in the case of Pb-uptake, at pH 7, both materials show improved sorption capacities. This indicates the involvement of pH dependent surface groups in the mechanism of cadmium uptake. The origin of this phenomenon can be understood based on the Surface Complexation Model developed in our previous work [3] for analogous ligands grafted on SiO_2 [3]. According to this, the binding of Cd^{2+} and Pb^{2+} ions is determined by [i] their binding affinities towards the S-atoms and the imidazole in 4-imid-dithio while the imidazole is the only functional group in 4-imid-ald. On the other hand the high affinity of Pb for the S-atoms in 4-imid-dithio@PCox render this material stronger adsorbent for Pb-ions at all pH values. On the other hand imidazole has higher affinity for Cd binding than for Pb, thus the Cd-uptake by 4-imid-ald@PCox is higher for Cd than for Pb.

Competitive Metal Uptake: The data in Figure 2B, show that 4-imid-dithio@PCox has an almost 100% higher Pb-uptake affinity than for Cu^{2+}, and ~130% higher affinity for Pb^{2+} vs. Zn^{2+}. This is due to the high binding affinity of the imidazole/S unit for Pb^{2+} ions. Similarly, 4-imid-ald@PCox shows a significantly higher binding affinity for Cd^{2+} ions than for the Cu^{2+} or Zn^{2+} ions. In Table 1 we summarise the maximum metal uptake capacity for Cd^{2+} or Pb^{2+} when present simultaneously with Cu^{2+} of Zn^{2+} ions.

All experiments were performed at a neutral pH 7 for an initial metal concentration 50mg per gram of material. The binary-metal data, in Table 1 clearly exemplify the effect seen in the pH-edge data of Figures 2B and 3A. 4-imid-dithio@PCox shows a 4:1 to 2:1 selectivity for Cb over Cu or Zn respectively. 4-imid-dithio@PCox shows a 4:1 and 3:1 for Cd^{2+} over Cu and Zn respectively. The higher affinity for the bigger (Cd^{2+}, Pb^{2+}) ions is attributed to a chelation effect originating from the 4-imid-ald/dithio ligands on the oxidized pyrolytic carbon matrix.

Table 1 Maximum Metal Uptake Capacity of the functionalized PCox materials at pH 7.0

	Metal **sinlge-sorbates** (mg of metal uptaken per gr of material)		Metal **Binary-sorbates** (mg of metal uptaken per gr of material)			
Material	Cd^{2+}	Pb^{2+}	Cd^{2+}(Cu^{2+})	Cd^{2+} (Zn^{2+})	Pb^{2+}(Cu^{2+})	Pb^{2+} (Zn^{2+})
4-imid-dithio@PCox	32.3	30.1	29.4(5.8)	11.2(6.9)	23.0(4.6)	25.7(13.9)
4-imid-ald@PCox	47.4	27.2	36.2(9.4)	33.2(11.4)	26.1(8.7)	30.2(12.6)

Comparison with analogous metal-sorbents: the present pyrolytic carbon-based materials can be compared with other chars e.g. such as pyrolyitc wood [13], biochar or activated carbon that have been used for Cd and Pd uptake [14-16]. The present materials achieve 30-40 mg of Pb uptaken per gram for an initial metal concentration 50mg/gr i.e. >70% metal uptake. Chars derived from several pyrolytic woods [13] achieved <5mg Pb per gram at initial Pb >100mg [see review in 13]. Activated carbon from *Phaseulus* a. huls tested from Pb, Zn, Cu, Cd as in the present case at pH 7 achieved metal uptakes of 6-16mg/gr [16]. No completion/selectivity data were reported. In [14] binary metal sorbates (Cd-Cu) were evaluated by activated carbon (Aldrich Darco-120)., at very low initial concentrations (0.6mg/gr). Cd uptake was severely outcompeted by Cu which was >95%uptaken vs. <50% of the Cd [14]. Thus, the present functionalized PCox materials constitute an example of high performance/high selectivity materials for Cd, Pd uptake.

CONCLUSION

Covalent rafting of appropriate organic ligands on PCox may result in significant enhancement of metal uptake by the adsorbent, compared to untreated Pyrolytic Carbon. Noticeably, the immobilised multifunctional ligands such as 4-imid-dithio and 4-imid-ald, have exhibited high Cd and Pb uptake-capacity at acidic as well as at neutral pH values. The high binding affinities of the Pb and Cd ions for the S-atoms of 4-imid-dithio and the idazole ring respectively result in different pH-edge profiles for the two metals. The data show that the presence or absence of protonable groups on the ligand determines the pH-edge profile in combination with the hydrolysis profile of

the metal ion under study. Thus both the nature of the ligand as well as its surface concentration are of equal importance for the sorbing capacity of the material.

Outotec Ettringite Process for Sulfate Removal from Mining and Metallurgical Waters

Laura Nevatalo[1], Tuomas van der Meer[1], Mika Martikainen[1] and Cristian Montes[2]

1. *Outotec Industrial Water Treatment, Finland*
2. *Outotec Chile*

The treatment of wastewaters from mining and metallurgical processes is becoming challenging due to tightening environmental regulation for water quality that is allowed for discharge to environment. Sulfate in form of sulfuric acid is one of the key components of acid mine drainage and acid rock drainage. Traditional lime neutralization neutralizes the acid and precipitates the metals, but sulfate will remain in the solution in gypsum saturation concentration. Removal of sulfate from these streams to meet the required concentration limits has been proven to be challenging due to high solubility of sulfate salts. Few technically feasible water treatment processes exist in the market that can be applied to decrease sulfate concentration below gypsum saturation level: biological sulfate reduction, membrane separation, ion exchange, evaporation and chemical precipitation. Some of these technologies are effective for treating wastewater, but there is typically a highly concentrated sulfate fraction left requiring still further treatment. Selecting the correct sulfate removal technology requires deep understanding of water chemistry and the effects of technology selection to overall water treatment plant capex and opex, and including also the necessary pre- and post treatment steps and solid waste management required around the core technology. Outotec has developed a sulfate removal solution: Outotec Ettringite process for treatment of gypsum saturated waters and waters with high Na_2SO_4 concentration, where sulfate removed to solid form as ettringite ($3CaO_3CaSO_4Al_2O_3*31H_2O$). Process equipment are reactors for ettringite precipitation, clarifier and filter for separation of ettringite solids and reactor for final neutralization with CO_2-gas followed by polishing $CaCO_3$ solids separation step. Typically the wastewaters to be treated contain 1-10 g/l sulfate and after ettringite process the sulfate concentration is 200 mg/l or even lower, this residual sulfate concentration can be controlled flexibly. Besides the sulfate concentration, the wastewater characteristics have an effect on the overall opex.

ABSTRACT

This study investigates the performance of synthesized organic and inorganic polymers in the flocculation of fine particles of suspended solids from mine water of different electrochemical properties.

Factors considered for the evaluation of the performance of coagulants included, coagulant type, pH conditions, turbidity removal efficiency, pH correction and sedimentation rate of the flocs.

It was observed that the monomeric inorganic coagulants had a relatively poor performance compared to the polymers. The organic polymer (GK-cl-P(AAm-co-AA)/Fe_3O_4 nanocomposite) was much effective in acidic solutions, while the monomeric inorganic polymer performed better under alkaline conditions; the response of the inorganic polymer af-PFCl to pH changes was inconsistent. The coagulants used were unable to correct acidic pH of the solutions. In general the coagulants could achieve a turbidity removal in the range of 67 to 99.5%, but GK-cl-P(AAm-co-AA)/Fe_3O_4 nanocomposite showed the greatest reactivity by achieving the fastest floc formation rate and shortest optimum sedimentation time of 5 mins.

Developed polymers have shown better flocculation potential and provide the advantage to reduce the formation of byproducts, improving the quality of mine effluents prior to discharge in the environment.

MINE WATER DRAINAGE COLLECTION AND TREATMENT – BIOLOGICAL ACTIVE TREATMENT

Sulfidogenic Diffusive Exchange System for the Treatment of Acid Mine Drainage

Alex Schwarz and Norma Pérez
Center for Water Resources in Agriculture and Mining (CRHIAM), Universidad de Concepción, Chile

ABSTRACT

Sulfate-reducing bioreactors are good treatment options for acid mine drainage (AMD). In this technology, AMD flows through a bed containing reactive material, where sulfate, metals and acidity are removed by the metabolic activity of sulfate-reducing communities. The substrates should be affordable and provide organic matter that promotes the growth of microorganisms. We hypothesize that increasing organic substrate availability by utilizing finely ground organic material will increase sulfate reduction kinetics, although new reactor designs such as diffusive exchange systems (DES) will be needed to accommodate these finer substrates while keeping AMD throughput.

In this research, utilizing a fine organic substrate in a sulfidogenic DES bench scale reactor, we treated acidic AMD (pH down to 2.5) for a period of 14 months. Although the reactor was operated in a metal and acidity overloaded mode for the whole period, it achieved stable operation, reducing sulfate, removing metals and adding alkalinity. To our knowledge, this is the first time a biochemical reactor is operated passively, without external alkalinity source, at such low pH and high metal load. This stable operation indicates that a bioprotection mechanism based on chemical gradients protected the microbial community within the reactive layers of low permeability. In addition, the system did not show any permeability reduction. The metals precipitated along the interfaces between the reactive and conductive layers, where sulfide and metal gradients met, consistent with chemical-gradient-based bioprotection. Hence, the sulfidogenic DES holds promise for the passive treatment of highly acidic and toxic AMD. Higher reaction rates are possible within these reactors, and microbial consortia are protected from toxicity while no permeability reduction is observed.

Keywords: biochemical reactor, bioprotection, diffusive exchange, passive treatment, AMD.

INTRODUCTION

The mining waste rock and tailings represent a potential hazard for the environment, especially when the residues contain sulfide minerals that can be a source of acid mine drainage (AMD). The exposure of the metal sulfides to oxygen and water, accompanied by microbial activity, leads to the formation of drainage rich in sulfate, acidity and heavy metals (Dold, 2010). The AMD problem involves both active and abandoned mines dedicated to the extraction of metals or coal (Blowes et al., 2003).

In mines located in areas with intermittent precipitations, such as in Northern and Central Chile, and steep slopes where no flooding occurs, water, oxygen and sulfides strongly interact increasing the potential for AMD formation; additionally, the high evaporation rate causes the accumulation of sulfate salts that generate stronger AMD (Nordstrom, 2011). The potential AMD sources in Chile are significant: in 2002, 3,000,000 ton/day of waste rock were generated, and 650,000 ton/day of tailings (Ministerio de Minería & Consejo de Minería, 2002). On the other hand, Chile has a legacy of contamination of water resources due to past mining operations, which has to be addressed (Instituto de Ingenieros de Chile, 2011; Banco Mundial, 2011). Leaking tailing dams, acid mine drainage and small scale mining result in contamination of water resources that are often used for irrigation downstream. In Northern and Central Chile, many rivers present concentrations of metals and sulfate that exceed irrigation water quality standards. Since the 1980s, levels of arsenic, copper and sulfate have increased (Banco Mundial, 2011). These problems demand long-term passive solutions that are low cost and make use of local resources.

Several physicochemical and biological techniques have been developed to treat AMD. In conventional active treatment, acidity and metals are removed by continuous addition of alkaline substances (such as NaOH, $Ca(OH)_2$, CaO, Na_2CO_3 and NH_3), which can be expensive, specially when needed in high quantities; also, costs of operation and maintenance of active systems are high (Watzlaf et al., 2004). During the last decades, research has focused on the development of passive treatment systems for AMD, because passive systems have shown high metal removal at low pH values (pH 3-6), sludges that are chemically stable, low operational and maintenance costs, reduced chemical consumption and minimal consumption of energy. The passive treatment systems use addition of limestone to generate alkalinity and precipitate metals as oxides and/or use biological processes in which sulfate reduction takes place through which alkalinity is generated and metals precipitate as sulfides.

In biological treatment systems such as anaerobic wetlands, remediation of dissolved metals is mainly caused by sulfate reduction, which simultaneously removes sulfate, metals and acidity. Metals are also precipitated as a result of some abiotic reactions that result from the reducing ambient that is generated (Kosolapov et al., 2004) such as precipitation of metal oxides or carbonates driven by a pH increase (Gadd, 2000). The precipitation of metals by sulfate reduction occurs when the produced H_2S reacts with the metals to produce insoluble precipitates (Zagury et al., 2006). For sulfate reduction to be successful a pH range of 5 to 8 is required; outside this range, reduction diminishes and the capacity of metal removal is reduced. At low pH (< 5), sulfate reduction is normally inhibited and the solubility of metal sulfides increases (Neculita et al., 2007). However, sulfate-reducing bacteria (SRB) surviving at pH of 2.5 have been found, although with only slight alkalinity generation (Tsukamoto et al., 2004). Also, a reduced anaerobic medium is required for sulfate reduction with redox potential (Eh) of less than -100 mV (Rabus et al., 2006). The substrate usually used to drive sulfate reduction is principally made of organic residues such

as animal feces, compost and agricultural residues (Neculita et al., 2008). Adequate proportions of different organic sources are required for long-term operation of the biological treatment system (Sheoran et al., 2010). The efficacy of these systems will be affected by pH variations, metal concentrations, and concentrations of sulfide produced in-situ, which may be also toxic.

The development of biological treatment systems must be focused on the adequate proportions of different organic sources, avoiding AMD toxicity to microorganisms, and studying the key bacterial populations involved in treatment. Research results suggest that a good organic energy source for sulfate reducing communities must contain several carbon sources (Waybrand et al., 1998; Zagury et al., 2006). Substrates with cellulose have been confirmed to be more efficient than lignocellulosic substrates (Waybrand et al., 1998). An optimum mixture must contain equal proportions of cellulosic and non-cellulosic organic residues (Neculita et al., 2008). The non-cellulosic organic residues (compost and manure) accelerate the activity of sulfate reducers at the start of the system (Wildeman (2006), cited by McCauley et al., 2009). The cellulose delivers the long-term organic matter and must be hydrolyzed and fermented by a microbial consortium that provides the simple carbon sources to SRB.

Our research addresses protection from toxicity. We take advantage of chemical gradient-based bioprotection, a mechanism by which some bacteria in a community induce pore-water metal gradients (Schwarz & Rittmann 2007a; 2007b). Bioprotecting gradients can occur over a broad range of scales: μm - mm in biofilms, mm - cm in freshwater and marine sediments, and cm - m in groundwater aquifers. An excellent example of this community-based bioprotection mechanism involves SRB, which produce sulfide that can coordinate toxic free metals to form solids. Results of previous analytical and numerical modeling (Schwarz & Rittmann, 2007a; 2007b) provide evidence that gradient resistance ought to work much better in diffusion-dominated systems, compared to advection-dominated systems. This insight led us to develop the diffusive exchange system (DES) approach to be used in permeable reactive barriers or constructed wetlands. In DES reactors, layers of low conductivity (low-K) containing reactive organic materials are intercalated between layers of high conductivity (high-K) that transport the AMD across the reactor. Because diffusion dominates transport in the reactive layers, microbial communities can take advantage there of the chemical-gradient mechanism for protection from toxicants. Specifically, we experimented with a porous layered system where the reactive sulfate reducing layers with low hydraulic conductivity were intercalated between sand layers with higher hydraulic conductivity. The sulfide produced in the reactive layers diffused to the sand layers where the metals precipitated. This system avoided the direct contact between microorganisms and the flowing AMD.

METHODOLOGY

The DES reactor, with horizontal gravitational flow, had dimensions of 120 cm x 60 cm x 10 cm (L x H x W) (Fig. 1). It was filled with horizontal layers of 10 cm thickness of reactive material and sand (3 each). The flow was controlled by means of a peristaltic pump feeding the upgradient well (Masterflex, 0.02–100 rpm). Both upgradient and downgradient, a 10 cm zone was included to facilitate distribution of influent flow over the reactor height and retain the reactive material, respectively. The reactor had a glass wall on one side, to allow observation of materials, and positions where precipitates deposited.

The geometric design of the reactor fulfilled the analytical criteria of Schwarz & Rittmann (2007a) for chemical-based bioprotection. In this case, the criteria were used to define the minimum thickness of reactive layers and maximum flow velocity.

The reactive material was a mixture of *Pinus radiata* bark compost, digested sludge from a local wastewater treatment plant, sand, and calcium sulfate to promote initial sulfate reduction. To inoculate the mixture, it was wetted with anaerobic digester content of the same wastewater treatment plant.

The reactor was fed with local spring water modified to obtain a pH of 2.5–3.5 and concentrations of 450 mg/L Fe (II), 100 mg/L Zn, 20 mg/L Mn, 5 mg/L Cu and 3,100 mg/L SO_4^{2-}. During 14 months, the flow was controlled at 1.5 ml/min. Concentrations of SO_4^{2-} (Method 4500E (APHA, 2005)), H_2S-HS^- (Method 4500-S2-D (APHA, 2005)), Zn^{2+} (Method 3500-Zn-B (APHA, 2005)), Fe (Method 3500-Fe (APHA, 2005)), Cu (Method 3500-Cu (APHA, 2005)), Ni (Method PAN (HACH)), pH, and Eh, were determined in the influent and effluent weekly. Influent pH was initially 3.5, but then changed to 2.5 to chemically stabilize the reactor feed, since at pH of 3.5, precipitates were observed in the feed tank, probably due to Fe oxidation and precipitation.

During the last 5 months, the effluent was also fed to a 10-L bucket (the "settler"), to test the effect of oxidizing conditions on treatment performance and effluent quality.

Finally, after 3 months, the possibility of rejuvenating spent organic layers was tested. A solution of 20 g/L of microcrystalline cellulose (MCC) (Sigmacell, 20 μm) was injected into reactive layers at 5–cm intervals (27 g of MCC in total).

Figure 1 Experimental system

RESULTS AND DISCUSSION

Although the reactor was operated under metal and acidity overload for the entire period of 14 months, it consistently reduced sulfate and metal concentrations, and added alkalinity. This is the first time a biochemical reactor has been operated passively, without an external source of alkalinity, such as calcite, at very low pH and high metal load.

This stable operation is indicative of a bioprotection mechanism based on chemical gradients protecting the microbial community within the reactive layers of low permeability (Schwarz & Rittmann, 2007a; 2007b; 2010). Additionally, the system did not show any permeability reduction. Metals precipitated along the interfaces between the conductive and reactive layers, where sulfide and metal gradients meet, consistent with the bioprotection mechanism based on chemical gradients.

Fig. 2 shows measured concentrations of chemical parameters at the inlet and outlet of the reactor for the 14-months operation period. For the last 5 months, values at the outflow of the settler are also shown. Influent concentrations were measured at the feeding well, located immediately

upgradient of the porous materials. Similarly, effluent concentrations were measured at the downgradient well. These wells were separated from the porous materials by a fine mesh. In the entry well, pH and metal concentrations already differed from nominal values in the feeding tank. This difference was significant during the first 3 months due to iron oxidation and precipitation in the feeding tank and well. Hence metal concentrations are shown from month 4 on. Chemical instability of Fe was finally avoided by reducing the pH in the feed to 2.5. Even then, feeding well values fluctuated around nominal values probably because feeding well composition is already affected by biochemical reactions in the reactor.

The sulfide peak occurred after the MCC injection. This peak was coincident with a decrease in effluent sulfate. Although, the stimulating effect lasted less than 2 months, higher MCC concentrations could be used to make it last longer.

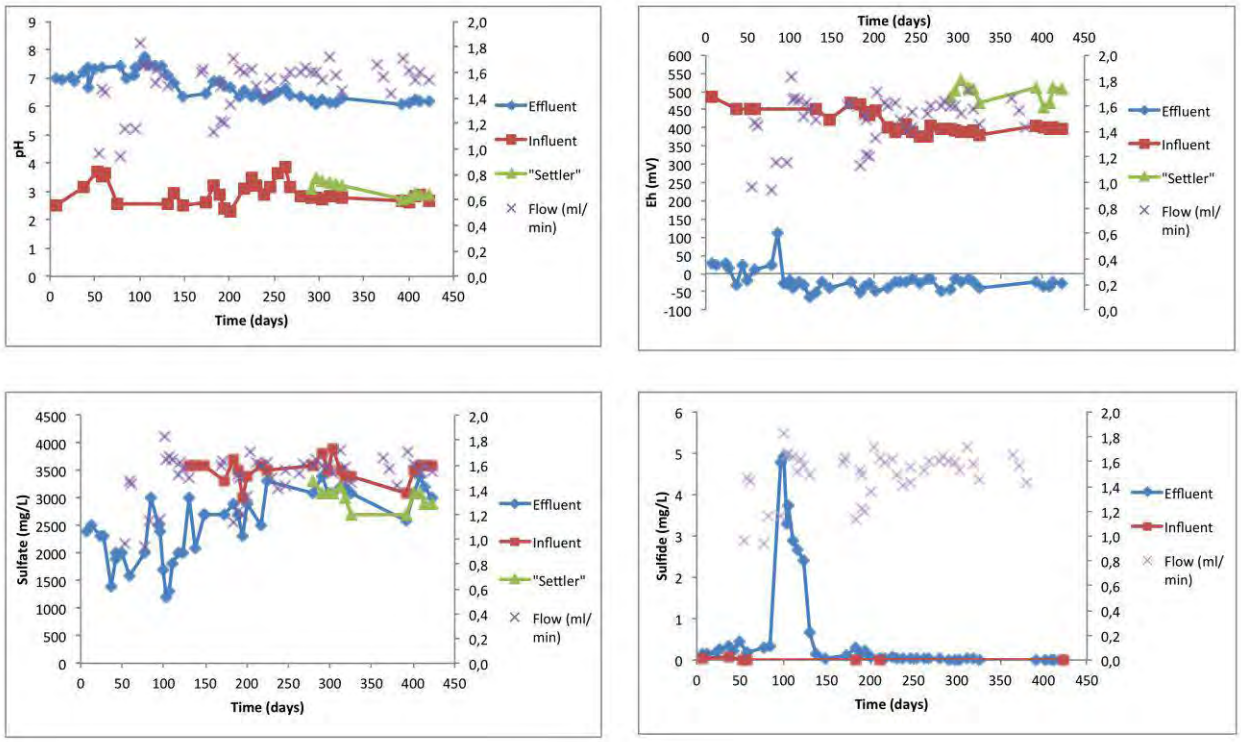

Figure 2 Measured values of pH, Eh, and concentrations of sulfate and sulfide

The effluent pH was near neutral all the time, and hence the reactor neutralized proton acidity, generating an adequate environment for the microbial community. On the other hand, the acidity coming from Fe (II) was only partially neutralized. Under oxidizing conditions in the settler, Fe (II) oxidation and Fe (III) precipitation occurred, and the pH dropped to influent values at which Fe (II) oxidation slowed down significantly. As the Fe graph shows (Fig. 3), the reactor itself removed little Fe, but a significant fraction was removed in the settler as hydroxides, thanks to the alkalinity added by the reactor, that also neutralized part of Fe acidity. Additionally, the reactor showed negative redox potentials, allowing successful establishment of sulfate reducing communities.

Zn removal (Fig. 3) occurred within the reactor, probably as sulfides, as evidenced by white precipitates along interfaces between reactive and conductive layers. Also, sulfide solubility

products are lower for zinc than for iron, hence sulfide generated in the reactive layers, reacted preferentially with zinc. Similarly, nickel was only removed in the reactor.

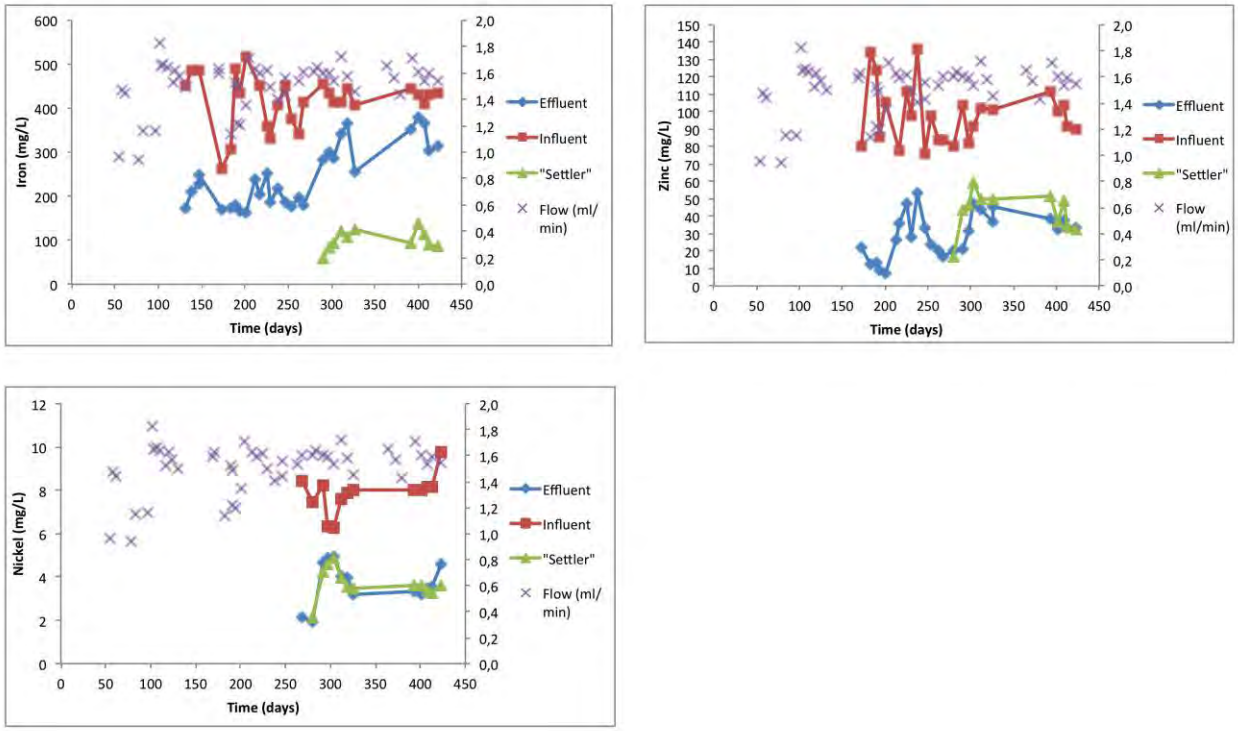

Figure 3 Measured concentrations of metals Fe, Zn, and Ni

Figure 4 shows white precipitates along the boundaries between layers, consistent with gradient-based resistance.

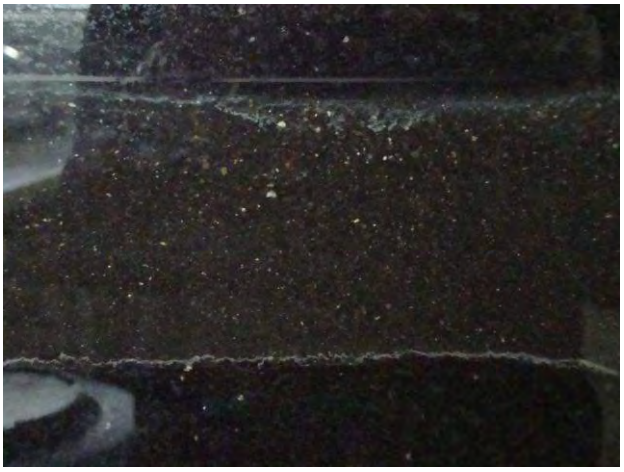

Figure 4 Location of precipitates along layer boundaries. The darker is the organic layer

CONCLUSIONS

DES reactors hold promise for passive treatment of highly acidic and toxic AMD, like the one generated by the copper mining industry in Chile. Within these reactors higher reaction rates are feasible, microbial consortia are protected from toxicity, and no permeability reduction due to precipitate formation is observed.

The key characteristic of DES systems is that reactive zones are separated from the zones of advective transport of contaminated water. An advantage of this zonation is that reactive and conductive zones can be optimized independently. The advection zone can be optimized to maintain an adequate hydraulic conductivity in the long term by using highly permeable materials. Similarly, higher sulfate–reducing rates in reactive zones of DES systems by using finely ground organic materials are possible.

Mitigating Acid Rock Drainage with Land-Applied Biochemical Reactor Effluent

James Gusek
Sovereign Consulting Inc., USA

ABSTRACT

Perpetual treatment of acid rock drainage (ARD) is unsustainable; ARD suppression at its source is the logical strategy to avoid or lessen ARD impacts. Innovative mitigation concepts have been advanced in recent years; the concept of land-applying biochemical reactor (BCR) effluent to suppress ARD is another promising strategic tool. The concept's elegance lies with the merging of two well-developed mine remediation/processing technologies: BCRs and heap or dump leaching of metal ores. In the proposed innovative approach, organic-rich effluent from a BCR would be land-applied to acid-producing mine waste (e.g., tailings, waste rock, and coal refuse) with solution application methods typically used in heap leach pads. BCR effluent is typically anoxic and contains biochemical oxygen demand, excess alkalinity, dissolved sulfide ion, and dissolved manganese. The process would capitalize on these characteristics to coat mine waste with films of biosolids and/or manganese oxide that would suppress biological and abiotic pyrite oxidation. To the author's knowledge, this technology has not been implemented in a formal way but anecdotal information suggests that a properly-engineered application could yield significant long term environmental benefits.

Keywords: ARD, bactericide, sustainability, heap leaching

INTRODUCTION

A Medical Analogue

If one can embrace the medical analogue, much of the mining industry currently suffers from a massive bacterial infection. When pyrite-bearing or sulfide-bearing rock formations, tailings, or mine wastes are infected by *Acidithiobacillus ferrooxidans*, the likelihood of forming acid rock drainage (ARD) is almost guaranteed. The "pharmacy" of antibiotics available is extensive, ranging from solid alkaline amendments like limestone to liquid "medicines" such as sodium lauryl sulfate and sodium thiocyanate. Many of these materials may be in short supply (locally), or carry inconvenient side-effects. The danger of re-infection is a concern that also needs to be addressed. A "probiotic", naturally-sustainable regimen that introduces a microbial consortium that outcompetes the acidophiles may be the key to why some previous antibiotic applications continue to work for decades. See Gusek and Rastogi, 2015.

Unfortunately, the "geo-medical" teams of geochemists, microbiologists, engineers, and mine managers lack the tools to surgically apply these active ingredients where they are needed most with a minimum of waste. The implementation of up-to-date best management practices has not healed the patient; the equivalent of an intravenous drip of a very inexpensive generic medicine followed by a pro-biotic protocol is clearly needed.

An "Intravenous Drip" for ARD Suppression

The answer to this problem may lie with the merging of two well-developed mine remediation/ processing technologies: biochemical reactors (BCRs) and heap or dump leaching of metal ores. In the proposed innovative technology, organic-rich effluent from a BCR would be land-applied to acid-producing mine waste (e.g., tailings, waste rock, and coal refuse) using solution application methods typically used in precious metal heap leach pads.

BCR effluent is typically anoxic and contains biochemical oxygen demand, excess alkalinity, dissolved sulfide ion and manganese. If all these antibiotic and probiotic characteristics can be preserved and the BCR effluent solution can be dispersed over a large area of mine waste (which could be either revegetated or barren), the downward percolating solution should coat the mine waste with a film of probiotic bacteria-supporting biosolids that would suppress biological and abiotic pyrite oxidation. While to the author's knowledge this has never been implemented, it is believed that heap leach solution application techniques could accomplish this inexpensively. The mine waste ARD source would behave similar to a trickling filter in a waste water treatment plant. ARD might be suppressed for decades, perhaps longer, before a "booster shot" of BCR effluent might be required.

ARD REFRESHER

The formation of ARD is a natural process. In the presence of air, water, and acidophilic bacteria, sulfide minerals such as pyrite oxidize and produce sulfuric acid; concurrently, iron and other metals are released into the water. The problem can be associated with both coal and hard rock operations where previously buried sulfide minerals are exposed to oxygen and water. The descriptions of the bio-geochemical reactions responsible for ARD are found in many technical

papers and will not be repeated here. However, it may be reasonable to revisit the general conditions required for ARD to form.

ARD Tetrahedron

Considered simply, the elementary ingredients required for the formation of ARD are analogous to the components needed for the burning of combustible materials. To start a fire, one must have air, heat, and a fuel source. To generate ARD, one needs air, water, a pyrite source, and the bacteria to speed reactions that would otherwise occur slowly: consider an "ARD Tetrahedron" concept (see Figure 1), with each requirement positioned at a vertex. If any of the primary ingredients are missing, isolated, or chemically neutralized, fire/ARD will not form. Pyrite will oxidize in the absence of acidophilic bacteria; however, these bacteria are reported to accelerate the kinetics of pyrite oxidation by an order of magnitude (Baldi, et al. 1992).

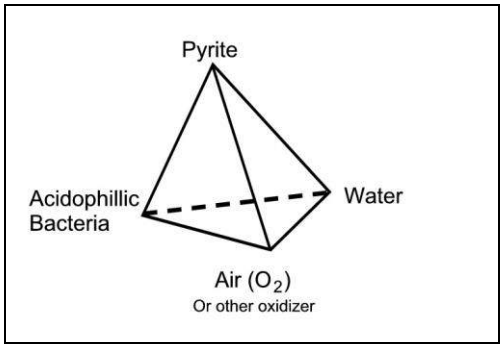

Figure 1 ARD Tetrahedron (Gusek, 1994)

Baseline Testing

The tendency of a given rock or material to produce ARD is predicted by a number of standard tests, including acid-base accounting, humidity cells, and column leach testing. Based on this author's experience, the microbial component of ARD production in these tests is rarely assessed. Even more rarely, probiotic measures such as the application of waste milk to create heterotrophic biofilms that outcompete acidophiles (Jin et al. 2008) have only recently been considered as viable technologies.

However, the concept of introducing competing bacteria is not new. Sobek, Benedetti, and Rastogi (1990) suggested that a probiotic process would complement the application of a slow-release acidophilic bactericide, sodium lauryl sulfate:

> "Inhibiting or destroying thiobacilli can significantly slow the rate of acid production. Anionic surfactants, organic acids and food preservatives (Onysko et al. 1984) act as bactericides and kill these bacteria; however; bactericides degrade over time and are lost because of leaching and runoff. To overcome the inherent short duration effectiveness of spray applications, controlled release systems to provide the bactericide slowly over a long time period were developed (Sobek et al. 1985).
>
> Control of acid generation for prolonged periods greatly enhances reclamation efforts and can reduce reclamation costs by reducing the amount of topsoil needed to establish vegetation. Three natural processes resulting from strong

vegetative cover for three years or more can break the acid production cycle. These processes are:

1) A healthy root system that competes for both oxygen and moisture with acid-producing bacteria;

2) Populations of beneficial heterotrophic soil bacteria and fungi that are re-established, resulting in the formation of organic acids that are inhibitory to *T. ferrooxidans* (Tuttle et al. 1977); and

3) The action of plant root respiration and heterotrophic bacteria increase CO_2 levels in the spoil, resulting in an unfavorable microenvironment for growth of *T. ferrooxidans.*"

Sobek, Benedetti, and Rastogi viewed antibacterial application as a method to reduce the volume of topsoil to revegetate potentially acid generating or PAG waste. They believed that at least three years of acidophilic bacterial suppression was sufficient to accomplish this goal.

The 21st century ARD-focused community of geochemists may be aware of how acidophilic bacteria promote ARD but they may not understand its kinetic importance. An informal survey suggests that inclusion of acidophilic inoculum, bactericides, and nutrients to support competing bacteria in humidity cell and column leach tests is rarely attempted because the effects of bactericides have always been considered temporary. As Sobek, Benedetti, and Rastogi (1990) suggest, that might be true but the limitation might be overcome by substitution of heterotrophic bacteria and fungi into the ARD generation zone coupled with a slow-release bactericide.

BIOCHEMICAL REACTOR TECHNOLOGY REFRESHER

Sulfate reduction in biochemical reactors (BCRs) has been shown to effectively treat ARD containing dissolved heavy metals, including aluminum, in a variety of situations. The chemical reactions are facilitated by the bacteria *Desulfovibrio* in BCRs as shown schematically in Figure 2 and the photo in Figure 3. However, a consortium of bacteria contribute to this effort as discussed in Seyler et al. (2003).

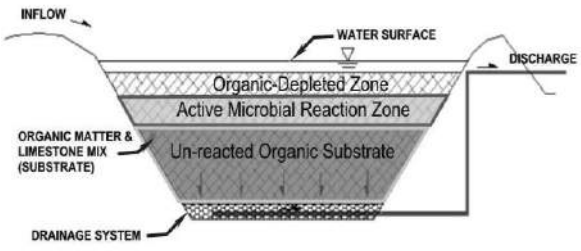

Figure 2 Down-flow Biochemical Reactor Schematic

Figure 3 A Typical Biochemical Reactor

The key conditions for sulfate reducing bacteria (SRB) health are a pH of 5.0 (maintained by the SRB itself through the bicarbonate reaction and/or the presence of limestone sand), the presence of a source of sulfate (typically from the ARD), and organic matter (from the substrate). BCRs have

been successful at substantially reducing metal concentrations, nitrate concentrations, and favorably adjusting pH of metal and coal mine drainages.

As discussed in Blumenstein & Gusek (2010), typical BCR effluent contains biochemical oxygen (BOD)/dissolved total organic carbon (TOC), and sulfide in varying concentrations. Ironically, when compared to the context of this paper, these are referred to as "nuisance" parameters that need to be addressed in order to allow the discharge of a BCR effluent to a natural receiving stream that might be impacted by BOD and the depressed dissolved oxygen characteristics of raw BCR effluent.

Fortunately, the BOC/TOC cited above are also probiotic nutrients that can support a microbial community that can occupy and quickly displace the niche occupied by the acidophiles.

It is noteworthy that BCRs do not remove manganese. Thus, any dissolved manganese present in the BCR present is available to create encapsulating and metal adsorption-capable films of MnO_2 ("desert varnish") under certain aerobic conditions.

HEAP LEACH TECHNOLOGY REFRESHER

Heap leaching technology was described by Agricola in the 16th century as a method for recovering alum for tanning of animal hides (Kappes, 2002). In America, a similar technology was used in Vermont in the early-1800's at the Elizabeth Mine for recovery of Copperas, or hydrated ferrous sulfate, that was used for curing and setting colors in hides and pelts, dye and ink manufacturing, and for treating timber (Hammarstrom et al. in Slack, 2001). Modern gold and silver heap leaching practices matured in the western USA in the early 1970s and are now used world-wide.

The recovery of metals from ore heaps or marginal mine waste dumps involves the application of a "barren" leach solution (typically sodium cyanide in the case of precious metals and sulfuric acid in the case of copper) to dissolve the metals to yield a pregnant or "preg" solution that is recovered by gravity and processed for the metal(s) of interest. After the metals are recovered from the preg solution, the resulting barren solution is recycled back to the heap to leach more metals. Several holding and process ponds are involved as shown in Figure 4.

Kappes (2002) provides an overview of the heap leaching process; design aspects related to the application of BCR effluent to mine wastes follow.

Solution distribution piping that is typically installed on top of the heap or dump is a leaching design feature of special interest with regard to ARD suppression. There are four mainstream methods for applying barren solution (Kappes, 2002):

- Drip emitters,
- Wobbler sprinklers,
- Reciprocating sprinklers, and
- High rate evaporative sprinklers.

To preserve the anoxic and geochemically reducing characteristics exhibited by BCR effluent, reciprocating and evaporative sprinklers would logically be avoided. The oxidation of BCR effluent as it traveled from the sprinkler head to the PAG rock surface or tailings surface would result in a deposit of biosolids and noxious odor.

Drip emitters or wobbler sprinklers would allow the well-buffered, soluble TOC containing solution to infiltrate into and percolate through the mine waste where ARD-suppressing biofilms should form along preferential pathways. This approach would be especially attractive in situations where the mine waste repository surface had already been revegetated. BCR effluent

would percolate through the plant growth medium and some buffering and organic matter addition would certainly bolster the productivity of the vegetative community.

A typical leach pad solution distribution system is comprised of a series of header pipes and sub-header pipes connected to a series of lateral pipes or hoses into which the drip emitters or wobbler sprinklers are installed. Whether or not the distribution piping is removed prior to a leach pad's or waste repository's receiving a fresh lift of ore-grade material will vary depending on site-specific economics. It may be more cost effective to abandon a piping network in place rather than expending the time and labor effort to dismantle, move, and reinstall it elsewhere on the site.

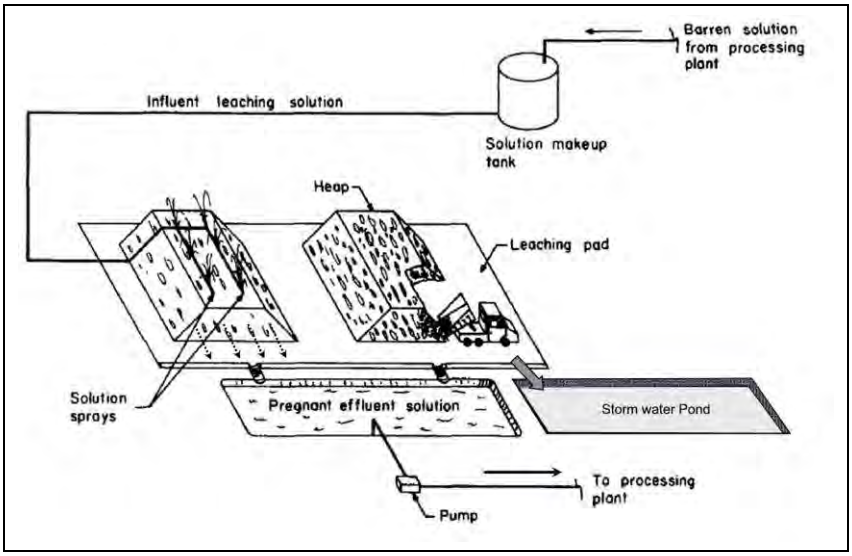

Figure 4 Heap Leach Pad Schematic (After Chamberlain & Pojar, 1984)

As subsequently discussed, it is unlikely that a BCR effluent solution distribution system would be abandoned in place due to the relatively temporary (compared to a "resource recovery" operation) deployment over an ARD-producing zone in the mine waste repository (which might include pit walls). Rather, the solution distribution system would be designed to be modular and easily transferred in a sequential fashion to where it would be needed next at the site.

If a heap leach pad contains PAG rock, it is probably only a matter of time before ARD becomes an issue. Cellan, et al. (1997) described the construction of a "Biopass" system at the closed Santa Fe gold mine in Mineral County, Nevada. The installation included retrofitting a geomembrane-lined solution pond into a BCR. The effluent from the BCR flowed by gravity through a buried pipeline to a leach field. The proposed ARD-suppressing process would differ from the Cellan et al. concept by recycling the effluent from the retrofitted pond(s) back to the source of the ARD. Of course, this will alter the water balance of the leach facility and a "circulating load" of mining influenced water would need to be managed. A new water balance estimate would be design necessity if BCR effluent is applied to the PAG waste in this fashion.

Faulkner (2015) described a "nuisance" condition where elevated BOD-containing BCR effluent from a newly commissioned unit was land-applied to a waste rock dump that exhibited elevated selenium concentrations. The selenium concentrations in the dump seepage co-incidentally decreased in response to the BCR effluent application. It is too early to say if the decreased selenium levels will persist after the land application activity was suspended.

VACCINATION VS MEDICATION?

Continuing with the medical analogy, vaccination to suppress ARD should ideally occur shortly after pyritic waste is either excavated or placed. Thus, vaccination would occur before the acidophilic bacterial community has a chance to mature. The medical sage advice of Benjamin Franklin, "an ounce of prevention is worth a pound of cure", is especially appropriate but it might be updated for a mine site application to read: "a tonne of ARD prevention is worth a hectare of passive treatment".

The advantages of pursuing this preventive protocol include:

- Closer control of ARD-suppressing solution application (focused only on PAG waste zones identified by geophysics, mining records, field testing, or other methods),
- Lower cost because the levels of stored acidity in the PAG waste (if it is fresh) should be low,
- Better management of ARD issues throughout the mine life instead of waiting until closure and attempting to gain control of a "Stage 4" geo-bacterial condition, and
- Lower costs of active treatment during operations.

The application of geo-medicines to suppress ARD on legacy sites that have been "cooking" for years offers a special challenge. This is the analogous "medication" scenario. As the surfactant-based bactericides such as sodium lauryl sulfate are organic compounds, they are susceptible to degradation when exposed to acidic conditions on the acidified mineral surfaces. In this author's opinion, any bactericide should be applied in a solution that is well-buffered and contains enough alkalinity to protect the bactericide's molecular integrity from the stored acidity in the mine waste. This suggests that medicating a "thoroughly-infected" mine waste material will be more expensive than the implementing vaccinating protocol described above for the same material.

The preference to engineer a "silver bullet" process to suppress ARD with bactericides and probiotic nutrients in a single "cocktail" application is a strong one. It will save costs and time. However, unpublished data suggests that some acidophilic bactericides are also toxic to probiotic bacterial communities. This finding suggests that a sequential application strategy may have a better chance of success in producing the desired outcome: decimation of the acidophilic community and its replacement with a self-sustaining heterotrophic community perpetually supported by organic acids from the healthy vegetation on the surface of the site.

Expected ARD Suppression Mechanisms

The percolating BCR effluent should contain at least five characteristics known to suppress ARD:

1. Dissolved organic carbon (measured as BOD or TOC),
2. Bicarbonate alkalinity,
3. Reducing oxidation reduction potential (ORP) of – 100 mv or less,
4. Low dissolved oxygen [DO] (<1 mg/L),
5. Dissolved sulfide ion, and
6. Dissolved manganese.

The alkalinity and low DO in the BCR effluent should decimate the acidophilic community. The sulfide ion and reducing ORP conditions should facilitate precipitating any dissolved ferrous iron

the solution encounters as a monosulfide (FeS). The BOD present in the solution should be oxidized and form a coating of biosolids on the mine waste particle surfaces. This biofilm layer should support a microbial community that outcompetes the acidophilic community and thereby suppress ARD formation. Based on the slow degradation of organic matter in municipal landfills, the beneficial effects of these combined mechanisms could persist for decades.

The benefits of manganese dioxide MnO_2 deposition would occur deeper in the rock/waste "column" under oxidizing conditions. The MnO_2 would tend to coat exposed rock surfaces along the preferential flow pathways. This reaction would only occur at circum-neutral pH such as that provided by well-buffered BCR effluent.

The proposed ARD suppression method is more appropriate to surface mining situations such as:

- Heap leach facilities,
- Tailing storage facilities,
- Waste rock repositories,
- Coal refuse disposal sites (fine and coarse refuse), and
- Pit walls.

Space limitations prohibit more detailed discussions on how BCR effluent application with heap leach pad drip emitters might be implemented in the above situations. However, it must be stressed that the long-term success of the proposed technology depends on the ultimate establishment of a robust vegetated cover to create a perpetual "probiotic" almost walkaway ARD remedy. Again, this "marriage" of BCR and heap leaching technologies is conceptual; to the author's knowledge, it has never been implemented.

MEDICATION CASE STUDIES

The application of BCR effluent to suppress ARD is a promising concept. Anecdotal information suggests that there may be sites in the USA where it is being evaluated. Consequently, only two case studies in the literature appear to be available to suggest that the concept could work with an appropriate level of design effort.

Antibiotic Case Study in Pennsylvania, USA

Plocus and Rastogi (1997) sequentially injected solutions of caustic soda (NaOH) and sodium lauryl sulfate at the Fisher Coal Mine in Pennsylvania USA in 1995. The PAG rock zone in a backfilled coal pit had been identified using geophysical techniques. The site was fully revegetated at the time of the two-step caustic/bactericide application through a network of shallow and deep injection boreholes that mimicked the pattern typically found in a heap leach pad. The effects of the injection process were dramatic. See Gusek and Plocus (2015). Chemistry of a toe seep at the site improved enough within 30 days that chemical treatment of the ARD was no longer required. In 2014, almost two decades later, this is still the case. The seepage chemistry is suitable enough to be polished in an aerobic passive treatment system. Bond release for the site is pending.

Probiotic Case Study in Tennessee, USA

An injection/treatment process similar to the one described by Plocus and Rastogi was implemented at the Sequatchie Valley coal mine in Tennessee. In this case, waste milk and a bacterial inoculum (biosolids) were injected into mine waste that had been reclaimed and revegetated. The project, completed by the Western Research Institute (Jin, et al., 2008 and ITRC, 2014) was undertaken to establish a bio-film of bacteria on the pyritic waste that would out-compete *Acidithiobacillus ferrooxidans* and thereby prevent ARD. While details are lacking, the technology was implemented in a 4 ha area exhibiting a seepage of about 0.12 m^3/min. (30 gpm).

Ground water upstream of the test plot exhibits typical ARD characteristics, depressed pH (5.5 to 6.0 standard units); the seepage downstream of the test plot exhibits a pH of 6.8 to 8 about four years after the initial injection event (ITRC, 2014). Plans are underway to evaluate this technology in a more con-trolled manner at the Sequatchie site.

It is interesting to note that this probiotic application did not include a specific bactericide as implemented by Plocus and Rastogi. This might be due to how the casein protein in milk behaves when it contacts an acidic environment: by curdling into a globular mass. One could theorize that this property imparts a "heat-seeking missile" effect to the patented process of using dairy products to suppress ARD. The milk proteins should selectively coat rock surfaces that are acidic. Regardless, conventional wisdom suggests that BCR effluent (with its high dissolved organic matter content) would be more similar to milk than to the two ARD-mitigating solutions that Plocus and Rastogi used sequentially at the Fisher site. Similar to milk's behavior, when BCR effluent encounters oxidizing conditions on a rock surface, a film of organic biosolids should be selectively deposited.

PRELIMINARY "MEDICATION" COST MODEL

Ultimately, the cost of implementing this ARD mitigation alternative would need to be compared to the costs of perpetual treatment. As a starting point, a drip irrigation cost estimating spreadsheet available from the University of Delaware Agricultural Extension (U. of D., 2014) was used to develop the cost of installing a drip irrigation system on a hypothetical 8.1 ha ARD "medication" situation site. The irrigation system was sized with a drip row spacing of about 1 meter to apply about 152.4 cm of BCR solution for over the span of a year.

This would amount to about 33.8 m^3 per day or 12344 m^3 per annum. The capital cost of the installation was about US$14500. The annual operating cost was estimated to be about US$19000, most of which was labor. Factoring in the useful life of the various capital components yielded an annual fixed cost of US$7200 to yield a total annual cost of about US$26000.

Gusek and Schneider (2010) cited a projected BCR unit treatment cost of US$0.31 per m^3 of effluent spread over the assumed 20-year BCR lifespan. This would amount to about US$4000 per year. Combining the drip sprinkler and BCR cost yielded an annual cost of about US$30000 per year or about US$3700 per ha or US$1500 per acre. Of course, the actual volume of BCR effluent required, its application rate, and duration may need to be adjusted for site-specific conditions which would be based on small scale field tests.

CONCLUSIONS

The re-purposing of BCR effluent to suppress ARD formation is a scientifically sound concept. It has never been implemented but if it works as expected, ubiquitous ARD suppressing materials such as wood chips, spoiled hay, straw, and animal manure could be locally procured to reduce costs and provide sustainable supplies that would be naturally grown, not manufactured. Carbon sequestration may be a small side benefit of the process. The upside potential of this innovative merging of two common mining technologies could provide a paradigm shift in mine remediation strategy that has incalculable benefits to society world-wide. This emerging technology could be another step on the "pathway to walkaway" with regard to mine closure.

The Utilization of Cellulosic Biomass in treating AMD and the Subsequent Generation of Fermentable Sugars

Edzai Magowo, Karl Rumbold and Craig Sheridan
Industrial and Mining Water Research Unit, University of the Witwatersrand, South Africa

ABSTRACT

The drainage from closed and abandoned mines is often acidic with elevated heavy metal concentrations. The interaction between acid mine drainage (AMD) and the environment has a significant impact. Whilst temporary remediation can lessen this impact, complete amelioration is only possible using active and/or passive treatment. Active technologies are often costly and can produce a secondary waste stream which may require additional treatment. In this project we explored a passive option combining different technologies. We recognise AMD as a resource of sulphuric acid which we used as a pre-treatment on cellulosic feedstock. Following this, we enzymatically digested the partially hydrolysed cellulose to produce fermentable sugars (which could be used to produce bioethanol). Concurrently, the pH of the AMD increased from 2.11 to 5.46 and 62% of the iron was removed from solution. Previous research has shown that sulfate is also remediated (primarily through dissimilatory sulfate reduction [DSR]). In this research we were successfully able to combine two separate, yet established technologies and were able to remediate AMD with a cellulosic feedstock through DSR and Fe precipitation, whilst being able to use the cellulose residue as a feedstock for bioethanol production.

Keywords: Cellulose, AMD, Fermentation Feedstock

INTRODUCTION

Acid mine drainage (AMD) refers to the outflow of acidic water from (usually abandoned) metal and coal mines. It is characterized by low pH and high concentrations of sulfate and heavy metals (Acid mine Drainage (AMD) South Africa, 2011). It is considered the most important mining industry related pollution problem (Rob and Robson, 1995; Johnson and Hallberg, 2005; Kuyacak *et al*, 2011). AMD occurs when sulfide ores are exposed to the atmosphere, which can be magnified through mining and milling activities, where oxidation reactions are initiated (Jennings *et al*., 2008; Zipper *et al*., 2011; McCathy, 2011; Johnson and Hallberg, 2005). Upon exposure to oxygen and water, pyritic minerals oxidise to form acidic, iron and sulfate rich drainage. The oxidation of the pyritic minerals is the primary mechanism by which acid is released into AMD (Ackil and Kodas, 2006, Neculita *et al*., 2007, Sangita *et al*., 2010). The reactions involved in the formation of AMD are a multistep process involving oxygen-independent and oxygen dependant reactions. A general equation for the process is (Equation 1):

$$FeS_2(s) + 14Fe^{3+}(aq) + 8H_2O = 15Fe^{2+}(aq) + 2SO_4^{2-} + 16H^+(aq) \quad (1)$$

The net effect of these reactions is to release H^+, which lowers pH and maintains the solubility of ferric ions (Blodau 2006).

AMD treatment can be achieved through active, semi-passive or passive methods (Greben *et al*., 2009). A broad range of passive and active treatment approaches are available for dealing with AMD. Neutralisation (pH control) is the AMD treatment mechanism for both passive and active systems. By increasing pH to create alkaline conditions, the solubility of most metals is significantly decreased by precipitation (Taylor *et al*., 2005).

In previous work, biomass has been successfully used to treat AMD. The results indicated that grasses hold promise for remediating AMD, as a maximum of 99% iron removal, 80% sulfate removal, and a final pH of 8.5 was achieved from initial conditions of 2000mg/l iron, 6000mg/l sulfate, and a pH of 3. (Sheridan *et al*., 2013).

In this study, it is hypothesised that the lignin fraction of grasses and other cellulosic feedstocks contain numerous reactive groups which bind to and remove metals from AMD. Simultaneously the sulfuric acid in the AMD hydrolyses hemicellulose and exposes the cellular structure of cellulose whereby it can be subjected to a subsequent enzymatic hydrolysis step. In this study, we assess the potential use of the acidity present in AMD to (at least) partially hydrolyse cellulose. This would result in partially remediated AMD as well as a fermentable feedstock which could be utilised to produce, for example, bioethanol.

Materials

Two different cellulosic feedstocks were tested in this study: sugarcane bagasse and switch grass. Sugarcane bagasse was originally obtained from Illovo Sugar Company based in Kwazulu Natal. The switch grass, *Panicum virgitum* (an indigenous perennial grass) was obtained milled from the laboratory of the School of Chemical and Metallurgical Engineering. The second batch of switch grass was collected from the African Leadership Academy garden. It was obtained already dry. The

enzyme (cellulase) was supplied by Yakult Pharmaceutical Ind. Co., Ltd from Tokyo, Japan. The enzyme was obtained in powdered form. The product name of the enzyme is Cellulase "Onozuka" FA. The enzyme was composed of cellulase 12% and lactose 88%.

METHODOLOGY

The AMD feed was exposed to different cellulosic feedstocks for a period of 14 weeks. The resulting materialwas subsequently enzymatically digested with cellulase. The pH of the AMD exposed to the biomass was measured using a bench top pH meter. The iron concentration was analysed using the Merck test kit number 114761 and the Merck spectroquant Pharo 300 according to the manufacture's manual. Reducing sugars were measured using a 1200 series Agilent HPLC. Scanning electron microscopy was done using an FEI Quanta 400 E-SEM.

RESULTS

Dissolved iron and pH changes

Figure 1 and Figure 2 show the increase in pH and the decrease in the dissolved iron concentration during treatment of AMD using different lignocellulosic biomass over the 14 week experimental period.

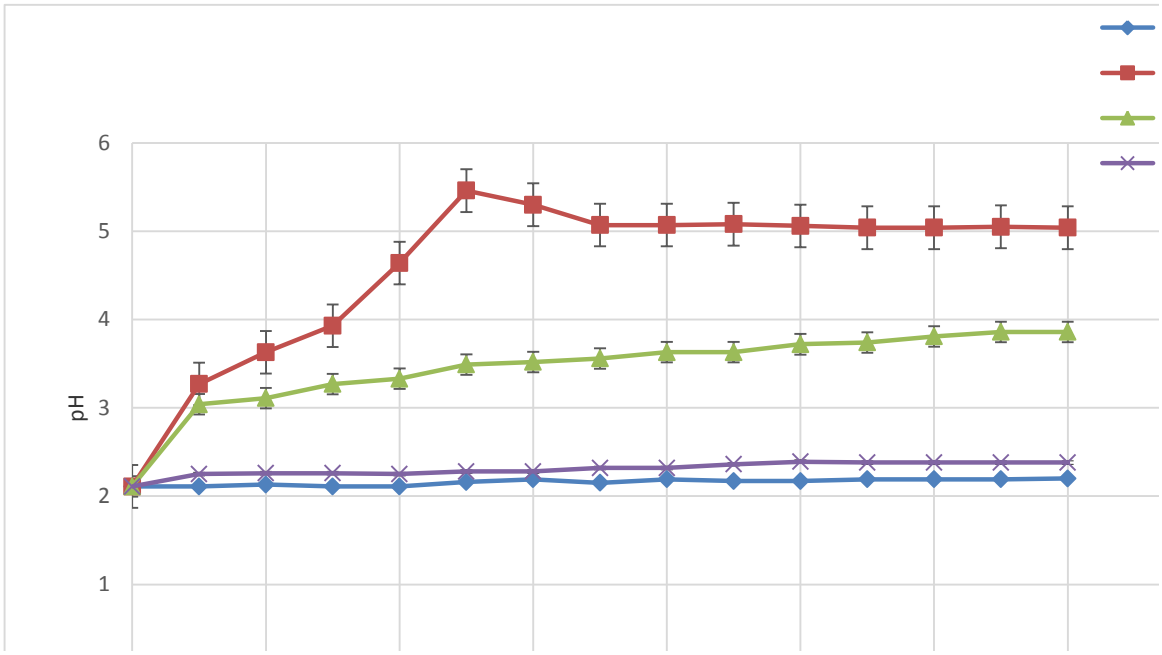

Figure 1 Changes in pH as effected through different types of lignocellulosic biomass

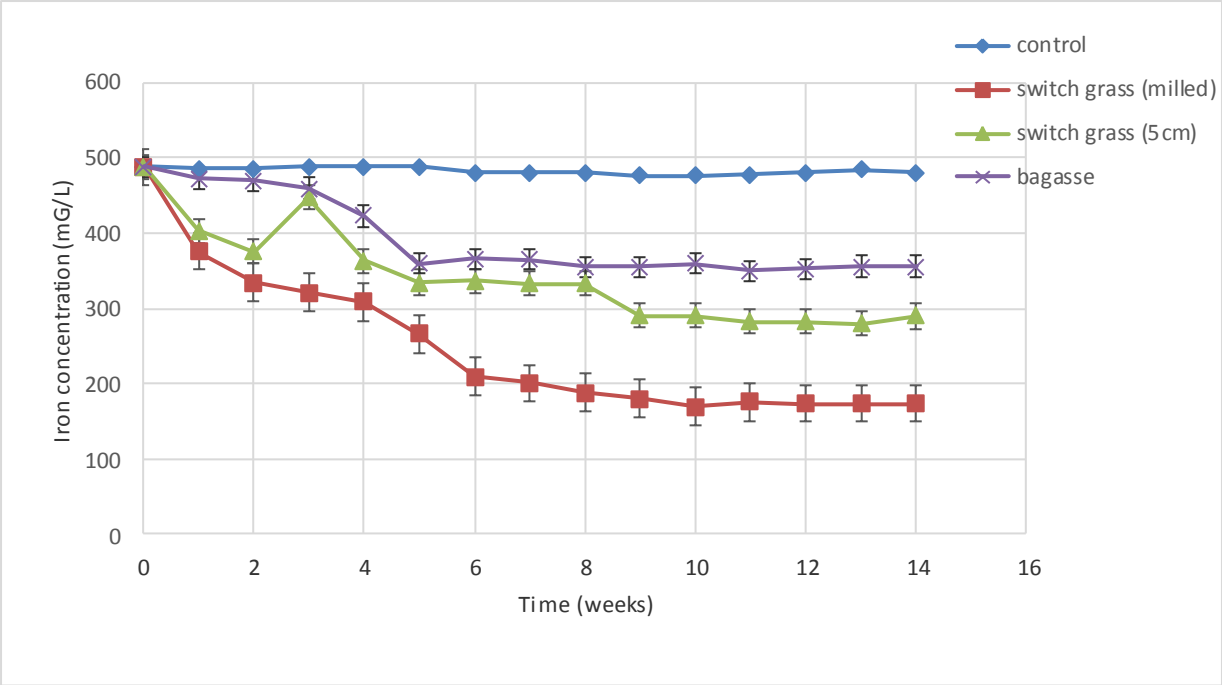

Figure 2 Changes in Iron concentration as effected by different types of lignocellulosic biomass

The data presented in Figures 1 and 2 indicate that the three sources of cellulosic biomass were able to effect some remediation of AMD. In all three cases dissolved iron concentration was reduced and pH was increased. The milled switch grass (≤2mm) was the most effective in the remediation of AMD. The milled switch grass was able to remove 65.2% of dissolved iron and increase the pH from 2.11 to 5.30. The maximum pH was obtained in a relatively shorter period of time (5 weeks). The switch grass (5cm) was able to remove 42% of dissolved iron and increased the pH from 2.11 to 3.86. Sugarcane bagasse had the least remedial effect on AMD. Sugarcane bagasse removed 28% of iron from AMD and increased the pH from 2.11 to 2.36; this was achieved in 14 weeks. The pH and the iron concentration of the control which contained only AMD did not change much during the experimental period, indicating that the biomass (switch grass and bagasse) caused the increase in alkalinity and the decrease in dissolved iron concentration. Similar results were obtained by Ramla (2012). In Ramla's investigation, two indigenous grass species, *Hyparrheia hirta* and *Setaria spacenta*. Maximum pH values of 8.48 and 99% percentage removal of iron from the AMD solution was reported in that study.

These values are comparable with the ones reported in literature for the biosorption and precipitation of metals on switch grass and other biomasses. According to literature the main mechanisms of metal ion removal in bioreactors are precipitation in the form of sulfides, hydroxides and carbonates and sorption mechanisms such as adsorption (Neculita *et al.*, 2007). The greatest effect on remediating the AMD was observed for the milled switchgrass. The decrease in dissolved iron in solution can be explained by the presence of a large number of active sites on the milled switch grass due to the increased surface area caused by milling. Functional groups capable

of metal sorption in biomass include phenolic, hydroxyl and carboxylic groups. Milling exposes these functional groups to the dissolved ions. These functional groups in the biomass are protonated at higher pH and presumably available for binding dissolved metals (Neculita *et al*., 2007). This explains the fact that the increase in pH is accompanied by a marked decrease in dissolved iron concentration (Figure 5.1).Increases in pH of acidic water effectively removes some metals due to the precipitation of metals in the form of hydroxides (Goatham, 2013).

Microbial activity also plays a role in the remediation of the AMD. Microbial activity was observed in the two switch grass series with the milled switch grass seeming to support more growth. IT is most probable that this microbial population is comprised of sulfate reducing bacteria (SRB). As explained by Ramla (2012), the increase in pH can be directly related to SRB population growth. The substrate may have been providing nutrients to sulfate reducing bacteria which contributed to the growth of the microbial population. The SRB activity reduces sulfate to sulfide and produces hydrogen carbonate (Equation 2). The hydrogen carbonate partially neutralises the AMD, while the hydrogen sulfide reacts with dissolved metals in the AMD, resulting in the precipitation of metals as metal sulfides (Equation 3) (Taylor *et al*, 2005).

$SO_4^{2-} + 2CH_2O + 2H^+ \rightarrow H_2S + 2H_2CO_3$ (Equation 2)

$H_2S + M^{2+} \rightarrow MS + 2H^+$ (Equation 3)

Where CH_2O are the sugars and M^{2+} represents metal ion.

The release of glucose during the treatment of AMD using milled switch grass (≤2mm)

The release of glucose was observed only in the milled switch grass, suggesting that milling was a significant factor in the generation of glucose. Milling reduces cellulose crystallinity and disrupts the lignin-carbohydrate complexes. This aids the acid treatment process and the subsequent enzyme hydrolysis (Mais *et al*., 2002: Carmen *et al*., 2013). The change in concentration of glucose is shown in Figure 3. Glucose started to appear in the third week of treatment where a rapid increase was observed. The maximum amount of glucose obtained was 8.4mg/ml in the seventh week. Thereafter the concentration decreased to 4.9mg/ml after 14 weeks. The decrease in glucose concentration may be explained by the consumption of glucose by sulfate reducing bacteria (SRB). The generation of glucose and other reducing sugars during AMD treatment is attributed to acid catalysis, where the sulfuric acid in the AMD catalyses the breakdown of cellulose and hemicellulose to release glucose, xylose and other degradation products. Hemicellulose, comprised mainly of mannan and xylan, accounts for up to a third of the total carbohydrate in many lignocellulosic materials (Pingali *et al*., 2010). In a study by Roman (2004), much higher levels of reducing sugars (306g/l) were produced. In that study, production was also followed by consumption. The consumption was accompanied by an increase in pH from 5.8 to 7. The increase in pH was found to be related to sulfate reduction and the production of alkalinity within the bioreactor.

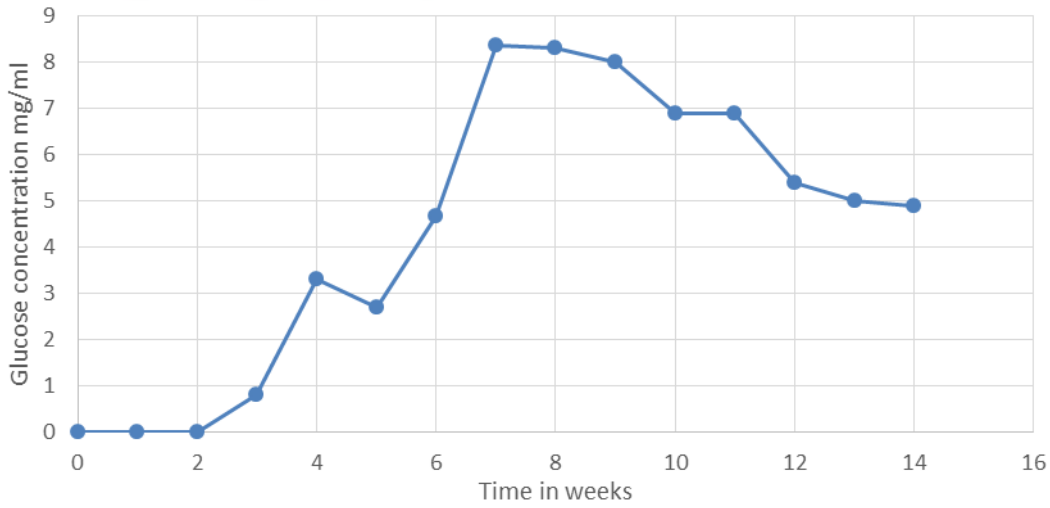

Figure 3 The release of glucose during treatment of AMD using milled switch grass

Scanning Electron Microscope (SEM) analysis of switch grass treated by water and AMD before and after enzymatic hydrolysis.

SEM was used to study the morphological features and surface characteristics of the switch grass treated by water and AMD before and after enzyme hydrolysis (Figure 4).

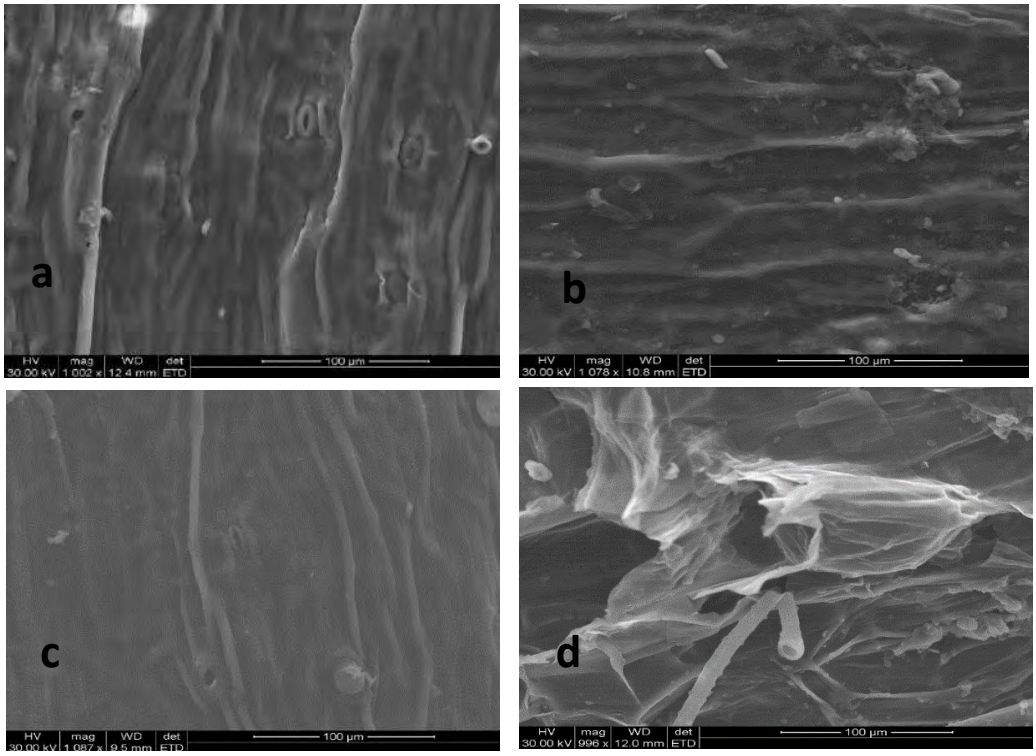

Figure 4 Scanning electron microscope images of switch grass (a) water treated, (b) AMD treated, (c) water treated followed by enzyme treatment and (d) AMD treated followed by enzyme treatment.

The SEM images reveal that pre-treatment induced significant morphological changes in the switch grass. Water treated switch grass exhibited rigid and highly ordered fibrils (Figure 4a). The fibres of the AMD treated switch grass appear to be distorted with some holes evident on the surface (Figure 4b). This renders the switch grass more accessible to cellulase, resulting in higher enzymatic hydrolysis rates and cellulose digestibility (Moxley *et al.*, 2008: Remli *et al*., 2013). The molecular structure of the water pre-treated and enzyme treated switch grass remained intact, showing no digestion occurred during the hydrolysis of the water treated switch grass (Figure 4c). The molecular structure of the switch grass which was pre-treated by AMD followed by enzyme digestion was completely destroyed (Figure 4d). The improved/altered morphological properties caused by AMD pre-treatment of switch grass appeared to be the primary source for the enhancement of enzymatic hydrolysis (Goshadrou *et al*., 2011). These micrographs are in agreement with the HPLC results shown in Table 1, which show high digestibility of AMD treated switch grass and no or very little digestibility in the water treated switch grass.

Enzymatic hydrolysis of AMD treated and untreated switch grass

Table 1 shows the concentrations of xylose and glucose after the enzymatic hydrolysis of the water treated and AMD treated switch grass as analysed using HPLC.

Table 1 Enzymatic hydrolysis of water treated and AMD treated switch grass.

	Water treated		AMD treated	
Enzyme %	Xylose mg/ml	Glucose mg/ml	Xylose mg/ml	Glucose mg/ml
0	0	0	0	0
0,5	0	0	1,9	0
2,5	0	0	3,3	3,8
5	0	0	0	4,8
10	1,4	0	3,4	3,7

The water treated sample was our control for this experiment. It is noted from Table 1 that the glucose yield for the water treated switch grass was zero for all the enzyme concentrations. The xylose yield was zero except for the 10% enzyme concentration which had xylose concentration of 1.4 mg/ml. The SEM images (Figure 4) showed that the water treated switch grass displayed no obvious signs of mechanical disruption of the general surface morphology. This rigid and compact structure of untreated lignocellulosic biomass hinders the effectivity of cellulase and prevents it from digesting the grass. The enzymatic digestion of the AMD treated switch grass show the concentrations of glucose and xylose in mg/ml. The maximum sugar concentration achieved with the milled switch grass were 4.8 mg/ml glucose at 5% enzyme concentration and 3,4 mg/ml xylose at 10% enzyme concentration. The enzyme concentration had a significant effect on the amounts of glucose and xylose obtained: there is a general increase of the glucose and xylose concentration with the increase in enzyme concentration. Small quantities of enzymes were ineffective in digesting the treated switch grass. The AMD treatment of the switch grass was therefore able to significantly improve the accessibility of the cell walls to enzymatic digestion, leading to greater sugar yields compared with the water treated switch grass.

DISCUSSION AND CONCLUSION

Switch grass has been shown in this study to have the capacity to effectively remove iron and acidity from AMD. The results indicate that milled switch grass (2mm) was more effective in remediating AMD than sugar cane bagasse or the large particle size switch grass (<5cm). The potential of switch grass, sugarcane bagasse and other lignocellulosic material to remove metals by adsorption is expected since such materials contain functional groups such as phenolic, hydroxyl, carboxyl and carboxylic (Harman *et al*., 2007). This theory is supported by Minawar and Riwandi (2010) who attributed the decrease in dissolved iron in the first two weeks of AMD treatment to iron retention by the organic matter rather than iron precipitation. In our study the milled switch grass which had a higher surface area was able to retain more iron resulting in lower dissolved iron concentration. Zagury *et al*., 2006 (cited in Munawar and Riwandi, 2010) explained that metal

removal tends to occur sooner than to sulfate reduction, through adsorption of metals to organic matter. Once reducing conditions are established metal precipitation rather than adsorption becomes the predominant mechanism of removal. Munawar and Riwandi (2010) reported the decrease of sulfate concentration in the third week of their study, using chicken manure mixed with AMD. This was attributed to sulfate reduction to metal sulfides such as iron sulfide. In our study microbial activity seemed to dominate in the third week of AMD treatment supporting Munawar and Riwandis' findings that sulfate reduction occurs at a later stage of AMD treatment. SRB activity produces hydrogen carbonate which increases the alkalinity of the AMD.

The milled switch grass was able to increase the pH of the AMD from 2.11 to 5.30 and to remove dissolved iron from the AMD by 65.2% by the fifth week. Both the pH and the dissolved iron content started to stabilise thereafter. To further increase the alkalinity and to reduce the dissolved iron concentration, periodic substrate loading may be considered in future for the long term remediation of AMD (Ramla 2012).

Santos *et al*., (2004) worked with different biomass concentrations and showed that an increase of the biomass (grape stalks) concentration up to 30g/L leads to a 20% reduction of the total content of dissolved iron in the AMD. In a similar study Greben *et al*., (2008) used cut grass serving as a carbon and energy source for continuous sulfate removal and obtained between 80 and 90% removal efficiency by adding cut grass loadings every two weeks. The increase in grass loadings provides new surface area for adsorption of metal ions, further reducing their concentration.

In our study the residue switch grass obtained from the AMD treatment process was prepared for a further enzymatic hydrolysis step. The preparation included washing to remove metal ions adsorbed to the surface. SEM was used to study the effects of the AMD on the switch grass. The results showed that AMD induced morphological changes in the switch grass (Figure 4). These changes are due to the hydrolysis of hemicellulose and to a lesser extent cellulose by the sulfuric acid in the AMD. The hemicellulose fraction is converted to its monomeric sugars which include pentose and glucose. This treatment is analogous to the pre-treatment of lignocellulosic biomass using acid. In literature dilute acid pre-treatments of lignocellulosic material are done at higher temperatures and pressure and are able to recover relatively higher amounts of fermentable sugars from the hemicellulose fraction of lignocellulose. Barrier et al., (1985) reported the conversion and recovery of sugars from the hemicellulose fraction treated with dilute acid to be more than 90% efficient. Dilute sulphuric acid in the range 0.5-1.5% and temperatures above 160 has been found the most favoured for industrial applications. Under these conditions high sugar yields from hemicellulose are obtained (Hisham and Mageed, 2008). In our study the conditions are mild (room temperature and pressure) and hence we expected reduced rates.

Glucose was detected during the treatment of AMD in the course of this study (Figure 3). A maximum glucose concentration of 8.4 g/ml was obtained in the seventh week of the study. After AMD treatment it is necessary to recover some of the sugars from the AMD/sugar liquor. The sugars in solution in the AMD are highly contaminated with metal ions and would need purification if they are to be recovered and to be used for further bioprocessing. It is difficult to recover the hemicellulose fraction of sugars from the AMD/sugar solution. The AMD/sugar liquor can be fermented to produce ethanol which can be recovered by distillation, or alternatively the AMD/sugar liquor could be used as a carbon and energy source for SRB in subsequent treatments. The remaining cellulose residue, instead of being discarded, could be further processed by

additional enzymatic hydrolysis as the cellulose residue contains the bulk of the glucose. Cellulase enzymes were used in our study to recover some of the sugars in the lignocellulose, with maximum values of glucose and xylose at 4.8 mg/ml and 3.4 mg/ml respectively. The xylose produced in the processing may also be fermented or used to produce other value added products. One possible use of the unconverted xylose is to produce fodder yeast (single cell protein) for animal feed (Barrier *et al*., 1985). This study has evaluated the potential of AMD treated switch grass in the production of fermentable sugars. From this study it can be concluded that:

a) Lignocellulosic material has the capacity to treat AMD,
b) The AMD treated switch grass has the potential to produce fermentable quantities of glucose upon enzymatic hydrolysis,
c) AMD is not only remediated but assists in a bioprocess to prepare second generation feedstock for industrial biotechnology.

The research is, however, at a very early stage of development. Substantial additional work is required to optimise the production of fermentable sugars as well as understanding the rates of AMD treatment. There is also still much work needed into developing a process which could be used commercially. This is the subject of ongoing research.

Biomass Retention and Recycling to Enhance Sulfate Reduction Kinetics

Robert van Hille, Tynan Marais and Susan Harrison
Centre for Bioprocess Engineering Research, University of Cape Town, South Africa

ABSTRACT

Biological sulfate reduction represents a more sustainable option for the removal of sulfate from acid rock drainage, particularly if the resulting sulfide is used for metal precipitation or is partially oxidized to sulfur. Sulfate reducing bacteria are relatively slow growing and attach poorly to most solid substrates, so washout is a concern at low hydraulic residence times. This paper describes two strategies to achieve high cell concentrations in sulfate reducing reactors and reports on the resulting improvements in sulfate reduction efficiency.

A linear flow channel reactor was fitted with carbon microfibers, which provided a large surface area for attachment, without significantly reducing effective reactor volume. The surface properties of the carbon fibers enhance biomass attachment and colonization of the fibers occurred within two weeks. The hydrodynamic regime within the reactor ensured even substrate distribution without physical agitation. The second reactor system involved coupling a cross-flow microfiltration unit, fitted with a ceramic membrane, to a conventional continuous stirred tank reactor. The retentate, containing the biomass, was recycled back to the CSTR.

The reactors were fed a synthetic solution containing 1 g/L sulfate, with lactate as the carbon source and electron donor, at a COD to sulfate ratio of 0.7. The hydraulic residence time was reduced from 4 days to 0.5 days, with steady state data collected at each residence time. Maximum volumetric sulfate reduction rates of 47.5 and 65 mg/L.h were achieved in the channel reactor and membrane coupled reactor system respectively. These represent improvements of 20% and 50% over a conventional CSTR, where washout of part of the community occurred at HRTs below 1 day.

Keywords: Sulfate reduction, biomass retention, membrane separation, biomass attachment

INTRODUCTION

The contamination of surface and groundwater by acid mine drainage (AMD) and acid rock drainage (ARD) and the consequences for the environment, agriculture and human health are serious concerns in the regions of South Africa impacted by mining activities. Acid drainage is generated via the oxidation of sulfide minerals, typically pyrite, when exposed to oxygen and water. The process is usually catalyzed by iron and sulfur oxidizing microorganisms. In South Africa, mine water can be divided into two broad categories. The first, AMD, originates from the rebound of groundwater through abandoned mine workings, once dewatering has ceased and is characterized by large volumes of heavily impacted water. The volume and composition of the AMD precludes the application of biological treatment options in most cases. The second type, referred to as acid rock drainage (ARD) in this paper, originates from diffuse sources, such as waste rock dumps, tailings impoundments, coal discard heaps and unworked pits. These sites are more numerous, are likely to affect a greater area and can persist for decades. Acid rock drainage, from diffuse sources as well as end-of-pipe sources, is more amenable to biological treatment.

A variety of technologies have been developed for the treatment of AMD and ARD. The established methods are based on oxidation, neutralization, precipitation and sedimentation. The oxidation converts iron and aluminum to their less soluble oxidized form, which makes subsequent precipitation more efficient. The most appropriate treatment is dependent upon the volume of the effluent, concentration type of contaminants and the pH of the water (Gazea et al., 1996). Acid drainage treatment technologies can be divided into two broad categories, active and passive treatment systems.

Active treatment typically involves the installation of agitated reactors or similar units, which require constant energy input. Furthermore, the addition of alkaline chemicals and reagents to treat the acidic effluent can become costly, given that the drainage may persist for several decades, or longer, at decommissioned mine sites (Gazea *et al*., 1996). Many of the active treatment technologies depend on the addition of lime or limestone, which are non-renewable resources. Lime addition to sulfate rich effluents typically results in substantial gypsum precipitation, which needs to be managed. The long-term sustainability of many active treatment technologies is therefore questionable, both from an economic and environmental perspective. There is a diverse range of active treatment technologies, such as chemical precipitation, ion-exchange, membrane technology and biological sulfate reduction.

Passive systems depend on processes that are kinetically slower than those involved in active systems and thus require longer hydraulic retention times (HRTs) and larger areas to achieve similar results (Hedin *et al*., 1994). Passive treatment options include anoxic limestone drains, permeable reactive barriers, natural and constructed wetlands and engineered biological treatment systems.

Biological treatment has the potential to be more cost effective and sustainable than the physical and chemical processes mentioned above. The biological treatment of ARD is centered on the activity of sulfate-reducing bacteria (SRB), which are able to reduce sulfate to sulfide, coupled to the oxidation of an electron donor, typically an organic carbon molecule. Sulfate reduction may be assimilatory, where the sulfide is incorporated in sulfur-containing amino acids, or dissimilatory, where the sulfide is released to the external medium. The latter process forms the basis of ARD remediation processes. A generalized reaction for dissimilatory sulfate reduction is shown below (Zagury et al., 2007; Oyekola et al., 2009).

$$2CH_2O + SO_4^{2-} \rightarrow 2HCO_3^- + H_2S \quad (1)$$

The sulfate is reduced to sulfide, coupled to the simultaneous generation of alkalinity, predominantly as bicarbonate (HCO_3^-). From an ARD treatment perspective the alkalinity acts to neutralize the acidity while the sulfide is available for the precipitation of metals as metal sulfides (Johnson and Hallberg, 2005).

A number of commercial processes, based on biological sulfate reduction, have been developed, but their widespread application has been constrained by three factors. These are the cost of the electron donor, the relatively slow growth of sulfate reducers and the associated kinetic constraints and the management of the sulfide product. The research presented in this paper addresses the second constraint by investigating novel reactor configurations aimed at biomass retention and recycling. The first and third constraints have been addresses by previous and ongoing research within CeBER (van Hille and Mooruth, 2013; Harrison et al., 2014) and by others (Janssen et al., 1995; Molwantwa and Rose, 2013).

METHODOLOGY

Sulfate reducing bacteria (SRB) culture

The SRB mixed microbial community was obtained from the Department of Microbiology, Biochemistry and Biotechnology at Rhodes University, originally from the anaerobic compartment of a facultative pond at the Grahamstown sewage treatment works, and has been maintained at UCT since 1999. The stock culture has been maintained on modified Postgate B medium consisting of: 0.5 g/L KH_2PO_4, 1 g/L NH_4Cl, 2 g/L $MgSO_4.7H_2O$, 1 g/L Na_2SO_4, 1 g/L yeast extract, 6 mL/L 60% sodium lactate solution (Sigma), 0.3 g/L sodium citrate. The same solution was used to feed all experimental reactors. Unless otherwise stated, all regents were analytical grade, sourced from Merck.

Reactor units

Continuously stirred biological sulfate reduction reactor

Continuous experiments were performed in glass reactors with a working volume of 1 L. The reactor height was 200 mm, with a liquid volume height of 118 mm, and diameter 104 mm.

Agitation was provided by an overhead stirrer powering a four-bladed marine impeller (58 mm diameter) at 300 rpm. The reactor was fitted with four vertical baffles (10 mm width) to prevent vortex formation. Temperature was controlled at 30°C by pumping heated water through the external jacket or placing the reactors in a temperature-controlled water bath. Feed solution was continuously pumped into the reactor using a variable speed peristaltic pump.

Sulfate reduction reactor with microfiltration unit

The reactor configuration for the cross-flow microfiltration consisted of the standard 1 L glass reactor coupled to a microfiltration unit. The contents of the reactor were pumped through the membrane unit (ceramic membrane with a 0.2 μm pore size) at a rate of 1.7 L/min, meaning the entire volume passed through the membrane every 35 seconds. As a result, the reactor could be considered well mixed and additional agitation by the impeller was not required. This was confirmed through mixing studies.

Linear flow channel reactor (LFCR) with carbon microfibers

The channel reactor provided a flow-through reactor with medium stratification in place of homogeneity. It was constructed from Perspex (11 mm thickness). The front wall of the reactor was fitted with three sets of sample ports, located 60 mm, 120 mm and 180 mm from the inlet. At each distance, there were three ports, 25 mm, 55 mm and 90 mm from the base of the reactor. Each port was fitted with a GC septum and samples were withdrawn with a hypodermic needle. The reactor was fitted with three feed ports (25 mm, 60 mm and 95 mm from the base) in the left wall and three effluent ports (15 mm, 50 mm and 85 mm from the base) in the right wall. When the top outlet port was utilized the liquid height in the reactor was 85 mm, giving a working volume of 2.125 L. The reactor was fitted with a lid and an airtight silicon seal. A port fitted 10 mm below the lid in the left and right hand walls allowed the headspace to be flushed. A strip (38 mm wide) of carbon microfibers (AMT Composites, Cape Town) was attached to the bottom of the lid so that the fibers were submerged in the liquid. The strip had a bundle of microfibers (180 mm long) attached at 7 mm intervals on each side. The reactor was operated continuously by pumping feed in from the uppermost feed port and collecting effluent from the uppermost effluent port.

Analytical methods

All pH testing was done on a Cyberscan 2500 micro pH meter. The meter was calibrated daily using standard (pH of 4.0 and 7.0) buffer solutions. Aqueous sulfide was quantified using the colorimetric DMPD method (APHA, 2005). Aqueous sulfate concentrations were measured by HPLC using a Waters Breeze 2.0 system equipped with a Waters IC-Pak A HR (Anion High Resolution) column and a conductivity detector. The system was run isocratically using a sodium borate-gluconate mobile phase at a flow rate of 1 mL/min. Sample injection volumes of 100 μL were used. To quantify the ion concentrations standard solutions (20, 40, 60, 80 and 100 mg/L) were prepared using sodium sulfate (Na_2SO_4) salt. A full volatile fatty acids (VFAs) analysis was conducted to quantify the concentration of lactic, acetic, propionic, iso-butyric, butyric, iso-valeric and valeric acids. The concentration of each VFA was determined using HPLC on a Waters Breeze

2 HPLC system equipped with a Bio-Rad Organics Acids ROA column and a UV (210 nm wavelength) detector. The system was run isocratically using a mobile phase of 0.01 mol/L H_2SO_4 at a flow rate of 0.6 mL/min. Sample injection volumes of 100 μL were used. To quantify the VFA concentrations, standard solutions (100, 200, 300, 400 and 500 mg/L for each acid) were prepared.

Experimental programme

Baseline

Baseline data were generated in a standard CSTR operated at 30°C, using the modified Postgate B medium as the feed source. The reactor was started at a HRT of four days and sampled at least once per HRT. Once steady state had been established and monitored for at least three HRTs, the feed rate was increased, reducing the HRT to three days. The process was repeated a number of times, collecting data at each HRT (**Table 1**).

The reactors were sampled by removing 10 mL of solution and immediately using 20 μL to perform a sulfide assay. The pH and redox potential were measured using the remaining sample. A subsample (2 mL) was transferred to a 2 mL Eppendorf tube, to which 40 μL of zinc chloride solution was added. The tubes were mixed on a vortex mixer, then centrifuged at 14000 × *g* for seven minutes. The supernatant was used to prepare samples for analysis of anions and VFAs by HPLC.

Table 1 Summary of operating conditions for baseline CSTR, membrane unit and channel reactor. HRTs refers to the total number of hydraulic residence times under each set of conditions

	Baseline CSTR and membrane reactor			Channel reactor		
Desired HRT (days)	Mean flow rate (mL/min)	Mean HRT (days)	HRTs	Mean flow rate (mL/min)	Mean HRT (days)	HRTs
4	0.170	4.10	11.96	0.361	4.09	2.47
3	0.219	3.17	7.61	0.465	3.18	5.64
2.5				0.594	2.49	4.37
2	0.339	2.05	19.24	0.713	2.07	5.29
1.5	0.466	1.49	9.49	0.950	1.55	6.79

1.3				1.135	1.30	4.03

Membrane unit

The purpose of coupling the microfiltration unit to the continuous reactor was to separate biomass from suspension and recycle it back to the reactor, while discharging a cell-free permeate. This was chosen to build up a very high cell density. It was hypothesized that the high cell density would

support efficient sulfate reduction at HRTs below one day, owing to the de-coupling of the mean cell retention time (MCRT) and HRT.

The reactor coupled to the membrane filtration unit was set up and operated similarly to the reactor used to collect the baseline data. The feed rates, overall hydraulic retention times and number of hydraulic retention times under each set of conditions was identical to the control reactor (**Table 1**). Once steady state had been achieved at a four day HRT the pump was turned on and reactor contents were pumped through the membrane. Permeate was pumped from the membrane unit at the same rate as feed was pumped into the reactor to maintain a fixed operating volume across the system. Under normal operating conditions no effluent was collected from the overflow port of the reactor. However, if the membrane became fouled, reducing the transmembrane flux, or the permeate pipe became blocked, the volume in the reactor would accumulate and discharge through the overflow port. When this occurred, the membrane needed to be de-fouled.

The reactor was sampled as described for the control reactor, while permeate was sampled by collecting the outflow for 5-10 minutes. Reactor and permeate samples were analyzed for pH, redox potential, anions and VFAs.

Linear flow channel reactor

The channel reactor was initially operated at a 5.5 day HRT (0.27 mL/min) to allow for colonization of the microfibers. This was achieved successfully over a period of 20 days. From day 20, the feed rate was increased to achieve a HRT of 4 days. Samples (2 mL) were removed daily from the middle (FM) and lower (FB) sample ports in the first and third (BM and BB) rows. The pH and sulfide concentration were measured immediately, after which the remainder of the sample was treated with 40 µL of zinc chloride (100 g/L) and centrifuged at 14000 × g for seven minutes to remove sulfide as zinc sulfide. The supernatant was filtered through a 0.22 µm nylon membrane filter and retained for HPLC analysis (VFAs and anions). Effluent from the reactor was collected in a sealed bottle over varying time intervals and the volume quantified to confirm the HRT. A portion of the collected effluent was treated for HPLC analysis, while the rest was used to measure pH and redox potential. The operating conditions of the channel reactor are summarized in **Table 1**.

RESULTS AND DISCUSSION

The data presented in this section represent a summary of steady state data at the different retention times across the three reactors. Steady state was assumed when the change in key parameters, particularly residual sulfate concentration, was less than 10% for three successive HRTs following a change in system conditions.

Baseline date

The steady state profiles for sulfate consumption and measured sulfide are shown in Figure 1. The theoretical sulfide concentration, based on the molar concentration of sulfate reduced, is also

shown. The sulfate reduction is relatively consistent across the range of HRTs from four days down to one day, with between 870 and 920 mg/L of the 1000 mg/L feed being consumed. Based on molar stoichiometry, the theoretical sulfide concentration was just below 300 mg/L. However, the actual measured sulfide concentration was significantly lower, suggesting either a loss of sulfide to the surroundings or further reaction of the sulfide.

The reactor unit was sealed and any offgas passed through a sodium hydroxide sulfide scrubber, where gaseous hydrogen sulfide (H_2S) would be converted to aqueous bisulfide (HS^-). Analysis of the bisulfide concentration indicated no significant loss of H_2S from the reactor. This is consistent with the steady state pH (7.4 ± 0.15). Under these conditions the majority of the aqueous sulfide would exist as the HS^-. The result suggests partial oxidation or precipitation of a portion of the sulfide, although no metal sulfide precipitate could be observed. An experiment to quantify the abiotic sulfide oxidation under similar solution chemistry conditions (data not shown) indicated that only a small portion of the missing sulfide could be accounted for by abiotic oxidation. Visual observation of the reactor showed an elemental sulfur deposit at the air/water interface. This deposition was clearly visible when the reactors were taken down, suggesting biologically mediated partial oxidation to sulfur.

There was a significant decrease in the amount of sulfate reduced at a HRT of 12 hours (dilution rate of 0.083/h), with the conversion efficiency falling to around 50%. Despite the reduction in the sulfate conversion, the conversion of lactate remained at 99%. Based on the amount of sulfate reduced, the expected residual lactate concentration at this HRT should have been over 1000 mg/L. However, a residual concentration of below 30 mg/L was detected. This indicates that the sulfate conversion was not limited by lactate concentration.

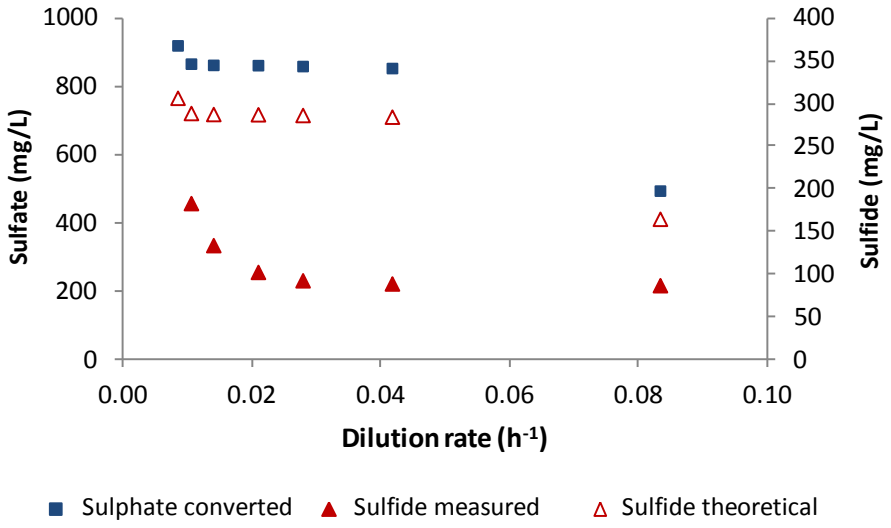

Figure 1 Sulfate conversion and measured and theoretical sulfide concentrations as a function of dilution rate. HRT plotted as dilution rate (1/HRT)

This observation also suggests that while sulfate reducers oxidized lactate at a rate near their μ_{max} another group of microorganisms characterized by higher μ_{max} and K_s values for lactate utilization were able to proliferate due to increased lactate loading at the high volumetric loading rate. Consequently, there was no accumulation of lactate. The decline in sulfate conversion was most likely a consequence of wash out of a portion of the sulfate reducing community when the reactor was operated at a dilution rate greater than their μ_{max}. These data are similar to those obtained by Moosa et al. (2002, 2005), Oyekola et al. (2009; 2010; 2012) and Baksaran and Nemati (2006). The study showed that the decrease in sulfate reduction efficiency coincided with a decrease in acetate formation and increase in propionate formation (Oyekola et al., 2009). Propionate production is an indication of lactate fermentation (Heimann et al., 2005). In addition Oyekola et al. (2012) performed a qualitative assessment of microbial community structure, which confirmed that the diversity of sulfate reducers decreased with increasing dilution rate.

Membrane unit

The redox potential in the reactor decreased from an initial value of around -350 mV to a steady state between -390 and -400 mV during the first 30 days of operation, as the sulfate reduction efficiency increased prior to attaining steady state at a four day HRT (day 30). During the same time the pH increased from around pH 7 to pH 7.4-7.5.

The redox potential of the permeate was typically similar to that of the bulk reactor fluid, except during periods where permeate flow decreased due to fouling or blockage of the tube draining the membrane unit. Under these circumstances oxidation of the permeate was near complete, resulting in a less negative redox potential. The pH of the permeate from the microfiltration membrane was consistently higher than the pH measured in the reactor, typically by 0.5 pH units.

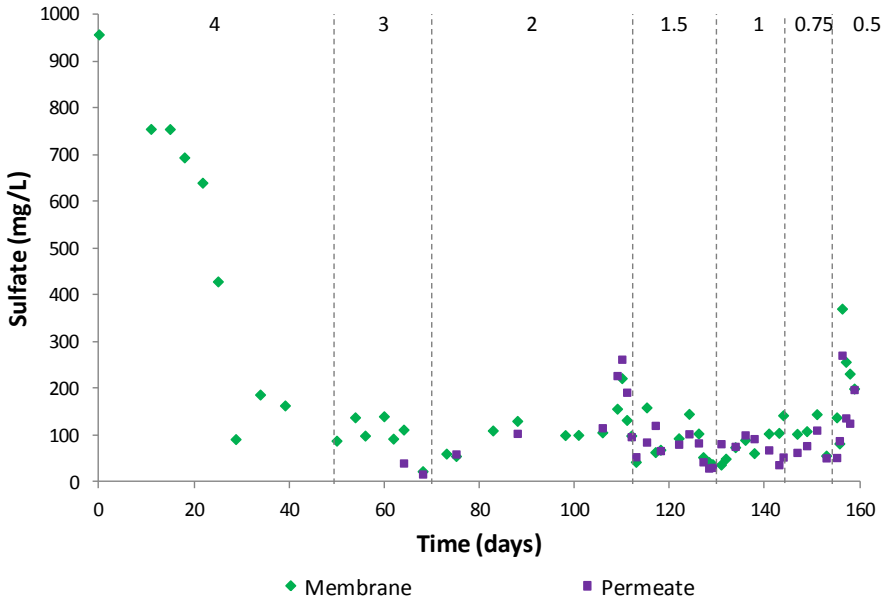

Figure 2 Residual sulfate data from the continuous reactor with microfiltration unit. Changes in HRT are shown by the dashed lines with the nominal mean HRT indicated. 'Membrane' refers to the sample from the bulk reactor fluid

The residual sulfate data (Figure 2) gave an indication of the efficiency of the system across the range of HRTs. The system took around 30 days to reach steady state at the initial four day HRT. The residual sulfate at steady state was approximately 140 mg/L, representing a removal efficiency of over 85%. This was consistent with the baseline data under similar operating conditions. The residual sulfate was relatively unchanged down to a HRT of 0.75 days and increased slightly at 0.5 days. The sulfate concentration measured in the permeate was similar or slightly lower in most cases, indicating that while partial oxidation of sulfide to sulfur occurred in the drainage tube, complete oxidation to sulfate did not.

The low residual sulfate, even at a HRT of 0.5 days, was indicative of very efficient performance. The recycling of the majority of the biomass, particularly under conditions where slower growing species would be washed out, resulted in a very high biomass concentration that could sustain efficient sulfate reduction at a high volumetric loading rate. The average VSRR measured across the 0.5 day HRT was 64.18 mg/L.h, over 50% higher than that achieved during the baseline study.

The sulfide concentration in the bulk fluid was similar to that in the baseline CSTR, while the permeate was consistently lower, fluctuating around 100 mg/L when the system was operating efficiently. The lower sulfide concentration, coupled with the increased pH suggested the partial oxidation of some of the sulfide to elemental sulfur. The silicone tubing used to drain the permeate is permeable to oxygen. Under oxygen limiting conditions the partial oxidation of sulfide is favored, according to the reaction below (Kuhn *et al*, 1983)

$$2HS^- + O_2 \rightarrow \tfrac{1}{4}S_8 + 2OH^- \quad (2)$$

The generation of hydroxide ions accounts for the increase in pH. As the pH increased, a portion of the remaining sulfide could be converted to polysulfides. The permeate was typically pale yellow color, consistent with the presence of some polysulfide. Sulfur production in the outlet pipes resulted in relatively frequent blockages, resulting in effluent draining from the reactor overflow port, rather than exiting as permeate. The problem was more pronounced at the shorter HRTs. At the 1.5 day HRT 76% of the total effluent was made up of permeate and 24% as overflow from the reactor. The proportion exiting as permeate fell to 67%, 69% and 44% at the 1 day, 0.75 day and 0.5 day HRTs respectively.

The sample from the reactor clearly contained suspended biomass, which became more apparent as the experiment progressed. The appearance of attached biofilm on the reactor walls and the presence of elemental sulfur in the bulk fluid prevented accurate quantification by either dry mass or optical density. The permeate sample was consistently cell free, indicating that the cells were recycled back to the reactor with the retentate. The absence of cells in the permeate was confirmed by light microscopy.

Linear flow channel reactor

The system experienced some perturbations during the initial operation and steady state, with respect to sulfate reduction, was achieved day 40 and on day 45 the HRT was reduced to 4 days. The sulfide data (Figure 3) show that a relatively high sulfide concentration was maintained in the reactor, even at a 0.5 day HRT.

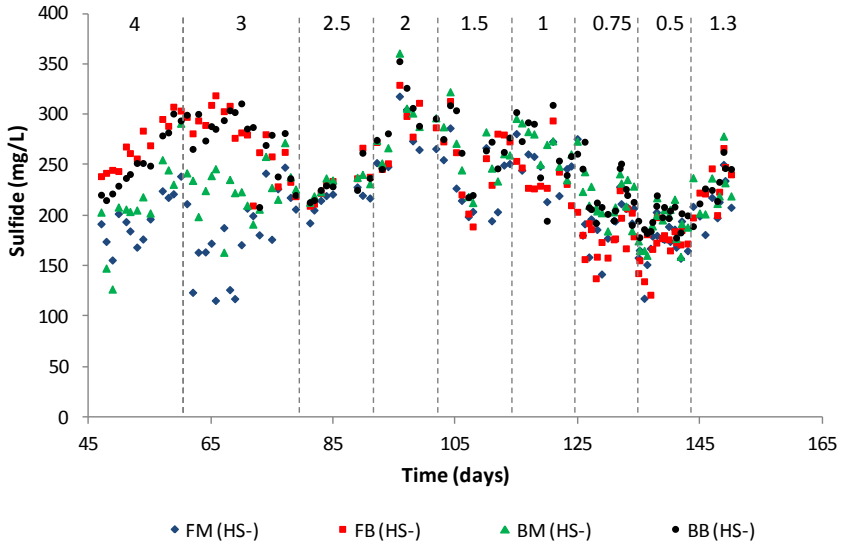

Figure 3 Aqueous sulfide concentration as a factor of HRT, measured at four points in the reactor. Changes in HRT are represented by dashed lines and mean HRT is indicated

At the longer HRT there was some inhomgeneity in the reactor, a function of the hydrodynamics within the reactor, with higher concentrations in the lower half of the reactor. While the sulfide levels did decrease to an extent as the HRT decreased, a relatively steady state was observed at each HRT and the decreased performance with decreasing HRT, below the critical maximum specific growth rate of the cells, observed in the CSTR, did not occur owing to a de-coupling of the hydraulic and biomass dilution rates. Biofilm growth on the carbon fibers was clearly visible, demonstrating biomass retention.

Comparison of performance across reactor configurations

The performance in each of the different reactor configurations can be compared by considering the volumetric sulfate reduction rate relative to the volumetric sulfate loading rate. At a feed sulfate concentration of 1 g/L, the performance was similar at HRTs from four days down to one day, with a sulfate reduction efficiency of between 85-95%. Significant divergence in performance was observed at lower HRTs, where washout of a portion of the sulfate reducing community occurred in the stirred tank reactors as the dilution rate exceeded the maximum specific growth rate. The two systems that were characterized by either recycling of the biomass (BSR reactor coupled to membrane filtration unit) or efficient retention of the biomass (carbon microfiber channel reactor) maintained higher VSRRs, owing to the requisite decoupling of the MCRT and HRT. At the HRT at which washout is first observed in the CSTR (0.5 day), for the channel reactor the VSRR was approximately 20% higher than the baseline study, while for the membrane system it was over 50% higher, despite the challenges associated with elemental sulfur formation. Maree and co-workers (2004) achieved very efficient sulfate reduction by recycling sludge from a clarifier back to a well mixed primary reactor, although the clarifier volume was equal to that of the reactor, which has capital cost and process footprint implications.

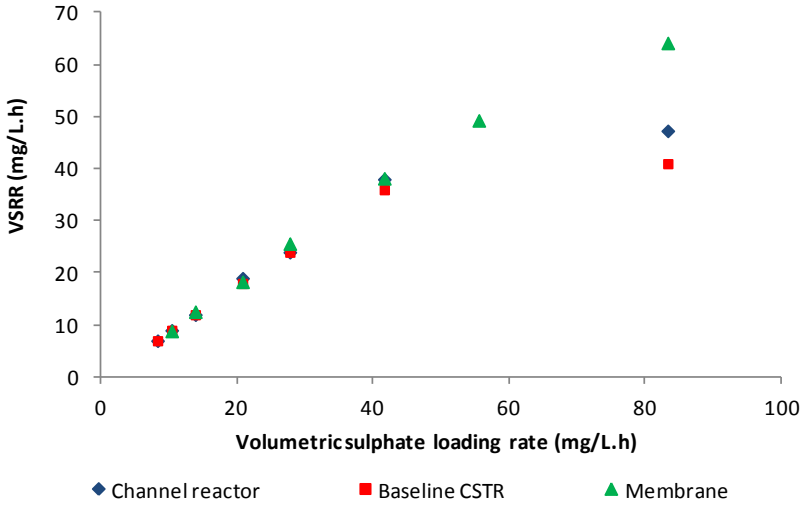

Figure 4 Comparison of the VSRRs across the three reactor configurations at a feed sulfate concentration of 1 g/L

CONCLUSION

Decoupling of mean cell and hydraulic retention times was achieved successfully in both the LFCR, where biofilm formation on the carbon microfibers was very efficient and ensured biomass retention and the reactor fitted with the microfiltration membrane, where the membrane permeate was consistently cell free, demonstrating biomass recycle. The maintenance of the biomass within the reactor resulted in significantly improved performance at low HRTs, with the volumetric sulfate reduction rate in the channel and membrane coupled reactors being 20% and 50% higher respectively than the baseline CSTR data at a HRT of 0.5 days.

In both systems, the complete elimination of oxygen was not possible, resulting in the partial oxidation of a portion of the sulfide formed to elemental sulfur. In the channel reactor this occurred primarily in a floating biofilm, similar to that observed in the dedicated sulfide oxidation reactor, with some sulfide oxidation also occurring in the effluent pipe. This suggests that sulfide oxidation and sulfur recovery could be coupled with sulfate reduction in this configuration.

The sulfur formation presented more of a problem in the membrane system as particulate sulfur blocked the permeate drainage line and peristaltic pump tubing, restricting permeate flow, as well as forming a layer on the outer surface of the membrane, reducing transmembrane flux. As a consequence, a significant amount of the accumulated biomass was lost as overflow from the reactor. Despite this, the membrane coupled system resulted in the most efficient sulfate reduction. Subsequent experiments have shown that active pumping of permeate is not required and this has eliminated the problem.

Permeable Concrete with Bio-Reactive Layers to Target Heavy Metals and Sulfates in Acid Mine Drainage

ABSTRACT

The aim of this research is to reduce heavy metal and sulfate content of acid mine drainage (AMD) through the methods of passive filtration by combining permeable concrete and organic materials to achieve a low cost, yet effective temporary treatment method for rural/poor communities who are affected by AMD. The acids are filtered through layers of alternating pervious concrete and biological composting layers. The concrete layers target removal of heavy metals such as iron, manganese, potassium, magnesium, etc. through precipitation as well as reduce sulfate content to a small degree along with total dissolved solids. The concrete layers aid in raising the pH of the AMD to more acceptable levels. The biological layers achieve sulfate reduction through the metabolism of sulfate- reducing- bacteria (SRB) - this process however will require time and the organic layer thus will be thicker and less permeable than the concrete layers in order to allow seepage to take place at a reduced rate. A wide variation of composting layers were tested including cow manure, chicken manure, sawdust, straw, zoo manure, leaf compost, grass cuttings and river mud to find an optimum mix of materials which allows for the greatest sulfate reduction through SRB's. Long-term testing and effectiveness of the rigs will be undertaken to establish limitations and lifespan of the filtration system. AMD from the Witwatersrand gold fields and Mpumalanga coal fields with exceptionally high sulfate content were used to test effectiveness of the organic materials over a short period of time with long term testing being conducted with a synthetic AMD due to limited supply of the reagent. The short term testing yielded reductions of sulfates in the region of 56% when using kraal manure as the biological reagent mixed with sawdust for added organic carbon. The filter also successfully raised the pH to 8 while removing a significant portion of heavy metals. The results show promise for using the technology as a low cost, temporary measure to protect locally impacted groundwater, especially for isolated and/or rural communities.

Keywords: AMD, SRB, permeable concrete, remediation

INTRODUCTION

Acid Mine Drainage (AMD) is the name given to outflows of water that contain high levels of acidity and heavy metals due to the reaction and oxidation of geological layers which consist of sulfide containing minerals, especially pyrite(FeS_2). The amount and rate at which AMD is generated is a function of the rock mineralogy and degree of exposure/presence of oxygen and water. The sulfides in the rock oxidise when in contact with these substances to create a highly acidic, sulfate rich mixture with characteristically low pH and often a high content of heavy metals in soluble form.

This acid generating phenomenon is a naturally occurring process resulting from the weathering and erosion of sulfide carrying minerals in exposed rocks weathering on hills and valleys or through ground water seepage. This however creates AMD at a slow rate due to the relatively small exposed surface area; and in the case of ground water seepage the lack of excess oxygen; therefore allowing the surrounding alkaline rocks to neutralise the AMD, and water bodies to dilute it sufficiently before it has a chance to significantly impact the environment (Durand, Meeuvis, & Fourie, 2010).

Mining activities however; such as deep pit excavation, crushing, quarrying, mine waste rock pilling, tailings and tunnelling; result in massive volumes of rock being exposed, which when weathered creates excessive amounts of acid mine drainage. This AMD has greatly adverse effects on the environment, its biodiversity, as well as long-term damage to waterways, aquifers and ultimately our drinking water (Coetzee et. al, 2010). AMD can also cause damage to structures such as culverts and bridge abutments exposed to waterways that have a high concentration of AMD as the high acidity and sulfate levels have an accelerated corrosion effect on steel reinforcing (Gurdeep, 2006). More importantly, AMD carries a health risk to human settlements, especially those of the mining communities often living in low cost, slum/squatter camp type environments adjacent or nearby mine dumps/tailings. Some of the Heavy metals contained in AMD can be extremely harmful if consumed in elevated consecrations and in some cases AMD has been found to be carcinogenic.

Extent of the problem in South Africa

AMD is an extensive problem with coal and gold mining, as marcasite and pyrite (or "fools gold" as it is often known) is highly prevalent in the mine wastes and surrounding mineralogy. South Africa has notably large deposits of these sulfur rich natural resources. The AMD problem faced by the mines in Johannesburg is being further accentuated with the gold mining operations ceasing and mines not being maintained after closure. This is resulting in uncontrolled amounts of AMD welling up inside the mine voids left from deep excavations as the ground water level is no longer being drawn down and controlled to allow for mining along the reef. To put things into perspective , the potential volume of AMD produced by the Witwatersrand Goldfields alone amounts to an approximated 350ML/day which is around 10% of the daily supply of potable water by Rand Water according to Hobbs et al (2009).

There is huge concern regarding the state of the water level at the central basin in Witwatersrand as ground water with high concentrations of AMD has been rising at an average rate of 0.59 metres

per day (m/d) since July 2009 which translates to approximately 15m/month (Akcil and Koldas, 2006).

If this rising water level is not treated and controlled it would threaten to flood the low lying tourist areas of the mine at Gold Reef City and of more consequence, pollute and compromise the shallow ground water resources along with causing damage to the dolomitic strata. This will ultimately affect the dolomites ability to sustain loadings in the southeast part of Johannesburg according to Coetzee et al. (2010). One of the largest concerns of AMD is the accelerated karstification of dolomite (which is soluble in acid) resulting in potentially large sinkholes and soil subsidence coupled with the consequential contamination of aquifers and decanting into waterways. This ultimately pollutes and impacts all types of biodiversity including with time our drinking water. This same threat is faced by the cradle of humankind in Krugersdorp and is of huge concern as the structural stability of the surrounding areas are in question threatening the heritage site and the artefacts contained within its soil as the dolomitic aquifers carry more and more highly acidic AMD into the area (Durand et al. 2010).

According to Case studies done by Hochmann et al. (2010) on coal mining in South Africa, an account of the mining community living at the Maguqa township near an open cast coal mine in the Brugspruit valley was given, where AMD carrying toxic heavy metals is flowing into the Brugspruit stream and from there into the Olifant's river system. The children of the township play soccer on the flat white surfaces of sulfate salt precipitates left by the AMD, oblivious to the potential health risks. Therefore there is a need for a rapid temporary solution which has the potential to reduce the risk to such impacted communities whilst a long term solution is sought.

Treating AMD

Treatment of AMD is complex, costly and requires a fairly large amount of capital and infrastructure to be put in place for the treatment methods to be implemented (Hobbs et al., 2009). There are a number of effective treatment techniques, all of which can be broadly characterised as either active or passive. Active treatments are those treatments which involve ongoing and continual input and often involve electrical and mechanical implementations that are highly sophisticated and engineered which make use of chemical dosing or similar techniques to ensure the remediation of the contaminated water [Shabalala (2013) , Skousen et al. (2000)]. Passive treatment techniques are those which can operate with little to no input over the long term and often require longer periods of time/processing in order to reach the same level of effectiveness as an active system and don't often involve chemicals or mechanical equipment (Jennings and Blicker 2008). Some of the more commonly used passive methods are discussed further below.

Anaerobic wetlands

This system is a modification of an aerobic wetland and incorporates a bed of limestone with a thick layer of organic rich medium above it to promote bacterial growth. This system creates anaerobic conditions when the AMD permeates through the organic material due to microbial activity leading to high oxygen demand. It is thus described as a sub-surface treatment method as it requires sub surface flow of the AMD to be effective unlike the aerobic wetlands where the AMD can flow along the surface. This system can thus treat highly acidic AMD through the dissolution of the fluid due to a limestone layer. This system however requires a large surface area and extended residence time

within the ponds for effective treatment with low/slow flow rates [Skousen et al. (2000), Zipper et al. (2011)].

Experiments conducted by Sexstone et al. (1993) involving anaerobic wetland setups resulted in good pH reduction resulting in almost neutral levels upon exiting the wetland (pH of 6.5) which was largely attributed to the limestone. The tests were run for a period of four years over which it was observed the systems became less and less effective with metal retention and pH reduction due to the system having a finite capacity and thus highlight the need for larger areas as smaller setups are less effective and have a shorter life span than respectively larger setups. Wieder (1992) documented that the performance of wetlands are different depending on the season and age of the wetland which was attributed to factors such as bacteria activity, current loading of the wetland and ability of the aquatic plants to absorb precipitated heavy metals.

Permeable reactive barriers (PRBs)

Permeable reactive barriers are essentially a permeable obstruction placed typically below surface which intersects the AMD plume as it flows along with ground water and treats the influent as it passes through the barrier. The treatment is achieved in the majority of cases through the use of Iron metal and silica sand, with some instances using organic matter to treat nitrate and sulfates depending on the AMD that is to be treated (Powell et. al, 1998). According to work done by Blowes et al. (2000) the use of solid organic matter such as wood chips, sawdust, compost and leaves have positive effects on sulfate reduction in AMD due to the proliferation of sulfate reducing bacteria which reduce sulfate to sulfide which in turn leads to the formation of insoluble metal sulfides. However one of the most important considerations of using a PRB for treatment is the fact that sulfides have low solubility in anaerobic conditions and thus if oxidation occurred metals could be released by the barrier (Blowes et al., 2000). Another drawback is the Installation of a PRB is quite costly as often impermeable structures are constructed to channel the AMD to the Barrier and these can be quite large and long such as a slurry piled wall.

One of the limiting factors according to Taylor et al. (2005) is the finite amount of reactive substrate available and the need for the AMD to have low oxygen content upon entering the system to prevent clogging. The organic substrate is consumed in the treatment process which creates void spaces that are then filled with the metal precipitates - compaction and the filling of these void spaces can lead to reduced porosity and effectiveness of the system.

Bioreactors and (SRB) Sulfate reducing bacteria

Most passive treatments that target AMD with a high sulfate content will make use of sulfate reducing bacteria (SRB). The bacteria consume organic forms of carbon (CH_20) under anaerobic conditions to produce bicarbonate; which promotes neutralization of the AMD; and H_2S which creates an environment where low solubility metals will precipitate out as shown in the Equation 1 [Shabalala (2013), Younger et al. (2002)]:

$$SO_4^{2-} + 2CH_2O \rightarrow H_2S + HCO_3^- \quad (1)$$

This process is highly dependent on the availability of an organic feedstock for the bacteria to proliferate and become increasingly effective. Temperature also plays a role with the bacterial activity where they become increasingly more active at higher temperatures and less so at lower temperatures [Akcil & Koldas (2006), Younger et al. (2002)].

Bioreactors essentially create a concentrated carbon rich environment where these SRBs can thrive and proliferate in order to effectively remove sulfates and heavy metals of fluids that pass through them. Bioreactors are commonly used with most sludge and waste water treatment facilities. The problem with some bioreactors arises where they become inundated with metal precipitations and lose their effectiveness. Replenishment of the carbon source is sometimes needed and removal of the heavy metal rich sludge can be costly and expensive to dispose of.

Use of Concrete in AMD treatment

The use of concrete in the treatment of AMD has not been extensively tested and its use in conjunction with biological layers is novel. There has been some experimental work done by Ekolu et al. (2013) with concrete in the removal of heavy metals, where it was shown that removal of iron content in the order of 95-99% was achieved through a single pass through a concrete cube. It was also found to have effectiveness in reduction of other such heavy metals and approximately 30% removal of sulfate content. It is also expected that the lime within the Portland cement will react to increase the pH of the AMD solution. Permeable concrete is most effective for the purposes of the research presented here as it will allow AMD fluids to pass through the cube while retaining heavy metals within its macro porous structure. The concrete cube will have a finite life much like the Alkali Limestone Drains solutions due to armouring and preferential flow paths forming through the cube.

METHODOLOGY

Filters were constructed out of permeable concrete and organic material in an attempt to combine the benefits of anaerobic wetland conditions, permeable reactive barriers, along with the benefits of heavy metal reducing concrete to achieve a low cost yet effective remediation system aimed at the local communities such as those in Johannesburg that are hard hit by rapidly proliferating AMD. Two phases of testing were undertaken. The first phase was aimed at finding a suitable medium for SRB proliferation and tests were conducted over a 2-3 week period to determine effectiveness of the biological layers. Once an effective medium was found, phase one testing was stopped and a long term filtration system was setup for phase 2. These long term setups have a drip system to pass AMD through them continuously and sulfate reduction levels will be monitored over time for a period of 3-6 months in order to gauge/quantify the effectiveness and ability to perform over the short to medium term. These phase 2 experiments are currently underway and are ongoing.

Permeable concrete

Concrete cubes and cylinders for the filters were batched using Sure build Afrisam 42,5 PPC cement, no fines and 9.5mm dolerite aggregates. Dolerite aggregates were chosen due to their hardness and resistance to acidity which is expected to increase the lifespan of the concrete in AMD remediation. Research conducted by Ekolu et al. (2013) showed that greater sulfate reduction was obtained with dolerites as opposed to granite and limestone. The mix design proportions used for the research are given in the table below:

Table 1 Mix design proportions

Material	**Quantities Used**
Portland Cement	325 kg/m^3
Fine Aggregates	0 kg/m^3
Coarse Aggregate (9.5mm aggregates)	1500kg/m^3
Water/Cement Ratio	0.3

These values are based on the need for greater permeability to allow movement of the AMD through the concrete while still maintaining workability and ease of placement along with maintaining suitable concrete strength. Once the concrete had been cast it was immediately covered to prevent any moisture loss and allowed to set for 24 hours. Thereafter casts were submerged and allowed to cure for 28 days as per standard cement curing processes.

Filtration systems

Filters for the first phase were constructed out of Perspex sheets and were rectangular with an internal dimension of 105mm in order to accommodate a standard 100x100x100mm concrete cube and have a length of 450mm in order to allow for sufficient space for two concrete cubes and a 200mm thick composting layer in between them. The experimental rigs were placed vertically and AMD was passed through the filter under gravitational force. The base plate as well as the midpoint of the filter has a nozzle to allow samples to be taken during filtration. An example of the phase one setup can be seen in Figure 1.

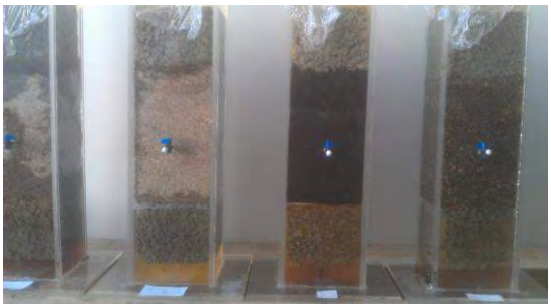

Figure 1 Short term experimental rigs in operation

An AMD taken from coal mine tailings in Mpumalanga with exceptionally high sulfate content (8200ppm) was used to test the effectiveness of the phase one setups. The composting layers used were varied in order to ascertain an effective medium which maximized SRB population growth and activity while not adding any adverse chemicals or metals to the system. The layers tested consisted of leaf compost, wood chips, kraal manure, chicken manure, zoo manure, elephant dung,

sawdust and straw. Combinations of the above along with additions of lime were also tested once an effective medium had been established.

Samples and testing

For the short term experiments samples were taken at 3, 7, 10, 14 and finally at 21 days. These preliminary phase 1 tests were stopped after 21 days as results were showing trend lines of favourable (or otherwise) at this point. Samples were extracted from the bottom, midpoint as well as the top of the filter during phase 1 testing. The samples were tested for sulfate concentration through the use of barium chloride, standard solutions and a spectrograph as per the test methodology stipulated in the sulfate testing methods IS:3025 (Part 24) - Reaffirmed 2003 and ASTM D516 methods.

RESULTS AND DISCUSSION

The results presented are an average of the three samples taken from the top, middle and bottom of the filters. The pH of the samples was checked and it was found that the concrete cubes were very effective at raising the pH of the AMD from 3 to an average of 7.68. The test setup with only permeable concrete cubes in them had a pH of 11 after 21 days.

In Figure 2, the data presented indicates that a mixture of kraal manure with sawdust in the proportions 80%:20% had the most significant remedial effect (a kraal is a South African word for an enclosure normally used to house cattle). The manure sourced from the Johannesburg zoo also had a significant effect on sulfate removal but is hard to come by and in short supply. Chicken manure and a mixture of zoo leaf compost with sawdust had the least effect.

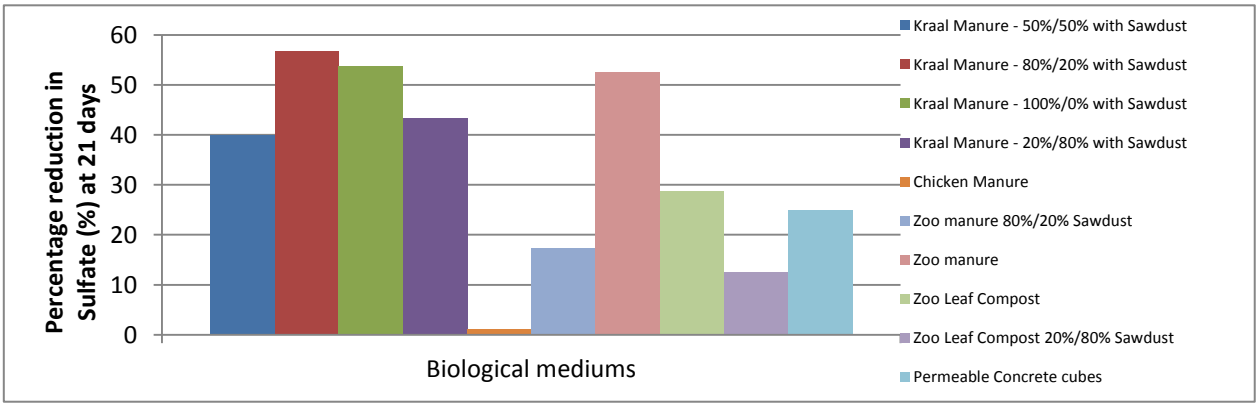

Figure 2 Sulfate removal after 21 days of operation for different organic feedstocks

The effect of residence time on the removal of sulfate for 5 selected scenarios is presented in Figure 3. Similarly to the data shown in Figure 2, kraal and zoo manure were the fastest removers of AMD with chicken manure having almost no effect after 7 days. This could be as a result of the ruminant bacteria which would occur in cattle, elephant, buffalo, and other herbivorous animal dung (which would not be present in the chicken manure). The sharp initial drop in sulfate concentration at the

start of the experiment (shown as the difference between AMD and the series) is attributed to the absorption of sulfates into the permeable concrete and organic materials. This effect, however, is short lived as the filter quickly becomes saturated and sulfate concentrations rise before DSR (Dissimilatory sulphite reductase) begins.

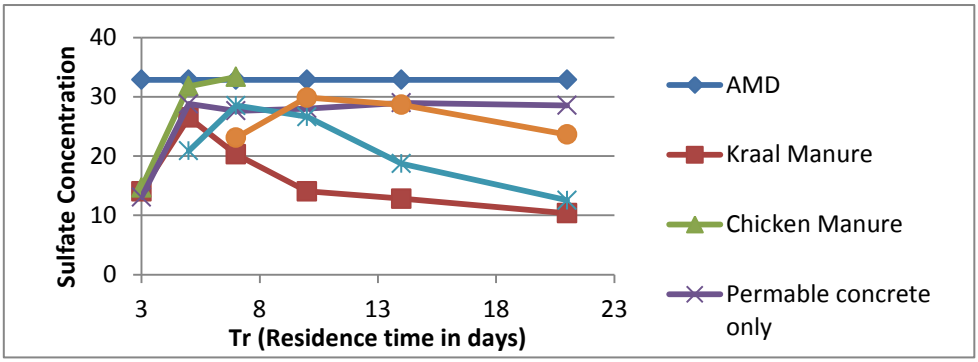

Figure 3 Effect of residence time on sulfate reduction

The permeable concrete cubes were able to reduce sulfates by 25% which is regarded as significant, as well as being effective at raising the pH of the passing AMD. The kraal manure was selected as the best performer and candidate for long term testing due to is ease of sourcing across Southern Africa, especially within the rural mining communities and areas, and is considered the best biological medium for the filters. As can be seen the organic medium typically becomes more effective at sulfate removal with time which correlates to the proliferation of SRBs and the curves typically represent a steady growth rate resulting in accelerated sulfate removal with time. The permeable concrete setups also show the initial drop in sulfates but show steady reduction of approximately 25% throughout the testing cycle which correlates well with the sulphate reductions found by Ekolu et al. (2013) in their experiments.

CONCLUSION

From the results of the research it is concluded that kraal manure is the most effective and readily available on a large scale of the organic feedstocks and when coupled with permeable concrete is able to effectively remove sulfates in a relatively short time frame (favourable results in 2-3 weeks) while raising the pH to almost neutral. The costs of the materials needed to construct these filters is significantly lower than other current passive solutions, and thus the filter system shows great promise as a low cost temporary solution to communities such as those like Maguqa township and others in Johannesburg where AMD is proliferating at high rates.

Due to the promise shown by the research over the short term it will be test further to ascertain the ability of the system to provide favourable remediation over longer periods, while quantifying limitations, capacities and performance of the filter system. The authors have already commenced with this long term testing, and it is ongoing.

Permanent long term solutions in South Africa more often than not require enormous capital outlay and infrastructure from government or mining bodies, and may take a number of years to be implemented. The hope is that the proposed filter system would be able to offer some short term relief to heavily affected receptors, especially in poor and/or rural communities.

ABSTRACT

Biological treatment systems can offer relatively low cost and minimal maintenance closure options for metal-rich adit discharge waters compared to conventional chemical-based water treatment facilities, however, sustaining the biological activity required to successfully treat the mine water in northern, cold climates has impeded its wider adoption. As part of an ongoing program to assess the potential of harnessing microbial sulfate-reduction to remove metals from mine water, a pilot bioreactor was built and operated at the Galkeno 900 adit in the Keno Hill Silver District (KHSD), located in central Yukon. The bioreactor operated year round at test flow rates between 0.5 and 1 L/s, achieving sustained removal of zinc (>99% removal; 5 – 6 mg/L reduced to 0.01 mg/L) and cadmium (0.0015 mg/L reduced to below detection limit (<0.0001 mg/L)), the primary contaminants of concern. Reductions in arsenic, antimony, and nickel loads of >80% were also observed under optimized flow rates, and the technology is being developed for closure of various adits across the KHSD.

Stimulation of sulfate-reducing conditions in underground mine pools that feed adit water discharge has also been advanced as the preferred option for water treatment for several underground mines in the KHSD. Such *in situ* treatment has been successfully piloted at the Platoro mine (CO, USA), where soluble organic carbon (molasses, methanol) was injected into the mine pool, which created sulfate-reducing conditions, causing >90% removal of zinc and arsenic. Annual injections of organic carbon were enough to maintain the low metal(loid) concentrations. Similar *in situ* treatment at the Schwartzwalder mine (CO, USA) lowered uranium concentrations by ~90%, from 22.8 mg/L to 1.8 mg/L, and the technology is currently being tested at the Silver King mine in the KHSD. Such relatively inexpensive and low maintenance options show great promise to the reliable closure of remote, cold climate mining sites.

Keywords: Bioreactor, mine pool treatment, zinc, uranium, cold climate

INTRODUCTION

Bioremediation of metal(loid) contaminated waters has garnered increasing interest in the past three decades as a relatively low cost tool to clean up former mining and industrial complexes, and provide closure options for operational sites. In particular, the semi-passive nature of many bioremediation systems, often requiring minimal maintenance and low power requirements, make them attractive treatment options in remote, cold climate settings which have limitations regarding power supply and year-round access. A number of bioremediation technologies harness the activity of sulfate-reducing bacteria (SRB), which are capable of coupling the oxidation of organic matter to the reduction of sulfate, to produce sulfide which reacts with many metals (e.g. zinc, cadmium, lead, nickel) to precipitate low solubility metal sulfide minerals. SRB are ubiquitous, thus simple addition of a soluble source of organic carbon to the contaminated waters, such as alcohol or molasses, is often enough to stimulate their activity.

Alexco Environmental Group has embarked on a multipurpose program to assess the potential of adding an organic substrate to mine adit water to support metals removal, whether within a constructed bioreactor or an underground mine pool, for use as a closure option for various historic adits in the Keno Hill Silver District (KHSD; Yukon, Canada). Although a number of bioreactor studies have been performed in cold climate settings (e.g. Ness, Janin & Stewart, 2014), there is a need for evaluating such technology on a site-specific basis, particularly under the challenging conditions of cold climate sites such as Keno Hill, which has a mean annual temperature of -3.3 °C. Treatment of subsurface metal-rich waters *in situ* by injection of soluble organic carbon to stimulate microbial activity has also received significant attention in recent years, showing promise for the removal of chalcophile metals (Saunders et al., 2005, 2008) and uranium (Anderson et al., 2003; Watson et al., 2013). Both such technologies have undergone (bioreactor) or are in the initial stages (*in situ* injection treatment) of testing at Keno Hill to evaluate their suitability as treatment options for the closure of historic adits in the District. This paper presents an overview of:

- The Galkeno 900 bioreactor trial at Keno Hill; and
- Case studies of *in situ* injection treatment of mine pools at Platoro (CO) and Schwartzwalder (CO) mines as an analogue for treatment at Keno Hill

METHODOLOGY

Bioreactor

The pilot bioreactor was constructed to treat a portion of water leaving the Galkeno 900 adit in Keno Hill. The adit water was circumneutral and the primary contaminant of concern was zinc, which typically ranged between 5 and 7 mg/L in the untreated adit water over the duration of the pilot test.

Construction

The bioreactor was approximately 90 feet by 100 feet and had a liquid-filled portion that was 10 feet deep. It was dug partially into the native ground with an excavator, and the remaining depth was created by forming a berm around the excavated area. The bermed/excavated area was lined with 60 mil HDPE liner to form a pond, and then filled with waste rock recovered from a local placer

mine. A geofabric was laid across the bioreactor, and soil from the excavated area and hillside was used to provide a 4 foot soil cover over the bioreactor, which acted as an insulating layer. All inlet and outlet piping was similarly buried to reduce the possibility of freezing. Water entered the bioreactor through an inlet valve and influent sump where it was pumped into a perforated distribution pipe, and the mine water then flowed through the bioreactor to a 0.75 inch hole perforated collection pipe on the far side of the bioreactor. Baffling was installed in two locations to create a tortuous flow path and increase the contact time of the water with the media within the bioreactor (Figure 1).

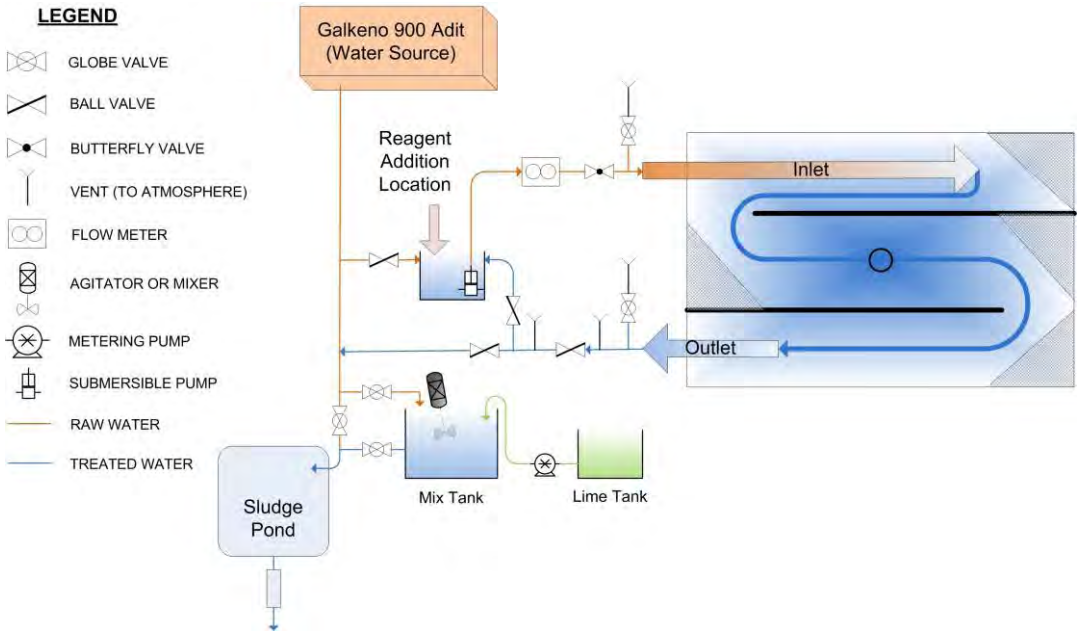

Figure 1 Pilot bioreactor layout

Operation

Following construction in October 2008, the bioreactor was filled with adit water, which was initially supplemented with sucrose (182 kg), methanol (416 L) and dried milk solids (1.8 kg) to stimulate indigenous microbial activity. Over the subsequent year, water was recirculated within the bioreactor to allow reducing conditions to develop. Further batches of methanol (416 L in January 2009) and sucrose (20 kg in July 2009) were added to promote the transition to sulfate-reducing conditions, assisted by the continuous addition of methanol via a metered pump (1 L/day, initiated in May 2009). Once sulfate-reducing conditions were established, the bioreactor began flow-through operation at 0.5 L/s in October 2009, transitioning to 1 L/s in December 2009, then to 0.75 L/s in August 2010. The pilot bioreactor was terminated in March 2011.

Overview of *in situ* mine pool treatment

In situ mine pool treatment is accomplished by delivery soluble organic carbon into the mine workings. Depending on the mine geometry and setting, the organic carbon can be injected in an upgradient area of a mine and the treatment is accomplished in the mine along the flow path.

Alternatively a recirculation approach can be taken, where water is pumped up from the mine workings from a shaft or other access location, amended with soluble organic carbon by mixing at the surface, then returned to the mine via a second pipe placed down another shaft. This recirculation loop allows for mixing of the subsurface water, while the injected organic carbon stimulates indigenous microbial activity. Prior to, or during, organic carbon addition, a tracer is injected (salt or organic dye) to determine the residence time of the mine pool. The form of organic carbon selected is dependent on the residence time; alcohol-based reagents (e.g. methanol) are preferred for short residence times (few weeks) or for sustaining treatment after initial phases of application, whereas slower degrading sugars or starch-based reagents (e.g. molasses) are employed for mine pools with longer residence times (few months or longer) or in the initial growth phase. Injections of organic carbon are typically spaced a few months to as long as years apart, depending on the extent and longevity of the water quality improvements observed, and the rate of recharge of oxygenated water or oxidized constituents (metals, sulfate, or nitrate).

Mine pool treatment can also be enhanced by the addition of ferric oxyhydroxide-based precipitates generated from water treatment plants (WTP). Application of the treatment sludge back into the mine is done by blending the sludge with starches and cellulosic matter to provide a slow release organic carbon source, which supports microbial transformation of the sludge and the subsequent formation of iron sulfide which tends to coat the subaqueous surfaces in the mine. Furthermore, density differences (e.g. sugar syrups are denser than water, alcohols (methanol/ethanol) are less dense than water) are used to target deep zones in mine pools that would not otherwise be accessible to mixing by recirculation.

Platoro, CO

The Platoro underground gold-silver mine is located at 10,000 feet elevation in the remote San Juan mountains of southern Colorado. Adit discharge water (pH 2.7), supplied by an underground mine pool, contains elevated concentrations of arsenic (*ca.* 50 mg/L) and zinc (*ca.* 17 mg/L), which a conventional lime-based WTP had difficulties in reliably treating to meet local discharge standards. *In situ* mine pool remediation was piloted in 2000 (single injection of soluble organic carbon in September) as a pre-treatment step which would lower the metal load exported by the adit and allow for more effective metal removal by the existing WTP. Annual treatment was initiated in August 2006 in which an alcohol and a molasses-based carbon source was injected into the mine pool to again drive the system towards microbially-mediated sulfate-reducing conditions. In August 2009, July 2010 and July 2012, a total of 15,000 m^3 of waste metal hydroxide sludge produced by the WTP was also injected into the mine pool to raise the pH. As the sludge was injected into the mine, potato and/or corn starch was blended into the sludge while soluble carbon addition continued. Throughout the sludge reinjection process the ratio of soluble carbon (sugars and alcohols) to insoluble carbon sources (starches) was carefully modulated based on observation of the redox of the mine pool. Also, the selection of the potato starch vs the corn starch was varied in response to both pricing variations and to target the optimal average particle size of starch to settle in the mine pool water at the same rates as the sludge particles.

Schwartzwalder, CO

The Schwartzwalder uranium mine is located in Jefferson County, CO. Prospecting and mining at Schwartzwalder started as recently as 1953 and was developed as a multi-level, hard rock underground mine. The mine was placed into closure in 2000. Since 2010, alluvial groundwater

around the mine has been collected and treated via ion exchange (IX). De-watering and treatment via reverse osmosis (RO) has also occurred to treat the elevated uranium concentrations (23 mg/L) present in the circumneutral mine pool/groundwater. *In situ* mine pool treatment was initiated in May 2013 as a pre-treatment step to the RO system in which molasses and methanol were injected into the mine pool. Three further monthly injections of methanol followed, and a second injection of molasses and methanol was made six months after the start of operations. Water quality was monitored biweekly.

RESULTS AND DISCUSSION

Galkeno 900 Bioreactor

During the initial nine months of bioreactor recirculation and organic carbon amendment, the concentrations of zinc, cadmium and arsenic declined (Figure 2), however, sulfate-reducing conditions were not yet established. Metal(loid) removal during this period is primarily ascribed to co-precipitation with, and adsorption on manganese and iron (oxyhydr)oxides that likely formed within the bioreactor during recirculation. Lower manganese and iron levels observed in the bioreactor compared to the adit water support this premise, as does the presence of manganese and iron-bearing (oxyhydr)oxide phases around the Galkeno 900 adit, and other adits elsewhere in the KHSD. A sharp increase in bioreactor concentrations of arsenic and cadmium (and a moderate rise in zinc) was observed in August 2009. This was coincident with sequential spikes in manganese and then iron concentrations in the bioreactor discharge, suggesting that the bioreactor had transitioned from oxic to manganese- and iron-reducing conditions, causing solubilization of the iron and manganese (oxyhydr)oxides that had been deposited earlier, and release of their sorbed and co-precipitated metal(loid) inventory. The subsequent rapid fall in zinc and cadmium concentrations in the bioreactor discharge from August 2009 onwards is interpreted as the onset of sulfate-reducing conditions and the associated precipitation of zinc and cadmium as sulfide minerals (Jong & Parry, 2004). Indeed, mineralogical analyses of material collected from the bioreactor interior at the end of the pilot by electron microprobe and synchrotron-based techniques indicated sequestration of zinc as biogenic sphalerite (ZnS). Arsenic concentrations declined more slowly, related to continued supply from dissolution of iron (oxyhydr)oxide hosts, but were still considerably lower than adit levels (Figure 2), likely adsorbed on, or incorporated into other biogenic metal sulfide phases such as mackinawite and pyrite (Omoregie et al., 2013; Saunders et al., 2008).

That it took almost one year to reach sulfate-reducing conditions in the bioreactor is partly a reflection of the slow growth rate of psychrophilic SRB at the temperature range of the adit water (1 – 10°C over the year). Based on the bioreactor volume, and the mass of sulfate removed from the bioreactor at a flow-through rate of 1 L/s, the sulfate reduction rate (SRR) was calculated to be 45 $mM/m^3/day$. This is in line with the SRR observed in arctic ocean sediments by Kostka et al. (1999), which was generally in the range 60 – 100 $mM/m^3/day$, suggesting that the bioreactor had a similar SRR as natural systems that have long term adaptation to cold environments.

Following the recirculation period and onset of sulfate-reducing conditions, the bioreactor operated year round in flow-through mode at various test flow rates. It achieved sustained removal of zinc (>99% removal; 5 – 6 mg/L reduced to 0.01 mg/L) to levels well below the site effluent quality discharge standard (0.5 mg/L) at flow rates of 0.5 and 0.75 L/s. Concentrations of cadmium, another constituent of concern at Keno Hill, were typically lowered from *ca. 0*.0015 mg/L to below detection

limit (<0.0001 mg/L) at all flow rates tested. Reductions in arsenic, antimony, and nickel loads of >80% were also observed at flow rates of 0.5 – 0.75 L/s. Changes in the flow-through rate in the bioreactor had little impact on the removal of cadmium and arsenic from the influent adit water, however, a switch from 0.5 L/s (21 day residence time) to 1 L/s (10.5 day residence time) impacted the treatment efficiency for zinc. The lower hydraulic residence time at the high flow rate limits the extent of zinc sulfide precipitation, and the higher flow rate restricts the ability for the particulate zinc sulphide formed to physically fall out of solution. Indeed, the majority of zinc leaving the bioreactor was in particulate form (>0.45 μm), suggesting that the coarse rock in the bioreactor was unable to filter out the zinc sulphide formed, in line with observations from other bioreactors studies (Gammons & Frandsen, 2001).

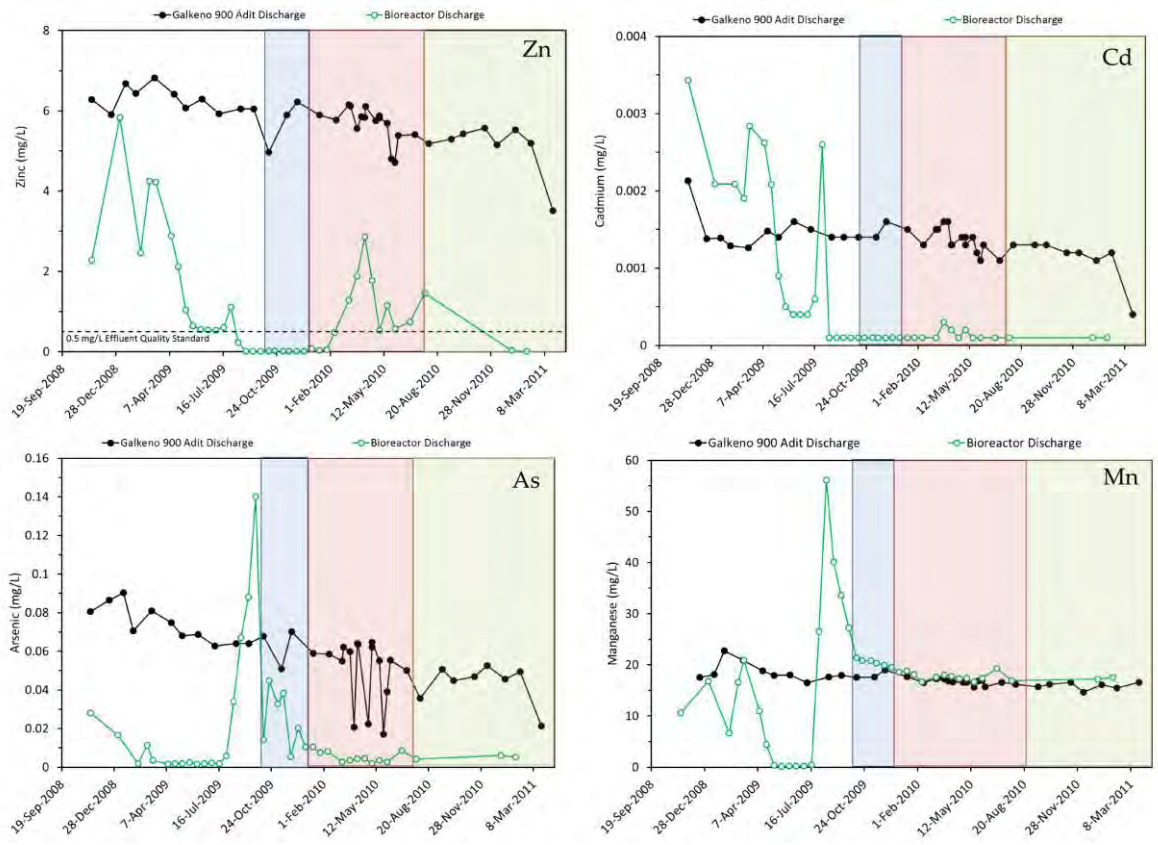

Figure 2 Concentrations of selected parameters in untreated adit water and bioreactor discharge water. Flow-through operation at 0.5 L/s, 1 L/s and 0.75 L/s, indicated by blue, red, and green shaded boxes, respectively

In situ mine pool treatment

Platoro, CO

The initial injection of soluble organic carbon into the subsurface mine pool at Platoro in September 2000 caused a rapid diminution in zinc and arsenic concentrations (Figure 3). The decline in zinc and arsenic levels was mirrored by a drop in total organic carbon (TOC) and sulfate. This points toward the oxidation of organic carbon by SRB, resulting in the precipitation of zinc sulfide (likely

sphalerite) and incorporation of arsenic into arsenic sulfide and co-precipitation with, and sorption on other authigenic metal sulfide minerals (Saunders et al., 2005, 2008; Omoregie et al., 2013; Kirk et al., 2010). Within three months of injection, arsenic concentrations had declined by >90%, reaching peaks of >99% removal over the following 6 – 18 months. The rate of zinc removal was slightly lower, reaching >90% removal seven months after treatment began, and also peaked at >99% sequestration 14 – 18 months after the injection of soluble organic carbon. Slight rises in zinc and arsenic concentrations were observed during freshet as oxidizing surface waters were introduced to the mine, however, substantially diminished concentrations of arsenic and zinc (>80% lowered) persisted for thirty months before a rebound was observed (Figure 3). It is interesting to note that the zinc and arsenic concentrations did not fully recover, and instead oscillated between 30% and 60% lower than their pre-treatment levels, suggesting some longer-term sequestration potential.

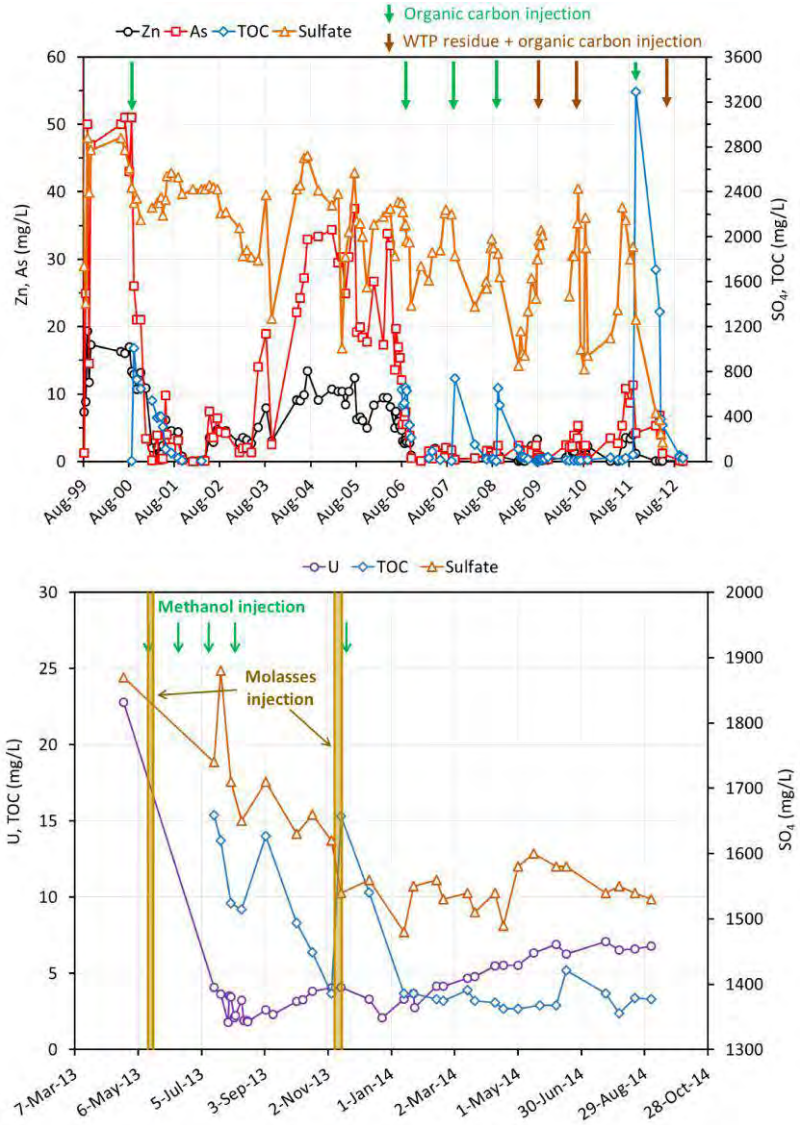

Figure 3 Change in mine pool concentrations of selected constituents at Platoro (top) and Schwartzwalder (bottom) during *in situ* mine pool treatment

A program of single, annual treatment injections was initiated at Platoro in August 2006. This maintained lowered arsenic and zinc concentrations with average removal efficiency of 97% and 93%, respectively, enabling the existing WTP to meet regulatory discharge requirements. Recycling of metal hydroxide sludge produced by the WTP into the mine pool caused the mine pool pH to rise from 2.7 to 8 within six weeks of the onset of sludge transfer to the mine workings. This further reduced the strain on the downstream WTP by reducing the amount of lime required to raise the pH and minimizing the amount of sludge requiring disposal.

Schwartzwalder, CO

Within three months of injection of molasses and methanol into the Schwartzwalder mine pool, the uranium concentration dropped by 90%, from 22.8 mg/L to 1.8 mg/L (Figure 3). This was accompanied by a decline in the concentration of sulfate and sulfide mineral-forming elements such as molybdenum, indicating that a sulfate-reducing environment was rapidly established in the mine pool. This was supported by the appearance of black suspended particulates and the development of a sulfurous odor in the mine pool water within the first few weeks of treatment. Numerous field-based studies (e.g. Anderson et al., 2003; Watson et al., 2013) have documented that such conditions are conducive to the reduction of soluble U(VI) to insoluble U(IV), resulting in the decline in uranium concentrations observed in the mine pool. Scanning electron microscope (SEM) analysis of the black suspended particulates revealed abundant microbial cells encapsulated in iron sulfide and uranium (Figure 4), the latter likely present as uraninite (UO_2) and/or monomeric uranium (Bargar et al., 2013).

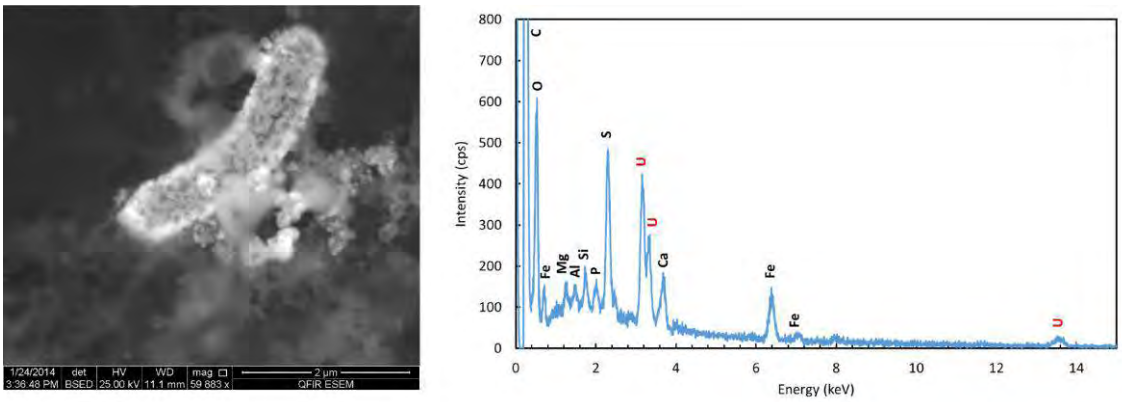

Figure 4 SEM image (left) and elemental analysis (right) on mineral encrusted microbial cell present in suspended particulates collected from Schwartzwalder mine pool a few weeks after treatment was initiated

U(VI) reduction can be mediated by direct, enzymatic activity by a range of metal- and sulfate-reducing microorganisms (Kostka & Green, 2011), or indirectly by the products of microbial sulfate-reduction (Gallegos et al., 2013), with a coupling of abiotic-biotic pathways likely (Barger et al., 2013). Indeed, the pool of iron sulfide (likely mackinawite) minerals formed can serve as a buffer to retard re-oxidation and re-solubilization of uranium (Dullies et al., 2010; Gallegos et al., 2013). Thus, although uranium concentrations in the Schwartzwalder mine pool started to rise three months after the last molasses/methanol treatment (Figure 3), the increase was likely slowed by the presence of reduced mineral phases that tempered the impact of any oxygenated water that

migrated into the system. Furthermore, ferric (oxyhydr)oxide minerals produced from the oxidation of iron sulfide phases can limit the release of oxidized uranium via sorption processes (Gallegos et al., 2013).

The low metal(loid) concentrations that were sustained in the Platoro adit discharge are likely due to the higher concentration of organic carbon that was injected (creating a large electron donor source to maintain ongoing sulfate reduction) compared to the Schwartzwalder site. The in-situ treatment of the Schwartzwalder mine pool was interrupted by a 0.5 m rainfall event which destroyed access to the site by large tanker trucks. Only 60% of the target carbon addition was achieved due to this disruptive event. It was important that dosage of the mine pool not exceed the overall targeted stoichiometry and that the rate of addition be carefully controlled because the RO membranes are susceptible to fouling with organic matter and because of the regulatory requirement that RO system operation commence with the organic carbon dosage of the mine pool.

CONCLUSION

When continuous flow was maintained to the Galkeno 900 bioreactor at acceptable flow rates, effective treatment was maintained, meeting discharge requirements for zinc, and reducing arsenic and cadmium levels to close to detection limits. The removal efficiency of zinc and nickel suffered at higher flow rates, likely due to a combination of reduced hydraulic residence time and poor filtration of the particulate metal sulfide phases formed due to the coarse nature of the rock used to construct the bioreactor. Design improvements for future bioreactors at Keno Hill include:

- Use of smaller fill material in the bioreactor to improve filtration and removal of metal sulfides within the bioreactor (Tsukamoto, Killion & Miller, 2004);
- Creation of longer, narrower flow paths to increase residence time and limit "dead zones" where little sulfate-reduction occurs; and
- Incorporation of solid phase carbon (e.g. sawdust, wood chips) into the bioreactor during construction to provide a secondary source of carbon in the event that addition of soluble organic carbon is temporarily suspended

In situ injection treatment at the Platoro and Schwartzwalder mine pools resulted in >90% removal of zinc, arsenic and uranium within a few months of the treatment injection. The low metal(loid) concentrations were sustained over many months, allowing further treatment injections to be made on an infrequent basis (annual in the case of Platoro), which is suited to remote mine sites. This treatment may be used as a stand-alone technology for sites where metal concentrations are within an order of magnitude of discharge standards, or as a pre-treatment option to reduce metal loads (and associated maintenance costs) entering more conventional downstream treatment systems. Based on these results, *in situ* injection is currently being piloted at the historic Silver King mine in Keno Hill.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the assistance of Jim Lancaster and Joe Lister in the construction of the Schwartzwalder treatment/mine pool dewatering and reinjection system, and Krystal Truax in data collection and management at the Schwartzwalder mine treatment project. Jim Lancaster and Jim Muntzert are also thanked for their support in the sludge transfer and treatment process at the Platoro project.

Investigation of Microbial In-Situ Remediation of Uranium Mine Site Pollutants in the Flooded Mine Königstein

Andrea Kassahun, Ulf Jenk and Michael Paul
WISMUT GmbH, Germany

ABSTRACT

Mining activities in the former uranium mine Königstein left acidic, highly oxidized drainage waters with pollutant concentrations (e.g. uranium) of several milligrams per litre. In the current process of mine flooding, pump and treat prevents pollution spreading. Since acid mine drainage will be generated over long periods of time, possibilities of in-situ pollutant retention within the pollutant plume are under investigation as cost saving alternative to decades of pump and treat.

A novel reactive zone technology for retention of inorganic mine site pollutants based on the stimulation of autochthonous sulphate reducing bacteria and a sequence of mineral forming processes was developed. The key process is the microbial mediated precipitation of iron sulphides, which bind pollutants and act as redox buffers under gradual transformation of their surface bound iron oxy(hydr)oxides when exposed to oxygen containing groundwater.

The stimulation of autochthonous sulphate reducing bacteria, whose existence in the mine sediments was previously shown, was tested in column experiments using a novel reactive material. It consists of silicate foam glass and zero-valent iron powder. In contact with AMD, the reactive material emits molecular hydrogen and serves as pH-buffer. Microbial colonization, precipitation of pyrite and other mineral species and pollutant accumulation to several weight percent (e.g. 1 to 3 wt.% for uranium, arsenic and zinc) were analysed at the surface of the reactive material after contact with mine waters and sediments for about one year. At redox transition to oxic conditions, iron oxyhydroxide crystallization was observed as coatings around reduced mineral formations ensuring a long term stable pollutant immobilization. Effluent pollutant concentrations during the column experiments remained beneath 150 µg/l.

Keywords: bioremediation, microbial sulphate reduction, biofilm, pollutant bonds

INTRODUCTION

From 1946 to 1990, SDAG WISMUT in former East Germany was the major foreign uranium supplier to the Soviet Union. During that period, around 215,000 tonnes of uranium were produced from more than 20 deposits. The Königstein deposit provided around 10 % of the total amount. Around 6,000 tonnes of U from the Königstein deposit were mined by acidic in-situ leaching. Mining activities caused primary uranium ores as well as sulphidic co-mineralisation to oxidize and shift to water soluble forms. The mine's inventory of mobile uranium prior to flooding was estimated 2,000 tonnes.

The Königstein mine is situated in the deepest of four sandstone aquifers. Groundwater would seep through the mine at natural flow conditions. At mine flooding, pump-and-treat prevents pollutant spreading into adjacent aquifers. Within the first fifteen years of flooding, 25 – 50 tonnes of uranium were discharged from the mine every year. Presuming constant mass flow rates, removal of the estimated amount of mobile uranium would last 40 to 80 years. Declining pollutant concentration with time will even prolong the period of potential pollution of adjacent aquifers.

In order to find cost saving alternatives to decades of pump and treat, the in-situ retention of mine site pollutants within a reactive zone was investigated. The aimed key process within the reactive zones is reductive precipitation of pollutants and thus their transfer back to water insoluble forms.

METHODOLOGY

For initiation of reductive pollutant precipitation, reducing geochemical conditions and a surplus of sulphide ions is required. Therefore, microbial sulphate reduction by autochthonous SRB is to be stimulated within the reactive zone. Microbial screening of mine drainage water, sandstone and iron hydroxide sludge samples was carried out to assess the presence of autochthonous SRB. DNA extractions were performed and 16S rDNA clone libraries were constructed [Seifert et al, 2008].

Batch tests were used to stimulate and quantify microbial sulphate reduction and to identify pollutant fixation at sulphate reducing conditions. Mine drainage water (1.07 l) was added to a mixture of milled sandstone (50 g) and milled iron hydroxide sludge (17.5 g) in gas tight glass bottles. Stimulation of SRB was performed by addition of ZVI (3 g cast iron powder) releasing H_2 as substrate for autotrophic microbes and iron ions to stimulate the formation of reduced pollutant precipitates. The headspace of the test bottles was first flushed with N_2 and later with a mixture of H_2/CO_2 after each water sampling. Tests were conducted for 240 d. Sulphate reduction rates were obtained from $^{32/34}S$ isotope analysis at dissolved sulphate ions (Helmholtz Centre for Environmental Research). Pollutant fixation was investigated by ICP-OES analysis of mine water solutes and XPS (X-ray photoelectron spectroscopy) analysis of pollutant coordination within the sediment (SGS Institute Fresenius).

To induce autotrophic sulphate reduction and pollutant precipitation within the flooded mine, a reactive material was developed. It consists of silica covered foam glass. The silica cover contains cast iron powder. The granules (1-3 cm diameter) float at mine typical pressures. They provide substrates that favour microbial growth and mineral precipitation. The reaction sequence of microbial sulphate reduction and mineral precipitation induced by the reactive material was investigated in column experiments. 25 kg of sandstone (< 3 mm), 4.5 kg of iron hydroxide sludge and 2.4 kg of reactive material were place in horizontal glass columns equipped with water in- and outlets as well as sample ports for water, gas and solids. The columns were filled with 8 l of mine water and exposed to continuous mine water flow-through at ~250 ml / d for 250 days. Pollutant fixation was investigated by

ICP-OES analysis of mine water solutes and REM-EDX analysis (TU Bergakademie Freiberg) of reactive material surfaces. For identification of pollutant bonds, sequential extractions were used [Graupner et al., 2007 for method description]. Microbial colonization was investigated by DNA extraction and classification using the clone bank constructed. Furthermore, $^{32/34}S$ isotope analysis of dissolved sulphate ions (Helmholtz Centre for Environmental Research) and GC-analysis of dissolved permanent gases were performed.

RESULTS AND DISCUSSION

Microbial screening

The mine drainage water was dominated by acidophilic iron oxidizing *Betaproteobacteria* (abundance of sequences related to *Ferribacter polymyxa*; second major sequence group with similarities to *Acidithiobacillus ferroxidans*), and heterotrophic acidophiles in minor parts.

A dominance of the sulfate-reducing bacteria *Desulfovibrio* (ca. 70%) in association with other members of the *Deltaproteobacteria*, members of the *Alpha-*, *Beta-* and *Gammaproteobacteria*, *Actinobacteria,* and *Firmicutes* was obtained for the analysed iron hydroxide sludge sample. The sandstone sample revealed a high bacterial diversity. About 20% of the analysed clones could be classified as sulphate-reducing bacteria, others were similar to aerobic and anaerobic bacteria with various physiological properties.

Fig. 1 depicts the frequency of the bacterial classes obtained by sequence analyses of clone libraries constructed with DNA of the sludge and the sandstone sample. The phylogenetic tree (Fig. 2) shows the distribution of sequenced clones belonging to the classes of *Firmicutes* and *Deltaproteobacteria* from the two clone libraries. Both harbor genera described as sulphate, sulphite, thiosulphate, and sulphur reducing bacteria. The obtained clones were used to create a fragment library for T-RFLP. This database was used to investigate further samples from the mine site, in which sulfate-reducing bacteria, like *Desulfovibrio* and *Desulfosporosinus* were detected [Seifert et al., 2008].

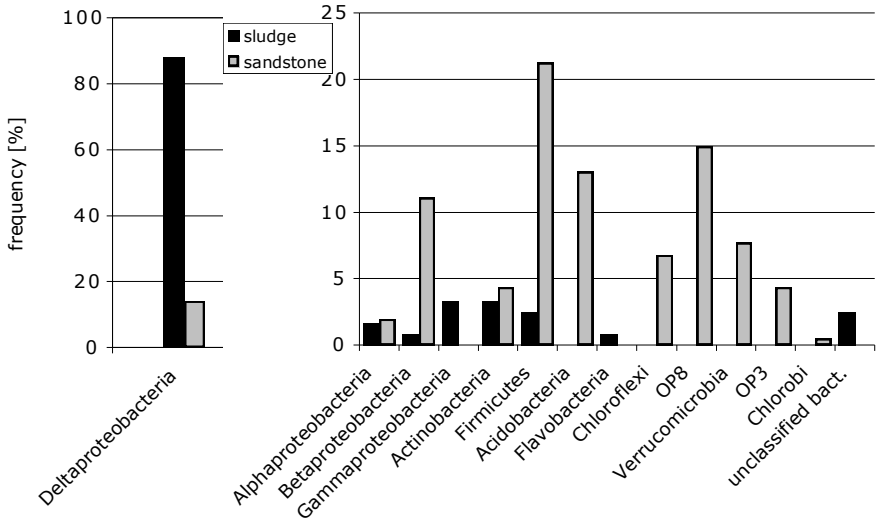

Figure 1 Frequency of bacterial classes obtained from DNA extracted from mine sandstone and mine iron hydroxide sludge [Seifert et al, 2008]

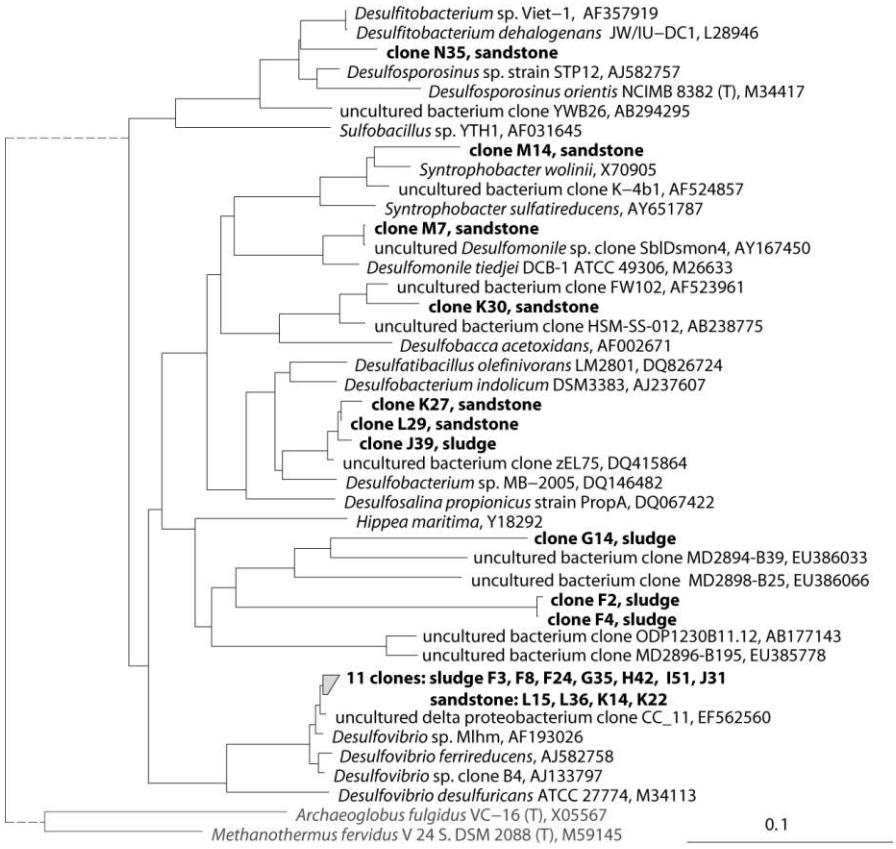

Figure 2 Phylogenetic tree of 16S rDNA sequences of *Deltaproteobacteria* and *Firmicutes* from the sludge and the sandstone sample (the sequence group within the *Desulfovibrionales* branch consists of 11 sequences from both samples; Seifert et al, 2008)

Batch tests

Tab. 1 contains the average mine water composition used for pollutant removal batch tests.

Table 1 Selected chemical parameter of mine water

pH	E_H [mV]	EC [mS/cm]	SO_4 [mg/l]	Fe [mg/l]	Ca [mg/l]	U [mg/l]	Zn [mg/l]	Ni [mg/l]	Pb [mg/l]	Cd [mg/l]	As [mg/l]
2.8	640	3	1,500	120	300	15	15	0.5	0.5	0.1	0.05

Resulting from anaerobic iron corrosion (eq. 1), redox potential decreased to -35 mV after 7 days while H_2 was detected in the bottles headspace and the concentration of iron ions increased by a factor of 3.5. After 35 days, redox potential further dropped to – 120 mV causing pollutant concentrations to fall below 200 µg/l. At the same time, pH increased to > 6.5 (Fig. 3 - upper graph).

$$Fe^0 + 2H_2O \rightarrow Fe^{2+} + H_2 + 2OH^- \quad (1)$$

Sulphate reduction was observed after a lag-phase of about 40 days in all batch tests. At first it was verifiable by a complete blackening of the bottles, which indicates iron sulphide precipitation. Because of excess of ferrous iron, no dissolved sulphide was detectable. Simultaneous decrease of iron and sulphate concentrations was measured from day 40 onwards until the end of the tests (Fig. 3 - lower graph). With decreasing SO_4 concentration in solution, the heavy isotope ^{34}S enriched within the remaining dissolved sulphate (Fig. 4). This serves as indicator of microbial sulphate reduction, since the light isotope ^{32}S is favoured in metabolism of sulphate reducing bacteria. T-RFLP investigations of batch tests aqueous phase (day 130) showed, that the microbial community was dominated by *Desulfovibrio sp.* and *Desulfosporosinus sp.*. Autochthonous sulphate reducing bacteria were stimulated successfully. The microbial sulphate reduction rate was 1-5 mg / l ·d.

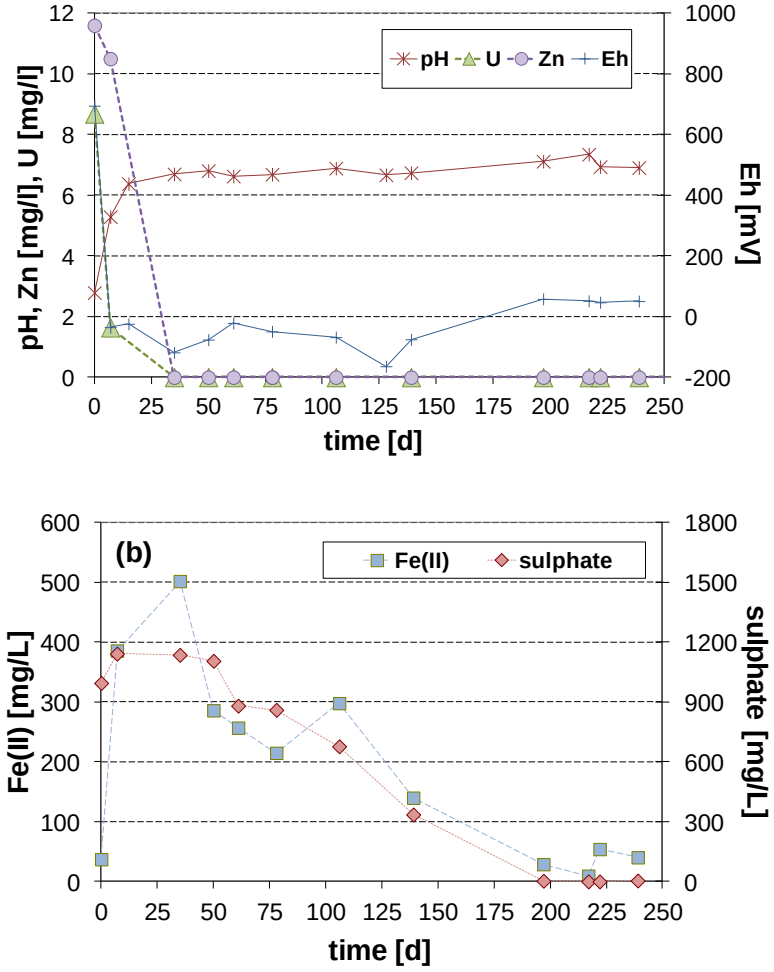

Figure 3 Selected solution parameter (above: pH, E_H, U, Zn; below: Fe, SO_4) during batch tests

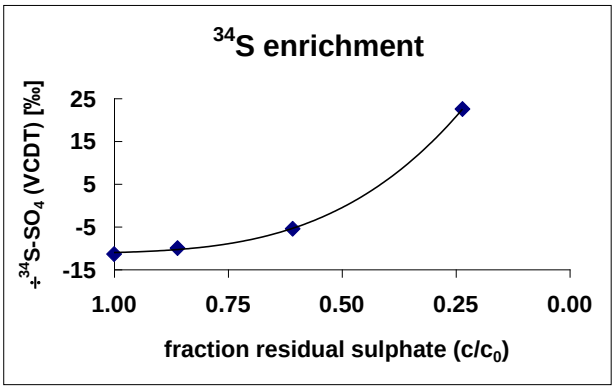

Figure 4 ^{34}S isotope enrichment in the residual dissolved sulphate of the batch test aqueous phases

XPS analysis of the solid phase (day 240) identified sulphur to occur completely reduced in monosulphide (50.9%) and disulphide phases (49.1%). This implies complete sulphate reduction and partly alteration of the initially precipitated iron monosulphide within the time period of the test. Iron was shown to be bond to sulphides (19.9%) and oxides (80.1%). The high percentage of iron oxides is related to the iron hydroxide sludge used in the test systems. Moreover, XPS analyses revealed uranium to be nearly complete immobilized in reduced mineral phases. It occurs predominantly tetravalent (80.1% UO_2) and partially in polysulphide phases (9.1% US_x (x>1)). 10.8% of the sediment bonded uranium remained hexavalent, most probably adsorbed to the iron hydroxide phase. Zn was found in ZnO coordination, which may result from $Zn(OH)_2$ precipitation with subsequent phase transformation. The test results indicate pollutant precipitation and iron sulphide formation as independent processes. Pollutant precipitation occurs prior to iron sulphide formation and is related to changes in pH and pe resulting from anaerobic iron corrosion. Microbial sulphate reduction is stimulated by H_2 evolving at anaerobic iron corrosion. Sulphide precipitates with ferrous iron to iron monosulphide, which in turn transformed partly to iron disulphide.

Column tests

The initial composition of the column feed is summarized in Tab. 2. Selected chemical parameter of the column effluents are depicted as function of test duration in Fig. 5 (above: U and Zn; below: pH, redox potential, dissolved H_2, H_2SiO_3). The pollutant concentrations[1] of the column effluent remained beneath 150 µg/l over the entire test period. Column passage caused a rise in pH from pH=3 to pH>8 and a drop in redox potential from Eh=770 mV to Eh≤250 mV due to immediate silica dissolution at the surface of the reactive material.

Table 2 Initial concentrations of column feed

pH	E_H [mV]	EC [mS/cm]	SO_4 [mg/l]	Fe [mg/l]	Ca [mg/l]	U [mg/l]	Zn [mg/l]	Pb [mg/l]	As [mg/l]	H_2SiO_3 [mg/l]	TIC [mg/l]
2.9	770	1.5	625	65	110	8.9	6.7	0.5	0.03	25	3

[1] also for Pb, As, Cd and Ni (not depicted in Fig. 5)

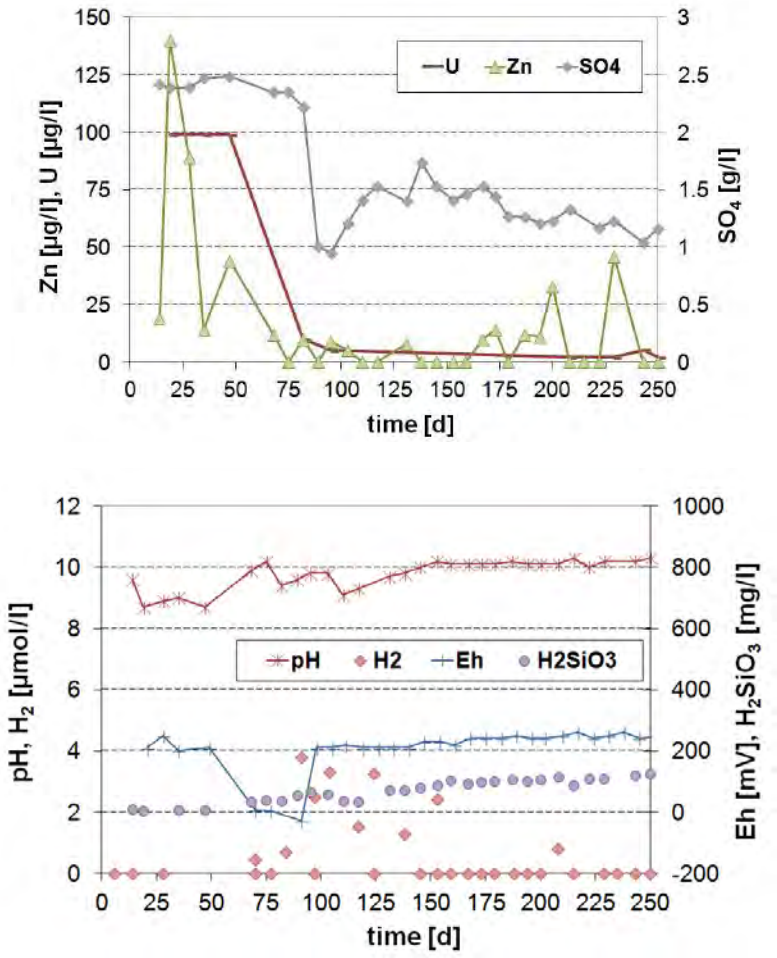

Figure 5 Selected parameter of column effluent (above: U, Zn, SO_4; below: pH, E_H, H_2, H_2SiO_3)

Around 70 days after the experiment started, anaerobic oxidation of the silica embedded ZVI set in as indicated by H_2 formation and redox potential decrease. At the same time, dissolved silica concentrations of the column effluent increased (Fig. 5 - lower graph). Dissolution of reactive material silica coatings led to pH buffering and exposure of the embedded ZVI. H_2 was detectable in water and gas samples sporadically until the end of the experiments (gas phase data not shown). Due to high pH, mine water iron precipitated within the column immediately and the effluent did not contain any dissolved iron. At the beginning of the experiments, sulphate concentrations multiplied by factor 4 during column passage because of sulphate leaching from the rock material (Fig. 5 - upper graph). At day 90, effluent SO_4 concentrations declined sharply, while anaerobic iron oxidation and H_2 supply was ongoing already. Because SO_4 feed concentrations stayed constant (data not shown) and microbial sulphate reduction counts for a maximum concentration decrease of 160 mg/l only (32 days residence time within the column; 5 mg/ l · d maximum SO_4 reduction rate), sulphate leaching rates and mineral reactions affect the effluent sulphate concentrations significantly. This prevents clear evidence for microbial sulphate reduction from concentration decrease and ^{34}S enrichment in the residual sulphate. ^{34}S isotope data of the effluent sulphate show only a slight enrichment of the heavy isotope (Fig. 6).

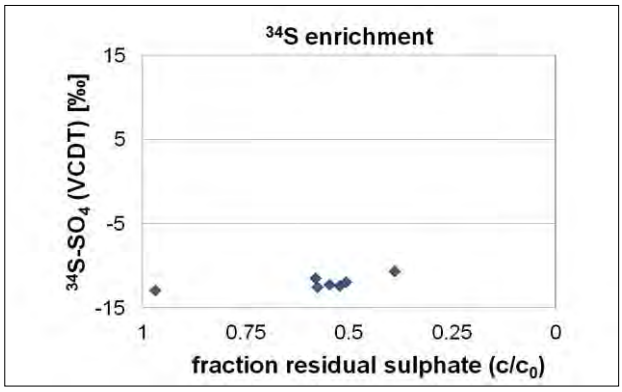

Figure 6 ^{34}S isotope enrichment in the residual dissolved sulphate of the column test effluent

The presence of sulphate reducing bacteria in the column effluent at the end of the experiment was confirmed by T-RFLP investigations. 35 % of the identified microbial DNA was assigned to sulphate reducers. Iron and sulphur oxidizing bacteria and nitrogen fixing bacteria were also identified. Next to species which were detected before in mine water and sandstone samples, the column effluent also contained typical soil bacteria (*Bosea thiooxidans sp.*, *Solirubrobacter soli sp.*).

After the experiment, the reactive material was sampled from the column for investigation of pollutant content and mineralization. Fig. 7 shows REM photographs of the reactive material surfaces, which were found to be extensively colonized by microbes (A). Within the biofilm, pollutant enrichments were identified by EDX-analysis. The bright particles (B - strong backscattering in BSE mode of heavy elements) contain U, Pb, Fe, S and C and are interpreted as sulphidic and reduced mineralization. The smaller spheres are iron (hydr)oxides (C). Their EDX spectra contain U, As, Fe, C and lack S. The coexistence of reduced and oxidized minerals is possible due to their embedding in the biofilm matrix which allows for redox niches.

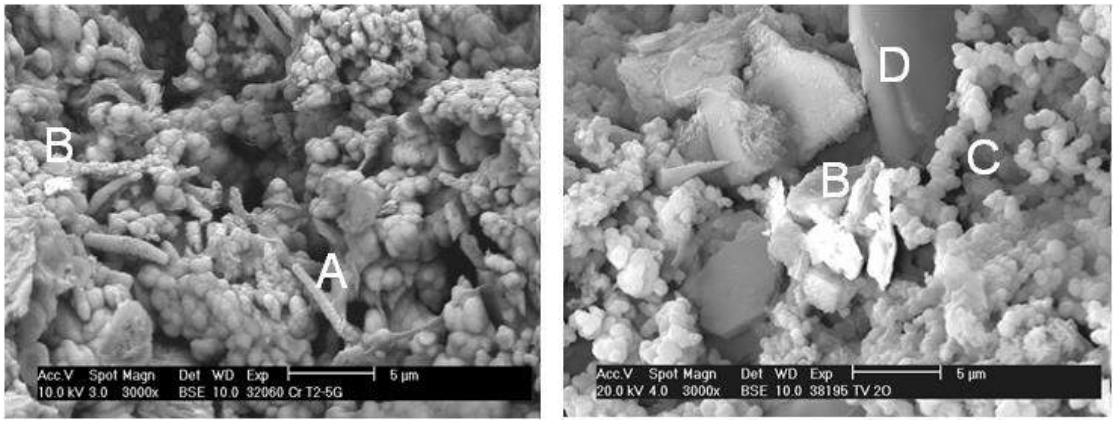

Figure 7 REM photographs of reactive material surfaces after the experiment (left: biofilm remnants and microbial structures with cell wall mineralisation (A) and heavy element accumulations (light coloured particle B); right: heavy element accumulation (light coloured particles B), iron (hyr)oxides spheres (C) and silica sheets (D)

The coexistence of oxidized and reduced minerals also occurred in a larger scale. The left photograph in Fig. 8 shows a glass column segment after the experiment with blackening of iron hydroxide sludge (orange) and sandstone dust (grey) in contact with reactive material. The right photograph shows the alteration of the reactive material (originally grey granules), on which mineral coatings precipitated (orange and blackish-red granules). Sequential extractions of the blackish-red coating revealed the highest pollutant content within the reduced mineral fraction, followed by the fraction content of amorphous iron hydroxides and biofilm organic substances (Fig. 8 – upper bar chart). In contrast, most iron is bond to amorphous iron hydroxides, followed by biofilm organic substances (Fig. 8 - lower bar chart). The reduced phases contain ~1 wt% iron, which equals 1.6 wt% iron monosulphide or 2.15 wt% iron disulphide, respectively.

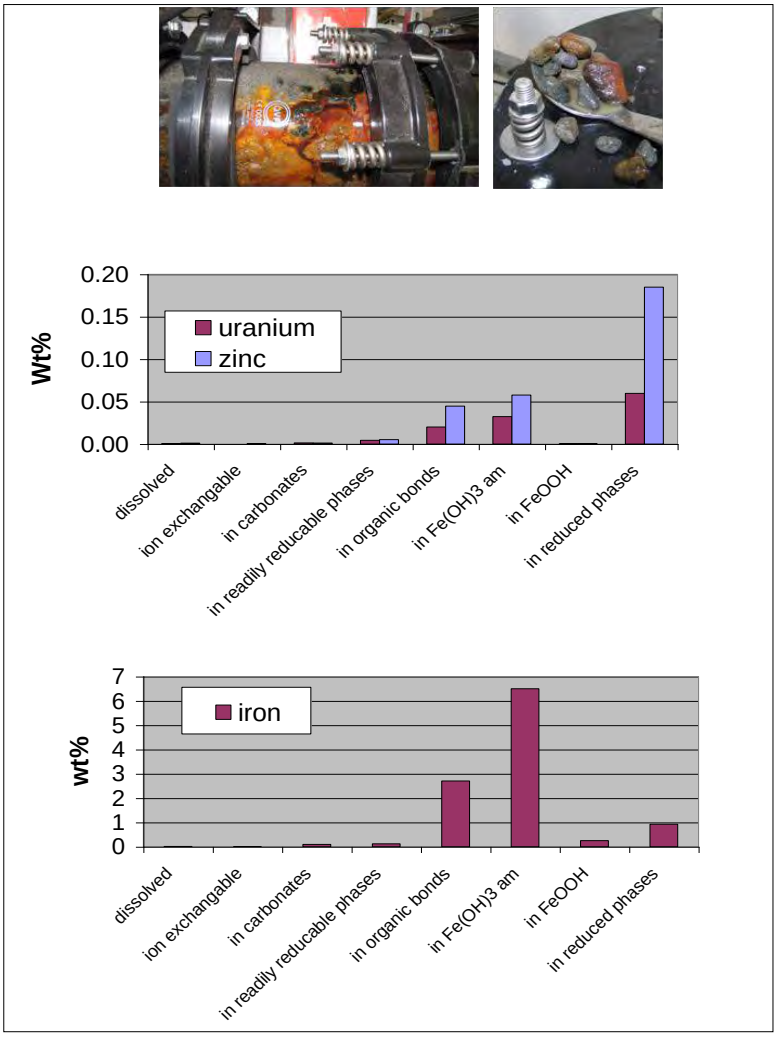

Figure 8 Photographs of glass column segment and reactive material after the experiment and bar charts on uranium, zinc (upper graph) and iron contents (lower graph) in different binding forms as extracted from the blackish-red reactive material coating after the experiment (sequential extraction)

CONCLUSION

The flooded mine Königstein hosts a diverse autochthonous microbial biocenosis. Its autotrophic growth can be stimulated by anaerobic iron corrosion products (OH^-, H_2). At anaerobic oxidation of cast iron powder in mine water, autochthonous sulphate reducing bacteria form sulphide ions at rates of 1 – 5 mg / l · d. The presence of sulphide facilitates pollutant immobilization by direct precipitation (e.g. lead, zinc, uranium) and by iron monosulphide formation, which in turn transforms to iron disulphide. Iron disulphide surface reactions reduce oxidized solutes and cause pollutant reduction comparable to ZVI (e.g. for uranium). Pollutant immobilization from acid mine water in contact with ZVI depends on sorption and reduction at ZVI surfaces, sulphidic precipitation, sorption and reduction at iron sulphides and its ferrous iron hydroxide surface layers as well as on redox buffering. The latter is based on the oxidant scavenger effect of elemental and ferrous iron oxidation with subsequent ferric iron hydroxide formation. If ferric hydroxide formation occurs in close vicinity to the reduced minerals, it may form coatings that protect them from re-oxidation. That is of special importance for preventing future pollutant remobilization in contact with dissolved oxygen upon completion of microbial activity stimulation.

A reactive material designed to carry ZVI, microbes and precipitates by floating in mine water is suited for in-situ-application of ZVI induced pollutant retention. Comparable to cast iron powder, the reactive material is able to emit H_2, to stimulate autochthonous sulphate reducers, to buffer pH and to induce pollutant and iron sulphide precipitation. Moreover, the material provides dissolved silica and serves as microbial growth support and biofilm carrier. This facilitates sustainable pollutant retention considerably. Biomolecules promote mineral formation by serving as precipitation templates. Biofilm matrices provide niches that allow for different redox conditions and thus for coexistence of reduced and oxidized minerals in very close spatial vicinity. Incorporation of silica in mineral precipitates decreases their water solubility. If exposed to mine water flow, mineral coatings form on the reactive material. They contain both reduced and oxidized pollutant bonds. Their iron hydroxide coatings encapsulate mine water pollutants also under oxidizing conditions.

Based on the investigation of underlying processes, microbial in-situ remediation seems feasible to inhibit the discharge of uranium mine site pollutants from the flooded mine Königstein.

ABSTRACT

Four upward flow sulfate-reducing bioreactors (SRBRs) were tested in duplicate for two hydraulic retention times (HRT; 3 and 10 days) to treat mine influenced water (MIW) over a 10 month period. Locally available organic materials (bark, compost and bark mulch) as well as two alkalinity generating materials (limestone or waste mussels shells) were used as SRBR substrates. Following the flow-through treatment period, the spent substrate mixtures were analyzed using a combination of wet chemical and mineralogical analyses, including a sequential extraction procedure (SEP), X-ray diffraction, X-ray fluorescence and scanning electron microscopy equipped with X-ray energy dispersion spectrometer (SEM-EDS). Results from the SEP indicated that (1) Al, Fe, Cu and Ni are mostly retained in the residual, sulfide or organic-bound fractions, (2) Mn is mainly concentrated in the exchangeable and carbonate fractions, and (3) Zn and Cd are predominantly associated with the reducible, sulfide or organic bound fractions. While Mn partitioning was influenced by the HRT (a longer HRT resulted in more Mn associated with the carbonate fraction), all other metals seemed to behave independently from it. Furthermore, the HRT had an influence on the localization of the metals within the substrate, as the short HRT resulted in larger concentrations of Fe and Al in the top part of the reactors compared to the long HRT which resulted in similar concentrations for both the top and the bottom parts. SEM-EDS microanalyses identified Fe, Cu and Zn associated with sulfur. These combined analyses allowed us to assess metal removal mechanisms in SRBRs as well as potential metal mobility during management of spent substrates used in MIW passive treatment systems.

Evaluation of Biological Diffusive Exchange System Prototypes for Acid Mine Drainage Treatment

Norma Pérez, Gustavo Chaparro and Alex Schwarz
Centre of Water Resources for Agriculture and Mining (CRHIAM), Universidad de Concepción, Chile

ABSTRACT

Acid mine drainage is a pollution problem affecting mining, and chemical and/or biological remediation are used to solve it. The use of biological treatment is restricted to low toxicity of the acid drainage; at low pH and/or high metal load, chemical treatment steps must be applied prior to biological treatment. This investigation works on a new biological treatment, the diffusive exchange bioreactor, which incorporates the principle of transverse diffusion and uses fine organic material as reactive substrate, to minimize negative effects of toxicity, clogging, passivation and inefficient use of space. Our goal is to optimize a diffusive exchange system. Organic substrate source, method of inoculation, operation with toxic drainage and three bench scale prototypes were evaluated.

The sulfate reduction potential of several organic substrate mixtures was assessed in batch reactors for three synthetic acid drainages of increasing strength. Then, we test three diffusive exchange reactor prototypes using the optimum substrate mixture, and compare their performance with a conventional homogeneous biochemical reactor. The design goals were to protect microbial communities from toxicity and avoid clogging while allowing means for valuable metals recovery. The organic substrate mixtures had high sulfate reduction rates between 700 and 1500 mmol/m^3/day. The mixtures with cellulose fibers presented the highest rates. The reactors removed over 99% of influent metals (528 mg Cu/L, 85 mg Zn/L, and 95 mg Al/L) and between 28 and 33% of the sulfate. In the diffusive exchange systems, metal precipitation was mainly due to biological activity, and higher sulfate reduction rates were obtained with screened tubes of smaller diameter. In the homogeneous reactor, on the other hand, sulfate reduction was detected only after 44 days. Because hydraulic loads were low, all reactors performed well. In the future, however, under much higher hydraulic loads, we expect the diffusive systems to perform better.

ABSTRACT

The passive treatment of acid rock drainage (ARD) impacted waters using waste mussel shells utilises vertical flow successive alkalinity producing system (SAP) technology, with considerable industry acceptance in New Zealand. This paper discusses the seven year R&D pathway for this technology. The process is attractive to the mining industry as the shells are free-to-site in some instances, and the installation process is relatively straightforward.

Sulfate Reducing Bioreactors (SRB's) and oxic and anoxic treatment of ARD impacted waters are common passive treatment technologies employed by the mining industry. Mussel shells have significant advantages over these systems, being negative value (and thus free-to site, or even delivered for profit), having a high acid neutralisation capacity (> 80 wt% $CaCO_3$ equivalent), good hydraulic conductivity (~$1x10^{-3}$ m/s), and sufficient organics to support sulfate reducing bacteria catalysts for metal removal. This means that processing costs are reduced and the shells can be placed directly into the reactor.

Down-flow bioreactors using shells have been investigated to encourage the calcium carbonate induced neutralisation of ARD followed by SRB alkalinity generation and trace metal removal. Details are presented of two systems (fresh and weathered shells) that were established at the Solid Energy Stockton Coal Mine, West Coast, New Zealand. Results show the formation of an upper zone dominated by sediment transitioning into underlying Fe then Al precipitate zones that is eventually replaced by a deeper sulfate reducing zone. Metal removal efficiencies range from 96 – 99% for Fe, Al, Ni, and Zn. The longevity of the system is linked to permeability, which is controlled by layers of sludge that develop during treatment.

INTRODUCTION

Acid Rock Drainage (ARD) is typically, the greatest long-term environmental and financial liability for the mining industry where acid-forming waste rock is disturbed. It can result in a project 'hangover' after closure that requires water treatment in perpetuity. Hence other projects and new mines are required to support the cost of legacy treatment. The goal for many companies at closure is to implement passive treatment as a final, lower cost ARD treatment option compared to active treatment.

For remote locations, the use of convention media (compost, bark, sawdust, limestone, etc) for passive treatment is expensive and transport costs can be significant. In New Zealand, research into passive treatment of ARD has been ongoing for a number of years (e.g., Trumm et al., 2008; McCauley et al., 2009; Trumm, 2010; Mackenzie et al., 2011). More recently, since 2007 research investigating the benefits of waste mussel shells for passive treatment of ARD impacted waters has been completed in New Zealand (e.g., Weber et al., 2008; Crombie et al., 2011., Uster et al., 2014; Weisener et al., 2015; Trumm et al., 2015)

BACKGROUND

The green-lipped mussel (*Perna canalicuta*), known as the New Zealand Mussel is an endemic shellfish occurring along most New Zealand coast lines. More than 95,000 tonnes of mussels were harvested from farms in 2011 and greater than 80% of these mussels were exported as half-shells generating considerable shell waste (Uster et al., 2014). Significant cost are associated with the disposal of these shells, which means that any beneficial reuse option becomes a win-win outcome for both suppliers and end-users.

In 2007, a trial was conducted at the Stockton Coal Mine to determine the benefits of the addition of a 300 mm layer of shells beneath 5 m of potentially acid forming (PAF) waste rock (Weber et al., 2008). The trial involved 10 tonnes of mussel shells in a 4 m by 10 m lysimeter that was then covered with 3 m of PAF. A control lysimeter containing only acid-forming overburden was set up adjacent in the same manner. Leachate from the lysimeter treated with mussel shells had a pH of 6.7; acidity of 2 mg/L $CaCO_3$; 0.5 mg/L Fe and 0.2 mg/L Al versus pH 3.3 for the control; acidity of 350 mg/L $CaCO_3$, 8.5 Fe mg/L and 54.7 mg/L Al.

Subsequent work investigated the use of mussel shells as an alternative ARD neutralisation source in vertical flow sulfate reducing bioreactors (SRB) (e.g., McCauley et al., 2009; McCauley, 2011). Laboratory trials indicated that the shells provided significant alkalinity compared to limestone (McCauley, 2011; Uster et al., 2014) confirming the use of shells as an alkalinity source in a SRB type systems.

Key components of any material blend to be used within an SRB are a source of alkalinity, a source of organic matter suitable for bacteria, bacteria, and good porosity. Generally for SRBs this requires the use of materials such as sawdust, bark, compost, limestone, etc, which can be expensive. Mussel shells, as provided from the processing factory, have been chipped to reduce particle size and have a porosity of 0.72 (McCauley, 2011); an acid neutralisation capacity (ANC) or carbonate content of 786 - 894 kg $CaCO_3$/tonne as determined by the ANC test; and an organic (meat) content for fresh shells of 5 – 12 wt% (Crombie et al., 2011). In addition to this 'meat' the shells contain significant protein and chitin.

MANCHESTOR STREET PILOT SCALE MUSSEL SHELL BIOREACTOR

The Manchester Street Mussel Shell Bioreactor, a pilot scale trial, was constructed in June 2009 to treat the Manchester Street Seep (pH 2.8; 422 mg $CaCO_3$/L Acidity; 29 mg/L Fe; 51 mg/L Al) derived from acid forming waste coal overburden. Fresh shells were chipped to < 30 mm in diameter to enable full-weight loads for transport and were typically delivered within 24 hrs. Odour associated with the decomposing meat residue present in the shells was a key issue along the transport route and for onsite stockpiling.

A simple system was planned to minimise costs, which involved a downwards flow reactor design (Figure 1). Manchester Seep influent entered the bioreactor and formed a pond over the shells. This was created by having a riser on the outflow pipe that created a 200 mm water cover over the shells to control odour and ensure saturation of the shells. Water then flowed from this pond down through the shells into a drainage network, which then discharged to Ford Creek, a stream impacted by ARD. A total of 160 t of shells was placed in the reactor to produce a layer 2 m deep and 35 m by ~ 5m wide (range 2.7 -10.2 m).

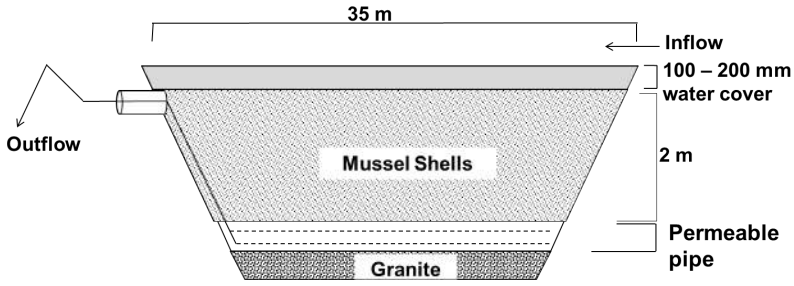

Figure 1 Manchester Street mussel shell bioreactor design.

Water samples from the influent and effluent were collected daily for 28 days and thereafter weekly. Field-based analysis included temperature, pH, EC, DO, odour, and flow. Laboratory analysis included acidity (mg $CaCO_3$/L), ammoniacal nitrogen, and dissolved Al, Fe, Ni, and Zn (Ni and Zn were selected to due being elevated in ARD impacted waters at site). Typical flows for the system were 0.04 – 0.59 L/s with a mean of 0.3 L/s. Often during higher flow (> ~1L/sec) the capacity of the mussel shell reactor was exceeded.

Monitoring results indicated that the mean pH (based on [H+]) of the seep increased from pH 2.8 to pH 6.9 after treatment, and for 59 out of 84 days the effluent pH was ≥7. The mean acidity recorded in the influent was 422 mg $CaCO_3$/L, which is significantly above the mean effluent of 0.3 mg $CaCO_3$/L. Metal removal efficiency was 96-99% for Al, Fe, Ni, and Zn (Crombie et al., 2011). Ammoniacal nitrogen and carbonaceous biochemical oxygen demand ($CBOD_5$) were initially elevated at 46 mg/L and 200 g O_2/m^3 respectively on day 16 before, decreasing steadily to a mean of 3.4 mg/L and 58.44 g O_2/m^3 respectively.

An autopsy of the mussel shell bioreactor was completed by draining the pond (and diverting the inflow) and digging several 300 mm square holes through the sludge layer into the shells (Figure 2). It was observed that the reactor had an upper sludge-sediment layer, a lower thinner orange layer, a white precipitate layer beneath that changed into a lower layer of black shells, which continued to the base of the reactor. It was expected these zones reflected a change from a low pH, high DO, high acidity, high metal ARD to a circum-neutral pH, low DO, low acidity, low metal environment. Samples were sent for laboratory analysis.

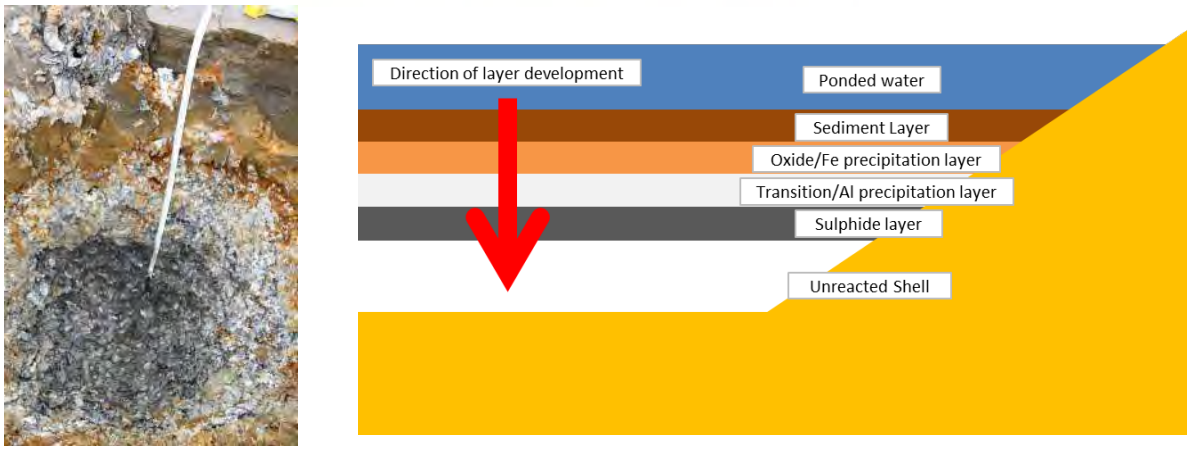

Figure 2 Manchester Street Mussel Shell Bioreactor (photo and schematic). Autopsy test pit (photo) showing sediment (TSS) sludge layer; Fe precipitate layer; Al precipitate layer; and at depth black unreacted shells. The tape measure is 800 mm from the surface to the base of the hole.

The red-brown sludge layer (~200 mm deep) forming on top of the mussel shells is likely to be a combination of road dust, sediment (TSS) transported into the reactor from the seep, and mineral precipitates derived from the AMD. Based on the depth of the sludge and pond dimensions 5 m^3 of sludge was calculated to have accumulated after one year. The median TSS for the seep that drains into the reactor is 18.8 mg/L, although intensive events can range up to 2,960 mg/L (McCauley et al., 2009). Analysis indicated that the Fe layer contained predominantly Fe (24,000 mg/kg) with minor Al (1,620 mg/kg) and less Si (32 mg/kg). Analysis of the white precipitate on the shells below the Fe layer confirmed it was a precipitate high in Al (~70% of the sample or 14,000 – 28,000 mg/kg).

Testing indicated that the neutralization capacity of the shells in the upper white precipitate layer had decreased compared to the black underlying shells. This was determined by flooding shells from the different layers with influent AMD in a sealed container and measuring the time to reach pH 7.0. Results (Crombie et al., 2011) indicated that significant buffering occurred at pH 4 - 5, most likely due to $Al(OH)_3$ precipitation (and acidity buffering). Acidity was neutralized in 1 day for the black shells and 3 days for the white Al layer shells suggesting its neutralization capacity was diminished. ANC testing of the shell from different layers showed that ANC increased with depth and the upper layers are providing significant carbonate neutralization as indicated by reduced ANC (Table 1). Weathered shells have a higher ANC again (956 kg $CaCO_3$/t), which is likely to be a function of less organics due to decomposition.

Table 1 Manchester Street mussel shell bioreactor autopsy results.

Layer	Mean Depth (mm)	ANC (Diloreto, 2013)	Rinse pH	Dominant region of metal removal	Metal removal mechanism
Sediment Sludge Layer	160	8.76	3.01		
Orange Fe Layer	340	288	6.86	Fe, As, Cr	As – Adsorbed Cr- co-precipitated
White Al layer	420	499	6.84	Al (peak), Cu	Cu - sorbed

White Al Layer	550	825	7.54	Al, Zn, Ni	Ni- Co-precipitated with Al Zn - sulfides
Black Shell Zone	1050	846	8.64		Sulfides: wurtzite
Weathered shell from stockpile	Stockpile	956	8.77	-	-

Table 1 indicates that rinse pH increases with depth with a significant increase in pH from the sediment sludge layer to the orange Fe oxide layer. This suggests that the dominant zone of carbonate neutralization is within the orange Fe oxide layer raising the pH to > 6. The system can be divided into five layers if the Al-rich layer is divided into two zones based on the redox gradient and that together with pH this controls the metal removal mechanisms. Key observations from selective extractions (Table 1) indicate a variety of removal processes as shown in Table 1 (Diloreto, 2013).

The longevity of the bioreactor is compromised by the low permeability ferruginous-sediment rich sludge. The autopsy pits that were dug allowed ponded water to drain quickly indicating the higher permeability of the underlying shell layers. Therefore sludge management will be an important component of successful operation of down flow reactors using mussel shells.

Results indicated that ~0.035 tonnes of acidity were neutralised by the mussel shell bioreactor per day. The cost of water treatment for the site in 2011 was ~$320 per tonne of acidity. The cost of installing the mussel shell reactor was approximately $5,300, thus if the system neutralised ~17 tonnes of acidity, the payback of the capex to construct the mussel shell reactor had been achieved. Based on a neutralisation rate of 0.035 tonnes of acidity per day the reactor would achieve pay back after 480 days. This initial trial suggested that the technology had merit and a larger operational trial was planned.

WHIRLWIND STREAM OPERATIONAL MUSSEL SHELL BIOREACTOR

The Whirlwind Stream, towards the southern end of the Stockton Coal Mine and impacted by ARD was selected as a site for the construction of an operational mussel shell bioreactor capable of treating up to 6 L/sec flow, although expected flow rate for the site was ~1 L/s. Results indicated that the seep has less concentrated ARD chemistry compared to the Manchester Seep having pH = ~3.3; dissolved Al = 7.3 mg/L; dissolved Fe = 1.1 mg/L; acidity = 71.5 mg $CaCO_3$/L. In this system the Whirlwind seep flows into an upstream settling pond prior to entering the mussel shell bioreactor (see Weisener et al., 2015 this volume for schematics of the system). It was expected this would reduce the suspended sediment load significantly. Design data is provided in Table 2.

Table 2 Whirlwind Mussel Shell Bioreactor design specifications. Calculations are based on a shell density of 990 kg/m3 and a mussel shell ANC of 800 kg/t.

Parameter	**Rough size**
Average Plan Dimensions (m) (Shell layer)	14.0 x 21.5
Average Plan Area (m^2) (Shell layer)	302
Average Shell depth (m)	1.2
Ponding depth (m)	0.2 - 0.6
Freeboard (m)	0.8 - 0.4

Volume of shells (m^3)	366
Mass of Shells (T)	362
Pore volume (m^3)	192
Residence time (days) (@ 1 - 6 L/s)	2.2 - 0.44
Total ANC (T $CaCO_3$)	290

The pond height in the Whirlwind bioreactor was controlled by a riser from an underdrainage network providing 200 mm ponding depth above the shells. An overflow spillway was constructed at 600 mm above the shells. This provided 400 mm of storm water buffer until overflow to the spillway occurred. Based on the average plan dimensions (Table 2) this provided 120,400 L of capacity. Often after larger rainfall events the spillway was running and the discharge pipe from the mussel shell bioreactor was running at full capacity (6 L/s being the capacity of the drainage network).

One different aspect of this mussel shell bioreactor compared to Manchester Street was that weathered shells were used. As shown in Table 1 the ANC was higher, and the organic content was lower. It was the expectation of the authors that sufficient organic matter remained and little carbon was needed for the sulfate reducing bacteria. Results (Weisener et al., 2015) indicate that a similar geochemical gradient has occurred after 18 months although the thickness of the layers is smaller due to the lower ARD loadings per square meter. Carbon longevity still needs to be considered for this system and trials are in progress.

The treated water from the Whirlwind bioreactor was typically pH 7 and then entered the Whirlwind tributary at compliance water monitoring point S4 together with additional AMD impacted drainage. A significant increase in pH was observed at the S4 monitoring point within the Whirlwind stream after the mussel shell bioreactor was installed (Figure 3).

A key limitation for the longevity of down-flow passive treatment systems using mussel shells is the formation of a low permeability sludge layer. In June 2014, 18 months after the Whirlwind bioreactor was started a double ring infiltrometer was used to measure infiltration rates through the sludge layer that had formed on top of the reactor (22 mm thick). Results indicates that infiltration was in the order of 1.87×10^{-5} m/s, which based on the average plan area (Table 2) generated a flow of 5.7 L/sec for the system. This is within the design specifications of the system and ongoing monitoring will be undertaken every 6 months to measure any further decrease. It is proposed that the system has failed when permeability reduces such that treated flow is < 1 L/sec, or an infiltration rate of $<3.3 \times 10^{-6}$ m/s. At this point the sludge layer would be removed and additional mussel shells placed back in the bioreactor.

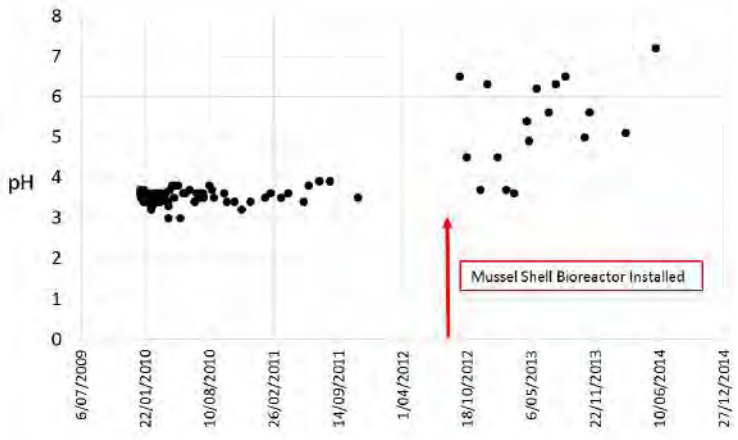

Figure 3 pH versus time profile for the S4 compliance monitoring point (affected by additional AMD impacted mine water) in the Whirlwind Tributary downstream of the Whirlwind Mussel Shell Bioreactor.

The Whirlwind bioreactor has been operating since September 2012. Ongoing research continues to investigate the bio-geochemical reactions occurring within the reactor (e.g., Diloreto, 2014; Weisener et al., 2015) and other research groups are considering other options for the use of mussel shells for passive treatment of AMD impacted waters (e.g., Trumm et al., 2015). A number of issues such as longevity; changing redox fronts, waste management, etc for mussel shell bioreactors still require consideration.

SUMMARY

A significant issue for passive treatment systems is longevity and surety that upfront capex costs will be a favourable use of resources for the treatment of AMD impacted waters in the long term. The short term performance of passive treatment systems are often well quantified, however, their long-term effectiveness is still poorly understood. Carbon exhaustion and hydraulic malfunctions are often amongst the most frequent reasons reported for system failure. As a summary, a risk analysis is presented for mussel shell bioreactors as a passive treatment technology for AMD impacted waters, based on the experience obtained from Stockton Coal Mine. The observations and approach developed is likely to transfer directly to other calcium carbonate shell waste from aquiculture (oyster shells, abalone, cockles, scallops, etc) as their physicochemical attributes are likely to be similar.

Table 3 Summary of key issues for down-flow mussel shell bioreactors. Traffic light classification is green for positive benefits or the process is understood and can be managed; red is negative aspects; and orange components are either indeterminate or need further investigations.

Component	Comment	Traffic Light
Material Characteristics		
Supply	• Limited by location of shells and reasonable transport distance. • Other shells may also be suitable (e.g., oyster, zebra mussels).	
Cost	• Low- or no-cost dependant on transport distance and commercial negotiations.	
Preparation	• No preparation costs as suppliers generally chip shells to increase density for transport to landfill.	
Blending	• No blending of shell with other materials required as it is a stand-alone product.	
Carbonate Neutralisation	• ANC values of > 800 kg $CaCO_3$/tonne expected with high surface area. • Carbonate alkalinity better than limestone based products on a weight basis.	
Organic Matter	• Greater organic matter content in fresh shells; unweathered shells contain less. • Longevity of organic matter unknown, although bacterial recycling may provide additional carbon. **Further investigations are underway.**	
Porosity	• Measured hydraulic conductivities of 1 x 10^{-3} m/s for fresh shells. • Porosity better than limestone for the same quantity of ANC / surface area	
Odour	• Can be a key issue for community and workforce. • Burial under a water cover removes the issue of odour; fine limestone application to the stockpile can also reduce the odour.	

Component	Comment	Traffic Light
Lifecycle Analysis	• Mussel shells are a waste stream and beneficial reuse of such materials provides a win-win for both the supplier and end-user. • $CaCO_3$ is not fossil CO_2 and can be considered renewable.	
Operational Performance		
Construction	• Shells can be placed directly into the reactor without further processing. • The system should be constructed such that excavators can access the site and remove any sludge as required.	
Start-up	• AMD impacted waters were fed in directly (no need to equilibrate system) • Sulfate reducing bacteria quickly populate the low DO high pH zones.	
Permeability	• Measured infiltration rates of 1.87×10^{-5} m/s determined; although this may decrease with time. **Further investigations are underway.**	
Longevity	• Such systems are expected to last 10-20 years and will be a function of cycling organic C, acidity and metal load. **Further investigations are underway.**	
Transitional pH, Eh profiles	• With maturity the defined geochemical layers may change resulting in the release of metals. Monitoring effluent discharge will provide early warning signs of such changes and system failure. **Further investigations are underway.**	
Maintenance	• It is expected regular maintenance is required to remove the formation of sludge on the surface of the reactor. Timeframes for this will be site specific. • Removal of the sediment sludge and Fe-oxide sludge in down-flow reactors could provide additional space in the reactor for upper shell layer replenishment.	
Sludge Disposal	• Oxidised materials from the upper layers can be disposed of in a "high and dry' environment. • Reduced materials need to be disposed in a structure that prevents oxidation of any sulfide minerals formed (e.g., permanently submerged, disused underground workings, etc)	
Health and Safety Concerns	• Potential for bacteria associated with rotting shellfish. • SRB reactors can produce H_2S and CO_2 and risks should be managed appropriately. • H_2S can create odour issues.	

ACKNOWLEDGEMENTS

This work was supported by Solid Energy New Zealand Ltd. Additional funding was provided by the Ministry for Business, Innovation and Employment, Contract CRL1202. The authors would like to thanks Fiona Crombie and William Olds for help with field trials and early reporting. Thanks to James Pope for reviewing the draft paper.

ABSTRACT

Acid rock drainage (ARD) impacted waters are a worldwide concern for the mining industry; both active and passive technologies are employed for the treatment of such waters. System autopsy and biogeochemical investigations are presented here for a novel, fully operational, mussel shell bioreactor used to treat low pH effluents elevated in Al, Fe, Ni, and Zn. This bioreactor is within the Whirlwind catchment at the Stockton Coal Mine, located on the West Coast of New Zealand. The Whirlwind bioreactor utilizes a mussel shell matrix, which is similar in concept to a vertical flow successive alkalinity producing system (SAP), for the passive treatment of an ARD seep derived from acid-forming overburden. The bioreactor has been in operation since September 2012; since construction it has effectively treated ≈99% of metals and continues to neutralize the influent acidity resulting in a circum-neutral effluent.

To understand the performance and functionality of the bioreactor a systematic approach has been undertaken to investigate the bio-physico-chemical dynamics of the system. An autopsy was performed in May 2013 (after 8 months operation) and in June 2014 to better understand the contributing biogeochemical mechanisms occurring. Within the bioreactor exists a complex redox gradient controlled by first order reaction kinetics, which are defined by both its physico-chemical environment (adsorption & precipitation) and microbiology (*i.e.* Complex Fe and S cycling). A horizontal and vertical grid pattern was used for sampling across, and within, the bioreactor. Bio-physico-chemical investigations to date indicate homogenous treatment across the bioreactor with no restrictions to vertical flow even with continued sediment loads to the system.

The work describes a comprehensive investigation of the chemistry, microbiology, and functionality of this novel passive treatment approach and sheds light on the functionality and performance for global technology transfer.

Keywords: geomicrobiology, mussel shell bioreactor, passive treatment, Acid rock drainage, metals.

INTRODUCTION

Acid Rock Drainage (ARD) within the mining industry is associated with the oxidation of sulfide minerals within exposed overburden and other waste rock sources including tailings. Unfortunately it remains an ongoing legacy for some mining operations worldwide. In the United States approximately 200,000 ARD sites exist; in Europe there are over 5000 km of watersheds impacted by direct ARD effluents some predating 1000 years (Lieβmann, 1992; Hochella *et al.,* 1999; Bakers and Banfield 2003; Schippers et al. 2010). The exposure of sulfide minerals to water and oxygen in the presence of bacteria (*e.g. Thiobacillus ferrooxidans*) will result in solutions with increased loads of dissolved metals, sulfate, and net acidity. The Brunner Coal Measures (BCM) associated with the Stockton opencast coal mine in New Zealand has a legacy of ARD which is well documented (*e.g.,* McCauley *et al*., 2010) (Figure 1).

Figure 1 The Stockton Coal Mine located on the West Coast of the South Island of New Zealand

The BCM were formed as part of a marginal marine setting consisting of carbonaceous mudstones, sandstones and coal containing elevated pyritic sulfide sequences (Flores & Sykes 1996; Black et al. 2005; Pope *et al.,* 2006). The sequence can result in significant acid generation and Fe, Al, and S release during the oxidation of pyritic overburden (Weisener & Weber 2010). Studies by McCauley *et al.,* (2010) have provide valuable baseline chemical data on the seep effluent chemistry associated with the Stockton Coal Mine, which has resulted in several viable remediation solutions for passive treatment of ARD impacted waterways. ARD control using passive treatment systems, some referred to as vertical flow wetlands (VFW), or biochemical reactors (BCR), have proven to be effective options to treat isolated geographically confined ARD seeps. These systems contain a porous media, which can range from organic mulch blended with crushed limestone, or systems unique to this particular study that utilise weathered mussel shells. The latter provides exceptional permeability and reactive surface area with extensive neutralization capacity and ability to remove 99% metals (McCauley *et al.,* 2010).

To gain a better understanding of the performance and functionality of the bioreactors using mussel shells, a systematic approach was used to investigate the bio-physico-chemical dynamics of the system. Physical sampling of an existing full-scale treatment cell was performed in May 2013 (after 8 months operation) and again in June 2014 to better understand the contributing biogeochemical mechanisms occurring within the system. Within the bioreactor exists a complex redox gradient

controlled by first order reaction kinetics, which are defined by both its physico-chemical environment (adsorption & precipitation) and a succession of microbial communities (*i.e.,* complex Fe and S cycling). Investigations to date indicate that homogenous treatment across the bioreactor with no restrictions to vertical flow even after continued sediment load to the system.

METHODOLOGY

Sample Collection

Samples for both bacterial and geochemical analysis were collected from the Whirlwind bioreactor (Figure 2) at 8 and 18 months after the system commenced treatment. Acid neutralization capacity (ANC) and metal distributions were performed on material collected at 8 months, while bacterial analysis was performed on 18 month samples. The samples were collected both horizontally and vertically from several pits within a square grid. Subsequent samples were collected at a 18 month time period in areas undisturbed by the previous 6 month sampling. Four vertical layers where targeted; the allochtonous overlying sediment, the iron precipitate layer, the aluminum precipitate layer, and the underlying unreacted shell layers. In addition to porewater and geochemical solid phase characterization, sub samples were also collected for molecular studies (*e.g.,* total DNA and RNA functional analyses). These samples were flash frozen using liquid nitrogen at site to preserve DNA and RNA for shipment to the laboratory.

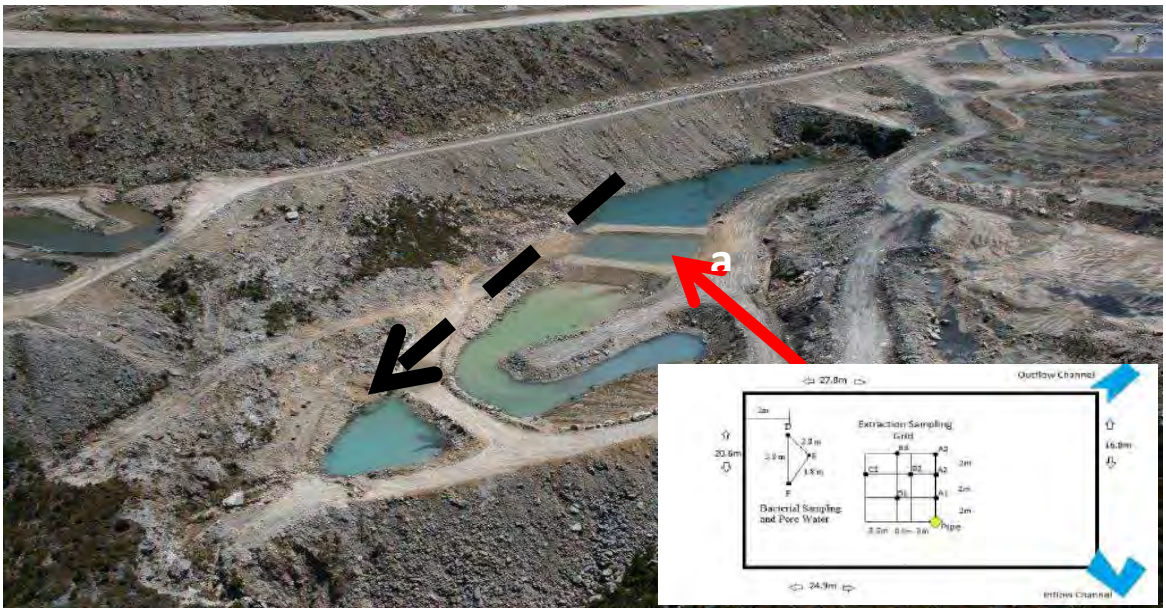

Figure 2 Emplacement of mussel shell bioreactor (location a); dashed line denotes direction of flow from the upper sediment pond, through the bioreactor and then two sediment ponds before discharge

Geochemical Characterization

The ANC test was used to evaluate the acid neutralization capacity of the bioreactor material from the different vertical sampling zones. This test was modified after Sobek *et al.* (1978), and the AMIRA ARD Test Handbook (AMIRA, 2002). Values from ANC testing are presented in kg of H_2SO_4 equivalent and as a percentage of $CaCO_3$ present. All Fe (total), pH and Eh values were measured from pore water collected from the bioreactor based on horizontal and vertical location and are shown averaged including statistical error. Approximately 100 ml of pore water were extracted from different depths within the bioreactor using rhizon pore water samples (Rhizosphere Research Products). Both pH and Eh determined from collected pore water was measured using Orion 8102BN probe by Thermo Scientific for pH and an Orion 01301MD (Duraprobe 4) by Thermo Scientific for Eh. Total iron concentrations were determined using ICPOES.

Bacterial Characterization

Three growth media were used to enrich the acidophilic iron oxidizers, neutrophillic iron oxidizers, and sulfate reducing bacteria (SRB). The media and method used for the enrichment of iron oxidizing bacteria was done using a modified 9K media described in Silverman & Lundgren (1958). Neutrophillic iron oxidizing bacteria were enriched using the Wolfe's media and methodology described in Emerson & Moyer (2002). The SRB were enriched using the Postgate media C and the methodology described in Postgate (1979). A Hucker's gram stain method (Gephardt *et al.*, 1981) was performed on samples extracted from bacterial enrichments. The bacteria were then examined using an Olympus BX61 petrographic microscope coupled with a Lumenera Infinity 1 digital video camera to determine relative abundances of gram (+) and gram (-) bacteria as well as examine their morphologies. Further characterization was performed using a FEI Quanta 200 FEG (Field Emission Gun) Variable Pressure Scanning Electron Microscope (SEM) with an EDAX® SiLi detector for bacterial morphology characterization. DNA extractions were performed using MoBio PowerSoil DNA isolation kit, following the manufacturer's instructions, and three sets of primers, which were used for amplicon targeting (PCR_1) within the 16S rRNA region for each sample. The thermocycling profile for PCR_1 conformed to the following parameters: initial denaturation for 5 min at 95°C followed by 34 cycles of 15 sec at 94°C, 15 sec at 48/55°C (bacteria/archaea), and 30 sec at 72°C, and a final extension of 1 min at 72°C. A second PCR was then performed for barcoding each of the samples (PCR_2), using a unique barcode for each sample as the forward primer and a universal reverse primer known as UniB-P1 (Table 1). The samples were diluted to a final concentration of 25 ng/μL and combined together in preparation for next generation sequencing using Ion Torrent platform (Life Technologies).

RESULTS AND DISCUSSION

Pore water and Solid Phase Characterization

A cross-section autopsy of the bioreactor shows a transitional environment dominated by geochemically distinct reactive layers of mineralization (Figure 3).

Figure 3 Geochemical gradient based on downward vertical flow within the mussel shell bioreactor

A summary of the average ANC profiles, Fe(III) distribution, pH and Eh from the bioreactor is provided in Figure 4. The ANC determinations, in terms of kg of H_2SO_4 (Figure 4a), as well as the distribution of Fe (III) within the vertical transect is shown in (Figure 4b). Both pH (Figure 4c) and Eh (Figure 4d) measurements show dramatic changes along the vertical depth suggesting a defined redox gradient. This assumption is supported by the physical appearance of distinct geochemical zones of precipitation observed in Figure 3. The top layer (0 – 10 mm thick) has a Eh of +199 mV and a measured pH of 3.6. This location correlates to ANC values of <5 kg H_2SO_4/t (<0.5 wt% $CaCO_3$) for ANC potential within the top sediment horizon. The capping allochthonous sediments is both oxidized and acidic with little, if any, capacity to neutralize incoming AMD effluent. The subsequent underlying iron oxide layer is dominated by reactive iron oxyhydroxides that extended from 11 to 40 mm depth and shows a rapid change in both porewater Eh and pH. Eh descreases to +26 mV and pH increases to 5.3 from 3.6. The ANC capacity within this layer increases to ~100 kg H_2SO_4/t (~10 wt% $CaCO_3$). The hydrolytic reactions involving iron observed within this layer are very characteristic of iron hydrolysis reactions that lead to its insolubility as pH increases above ~3.5. Below this reactive iron layer exists a thin zone dominated by white precipitates, which have been identified as amorphous aluminum hydroxide (unpublished data). The layer extends from a vertical depth of 40 to 62 mm with the reactor. Both Eh and pH continue to change with Eh from +26 mV to more reducing conditions of -33 mV and a subsequent pH increase from 5.2 to 6.5. The measured ANC values for the porewater collected within this layer is ~700 kg H_2SO_4/t (70 wt%

$CaCO_3$). The aluminum layer is characterized as a moderately reducing, circumneutral environment with high acid neutralization capacity. The bottom layer which extends from ~62 mm to 1655 mm (the base of the bioreactor) represents the unreacted mussel shell matrix. Porewater collected from within this layer shows low Eh values of -55 to -60 mV with an average pH of 7.2. The measured ANC values are slightly higher at 800 kg H_2SO_4/t (70 – 85 wt% $CaCO_3$). The unreacted shell layer represents a reduced environment with circum-neutral pH and a significant capacity to neutralize incoming acidic effluent. The redox reactions, which dominate the bioreactor, are controlled by a series of abiotic chemical and biotic catalyzed reactions, which give rise to favoured mineralogical phases, as well as direct influence to dominant microbial species present. Soluble Fe(III) (Figure 4b) correlates well with the observed iron oxyhydroxide interface noted in the profile.

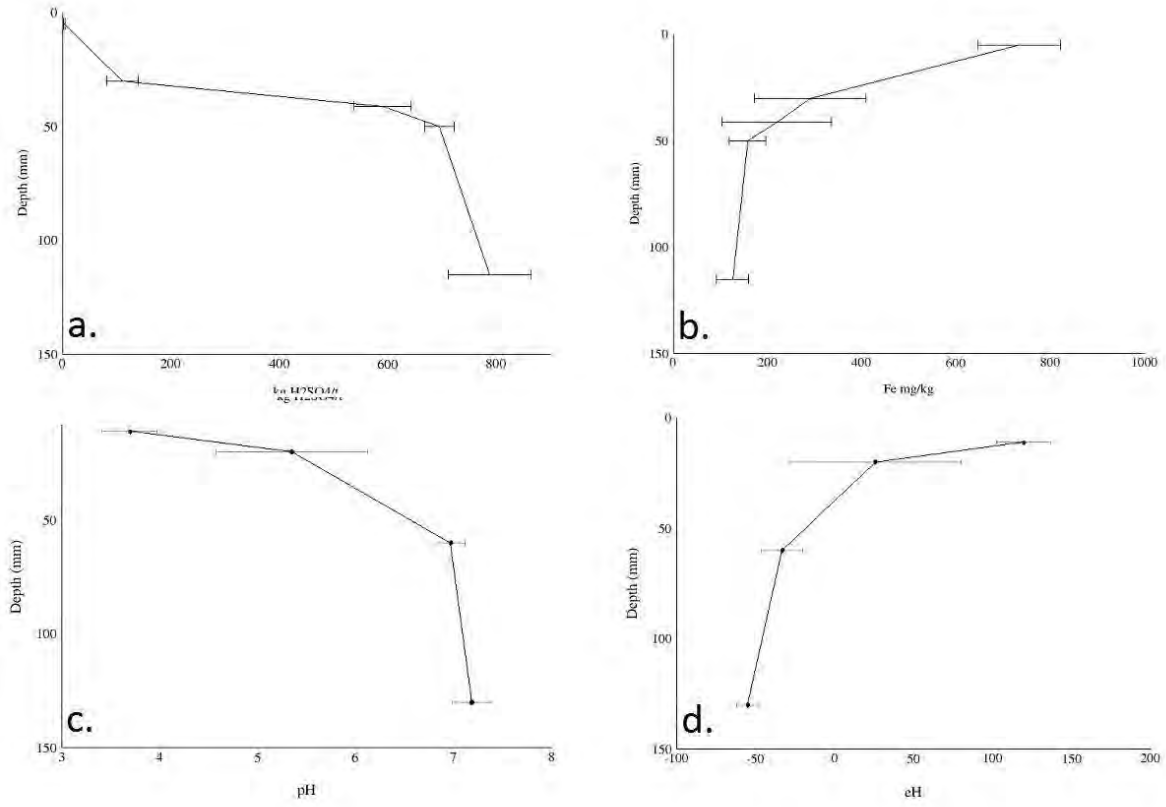

Figure 4 A summary of the of the neutralization capacity, iron distribution pH and Eh as a function of depth for the bioreactor (a) Acid Neutralization Capacity (ANC) at different depths (mm) within the bioreactor is based on kg H_2SO_4/T of material (b) Distribution of total Fe(III) within the vertical depth of the bioreactor (c) and (d) show pH and Eh profiles as a function of depth in the bioreactor

Bacterial Enrichment and Geochemical Conditions

The iron and sulfur dominant bacterial species were assessed using iron and sulfur enrichment cultures and molecular genomics (e.g. next generation sequencing- Ion torrent platform) to assess

the geochemical layers (Figure 5 & 6). This approach was used to differentiate prospective bacteria as a function of geochemical environments. A modified 9K media (Silverman & Lundgren, 1958) was used to target both iron and sulfur bacteria within the allochtonous sediment layer. This approach was successful allowing the enrichment of acidophilic iron oxidizers. The most common species at sites with similar effluent and geochemical conditions include *Thiobacillus ferrooxidans, Ferrobacillus ferrooxidans, Acidothiobacillus ferrooxidans, Aciothiobacillus thiooxidans, Leptospirillum ferrooxidans,* and *Ferrimicrobium spp.* (Silverman & Lundgren, 1958; Johnson 1998; Hallberg & Johnson, 2003; Johnson & Hallberg, 2003; Baker & Banfield, 2003; Hallberg, 2010; Schippers *et al.*, 2010). Based on the molecular characterization the dominant acid tolerant species identified was *Acidovorax sp*. This species is capable of metabolizing iron by coupling iron oxidation in the presence of nitrate and acetate. The dominant iron metabolizing species within the iron oxyhydroxide layer consisted of *Sideroxydans lithotrophicus* along with an increase in abundance of *Desulfotomacculum acetooxidans* a strict sulfate reducing anaerobe. The presence of *Sideroxydans lithotrophicus* within the iron oxide layer is interesting as this species is an neutrophillic aerobic oxidizer of Fe (II), and is capable of growing on other reduced mineral precipitates (e.g. siderite and pyrrhotite) at oxic–anoxic interfaces (Liu et al. 2012, Hedrich et al. 2011). Although suitable substrates within the reactor are possible other vectors should be determined considering the available HCO_3^- and Fe(II) in the transition zone making it possible for other enzymatic electron transport systems (EETS) to operate freely. No iron metabolizing bacteria were detected within the deeper profiles of the reactor including the aluminum oxide layer and the reduced unreacted shell matrix. A combination of both SRB enrichments and molecular investigation confirm the presence of *Desulfotomacculum acetooxidans* which is a spore forming SRB bacteria, and is more resistant to extreme environmental change (*e.g.,* periods of desiccation and oxic conditions) (Castro *et el.,* 2000). Postgate media C (Postgate, 1979) was used to enrich all SRBs present within the layers sampled from the bioreactor. In all layers positive growth was observed. Material collected below the sediment cap showed the fastest growth within the first 24 h compared to 2 - 3 week lag period for the cap sediment. This is likely due to oxygen stress at the top of the profile. Of note is the increased abundance of Archaea (e.g. methanogens) detected within the unreacted zone in Figure 5.

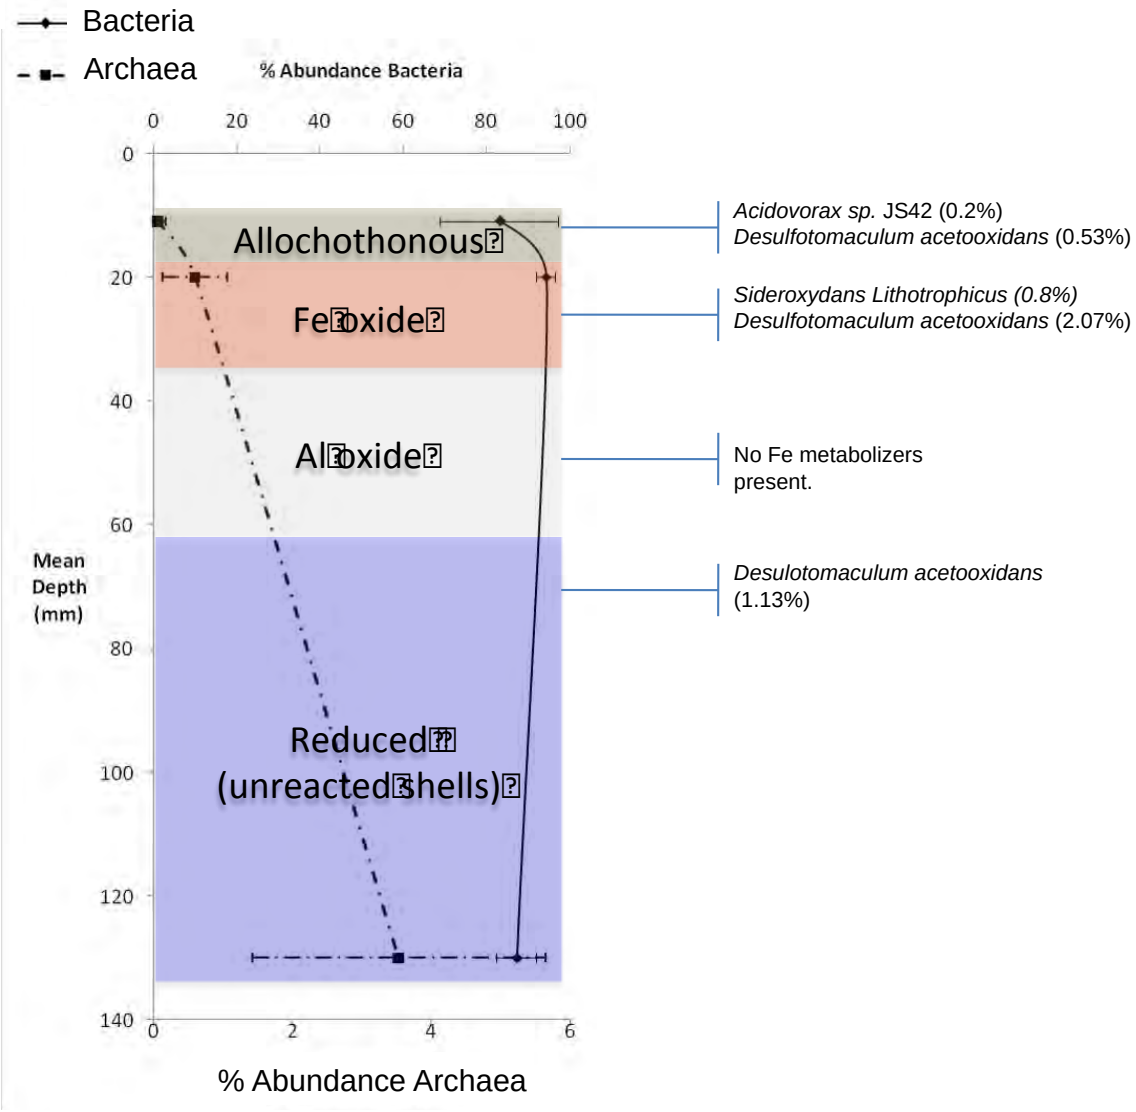

Figure 5 Correlation of iron and sulfur metabolizing bacteria and archaea within the bioreactor profile as a function of depth.

CONCLUSION

The formation of the geochemical profile within the mussel shell bioreactor and its influence on the development of microbial species is in part controlled by a series of abiotic chemical reactions that form during *in-situ* treatment of the ARD effluent. The rate of Fe(II) oxidation at pH values above 5 can be described by the following equation:

$$d[Fe^{2+}]/dt = k_1[Fe^{2+}][OH]^2 P_{O2} \quad (1)$$

where $k_1 = 8.0 \times 10^{13}$ min $^{-1}$ atm^{-1} mol^{-2}

It is noted that a 100-fold increase in the reaction rate occurs for every unit increase in pH (Gazea *et al.,* 1996). Given this situation the most important role of the *in-situ* reaction process would be adequate retention time for the dissolved constituents (Fe, Al) to oxidise and precipitate within the system. It should be noted that under these conditions the oxidation is slow, thus the contribution from iron oxidizing bacteria becomes increasingly important. The presence of acidophilic *Acidovorax sp.* and neutrophilic species such as *Sideroxydans lithotrophicus* and other chemoautotrophic species such as *Desulfotmacullum acetooxidans* (*e.g.*, SRB) which tolerate pH values 2-3 and 5-7 respectively will serve as key electron facilitators thus increasing the rate of iron oxidation or sulfur reduction by several orders of magnitude. Bacterial sulfate reduction in some respects is limited to very specific environmental conditions, which function best at pH >4 in the absence of other oxidising agents such as O_2 and Fe^{3+}(Postgate, 1984). The increase in SRB activity noted in the subsequent layers below the precipitated iron oxide layer confirms this fact. Additionally the abundance of amorphous zinc sulfide proximal to organic matter (data not shown) within this reduced zone (unreacted shells) is further testimony and results directly after iron is removed via oxidation and precipitation from waters flowing down through the reactor. These rapid precipitation fronts characterised by Fe, Al, and reduced metals contribute to the change in SRB activity and pH gradients. Preliminary investigations of the sulfur reducing consortia suggest a range of species able to capitalize on this, characterized by facultative acid tolerant species (gram + and -) near the surface of the reactor with a succession of species dominated by strict anaerobic chemotrophic neutrophilic SRBs within the reduced zones of the bioreactor. The SRB process involved in this case can be considered the reverse of pyritic sulfide oxidation with the end result contributing to the net consumption of acidity by the sulfate reduction process. In addition, considering that metal oxidation and hydrolysis reactions are not effective for removal of metals such as Zn, Tl, and Mn at pH values below 8 compared to bacterial produced hydrogen sulfide which readily reacts with metals above pH 3 forming insoluble metal sulfides in a reduced setting.

ABSTRACT

Green-lipped mussel is the largest seafood export from New Zealand, producing large amounts of shell waste which ends up in landfills. These shells, and waste mussel meat, provide a novel passive treatment approach for acid rock drainage (ARD). The shells provide a source of alkalinity and the meat provides a carbon source for sulfate-reducing bacteria. Until recently, these systems have been constructed with vertical downward flow. Dissolution of the shells results in precipitation of iron hydroxides on the top of the reactor, while reducing reactions deeper in the system form metal sulfides. The iron hydroxides on the top, however, can eventually reduce permeability.

In this study, three mussel shell reactors were constructed in series to treat ARD. Each reactor was constructed with an up-flow configuration in an attempt to establish reducing conditions throughout the reactor and prevent the formation of iron hydroxides. Inlet chemistry averaged: Fe (108 mg/L), Al (28 mg/L), Zn (6.3 mg/L), Ni (1.4 mg/L), and sulfate (2100 mg/L). The pH was raised from 2.9 to 8 through the reactors and alkalinity was produced. Metal removal rates ranged from 95 % to >99 %. Sulfate concentrations decreased by up to 500 mg/L, dissolved sulfide increased by approximately 60 mg/L, and dissolved oxygen concentrations decreased from near saturation to less than 1 %, all suggesting that reducing conditions were achieved throughout the systems. Microbiology work shows the systems to be dominated by sulfate-reducing bacteria. It is likely that Fe, Zn, and Ni were removed as sulfides. These results suggest that up-flow configurations may be a useful construction technique for mussel shell reactors, especially for ARD with elevated Fe.

Future work includes studies of permeability changes in down-flow reactors as hydroxides accumulate, biogeochemical investigations on both down-flow and up-flow reactors, and the installation of full scale systems using both techniques.

Keywords: Mussel Shells, Passive Treatment, Bioreactor

INTRODUCTION

The green-lipped mussel *(Perna canalicula)* is the largest seafood export from New Zealand. The aquiculture industry produces over 140 000 tons of shells annually (Aquaculture New Zealand, 2010). Native to New Zealand, much of the export is fully shelled mussels, which produces a large amount of shell waste. Although some of the waste is used as a lime amendment by the agricultural industry, much of it ends up in landfills.

Since 2007, various researchers have used waste mussel shells to treat acid mine drainage (AMD) in laboratory experiments, small-scale field trials, and large-scale systems in New Zealand. Mussel shells provide a source of alkalinity, and the associated waste mussel meat and other sea life (about 10 % by mass) provide organic material for sulfate-reducing bacteria (SRB). In the initial early laboratory experiments, the mussel shells were used as a replacement for limestone in typical sulfate-reducing bioreactors containing other sources of organic matter, such as compost, bark chips, and post peel waste strips (McCauley et al., 2009; Mackenzie, 2010; Mackenzie et al., 2011).

Later, large-scale field reactors were constructed with only mussel shells and their associated waste mussel meat. These reactors perform well, removing 96 to 99 % of iron, aluminum, nickel, and zinc and restoring pH from <3 to >7 (Crombie et al., 2011). Autopsy work by Diloreto et al. (in press, 2014) show that the metals are sequestered in distinct zones and in distinct forms within the reactors. The upper layer is dominated by a thick iron hydroxide precipitate, followed by a transition zone, below which is an aluminum hydroxide layer. Zinc sulfides and nickel sulfides are present below the aluminum layer. Mussel shells are nearly completely dissolved away near the surface, becoming more abundant with depth. Redox potential measurements (Eh) show a change with depth, from oxidizing conditions in the upper layers changing to reducing conditions within and below the aluminum hydroxide layer. The pH increases with depth, reaching neutral where shells are most abundant.

Performance of the mussel shell reactors over time is largely unknown. It is likely that the transition zone where conditions change from oxidizing to reducing migrates downward with time as the mussel shells are dissolved. If so, zinc and nickel sulfides precipitated in these layers may be oxidized and the metals released as the oxidation and dissolution front migrates downward. The iron oxide and aluminum layers would likely dominate the system with time, potentially reducing permeability and the system could fail once all the mussel shells have been dissolved.

All the previous systems (laboratory and field trials) were constructed with down-flow configurations. In our current study, we have constructed field-trial mussel shell reactors with an up-flow configuration to determine if reducing conditions would predominate over oxidizing conditions throughout the reactors, and if iron would precipitate as a sulfide rather than as a hydroxide. In addition, increased bicarbonate alkalinity generation in a fully reducing system may slow shell dissolution rates, increasing the lifespan of the systems.

METHODS

Three passive treatment systems were constructed using 1000 L plastic tubs (standard intermediate bulk containers) with PVC piping, alkathene piping and associated valves, and were installed at an active coal mine to treat AMD. Each system was filled with waste mussel shells from the fishing company Sandford Limited. The mussels were freshly harvested and shelled. The waste shells

contained approximately 10 % waste mussel meat, which included remnants of the green-lipped mussels, whole black-shell mussels, and miscellaneous sea life attached to the shells. Most shells were broken into pieces approximately 5 cm long (Figure 1).

Figure 1 Mussel shells in completed mussel shell reactor prior to filling with water

The systems were installed in series with an up-flow configuration, such that the inlet was at the base of each system and the water flowed upwards through the shell bed driven by sufficient hydraulic head. Sampling ports were located at the inlet to the three systems, between systems one and two, between systems two and three, and at the outlet from system three. Each system was covered with a tarp to exclude rainfall and sunlight.

The systems operated for a period of 141 days. Flow rates were varied to determine metal removal for different hydraulic residence times (HRTs). Inlet and outlet samples were collected fortnightly from each system and analyzed for dissolved iron (Fe), aluminum (Al), manganese (Mn), nickel (Ni), zinc (Zn), and calcium (Ca), nitrogen species, dissolved reactive phosphorous, sulfate, and dissolved organic carbon at a New Zealand laboratory using inductively coupled plasma mass spectrometry, colorimetry, ion chromatography, catalytic oxidation, and cadmium reduction techniques. Field measurement included pH, dissolved oxygen, and sulfide. Solid and liquid samples were collected from the top 10 cm of each system for microbiological analysis using Next-Generation Sequencing technologies.

RESULTS

Flow rates ranged from 40 to 660 ml/min through the system train, equating to HRTs ranging from 14 hours to 232 hours in each of the first two systems. The third system had slightly fewer mussel shells, resulting in a 9 % lower residence time compared to that in each of the first two systems.

The inlet AMD chemistry is dominated by sulfate (2100 mg/L), Fe (108 mg/L), Al (28 mg/L), and Mn (24 mg/L), with low concentrations of Zn (6.3 mg/L) and Ni (1.4 mg/L). The pH ranges from 2.9 to 3.1. Typically, Fe(II) comprises 5 % of the total Fe, dissolved oxygen is near saturation, and no dissolved sulfide is present.

As the water passes through the systems, the following metal removal rates are achieved: Fe (96 to >99 %), Al (>99 %), Ni (95 to >99 %), Zn (98 to >99 %), and Mn (0 to 22 %) (Figure 2).

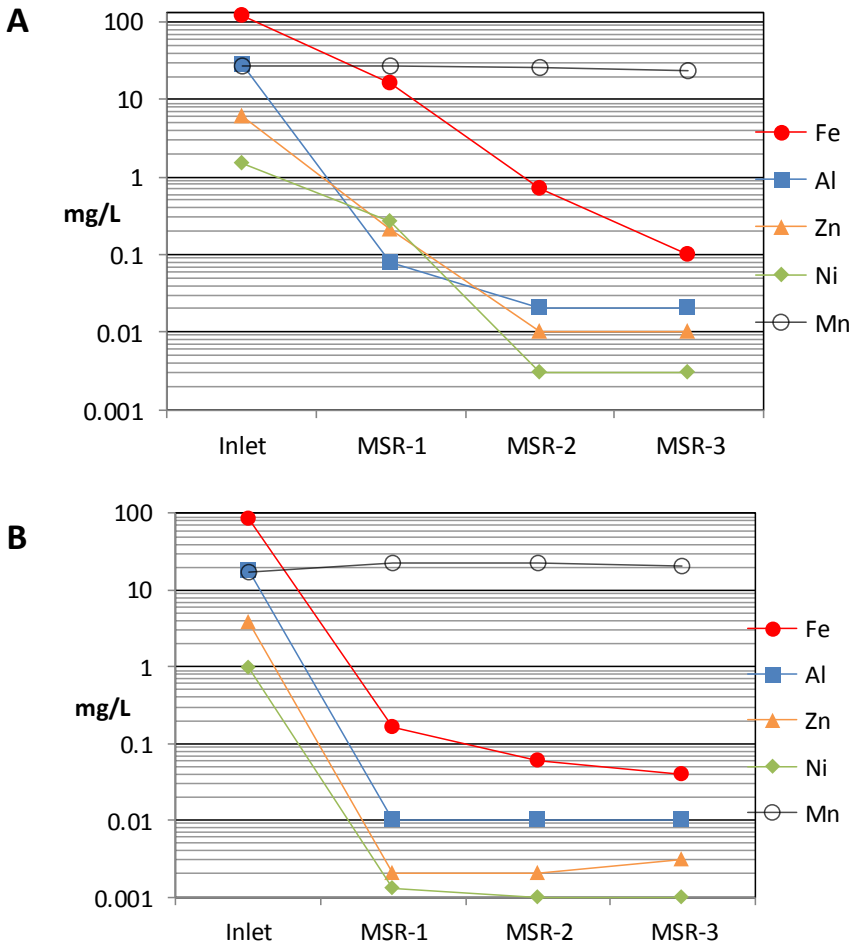

Figure 2 Concentrations of metals through treatment system. **A** HRT of 28 hours. **B** HRT of 95 hours. MSR-1, mussel shell reactor 1; MSR-2, mussel shell reactor 2; MSR-3, mussel shell reactor 3

Several parameters suggest that reducing conditions are being achieved in the systems. Sulfate concentrations decrease through the systems (by up to 500 mg/L) while dissolved sulfide concentrations increase (by approximately 60 mg/L) (Figure 3). Dissolved oxygen concentrations decrease from near saturation to below 1 % in the first reactor and ammoniacal nitrogen (reduced nitrogen) concentrations increase linearly through the three systems. The pH increases from 3 to 7.5 in the first reactor and shows some increase to near 8 through the second and third reactors (Figure 4). Concentrations of calcium (Ca) increase predominantly in the first reactor, while alkalinity follows a linear trend through the three systems.

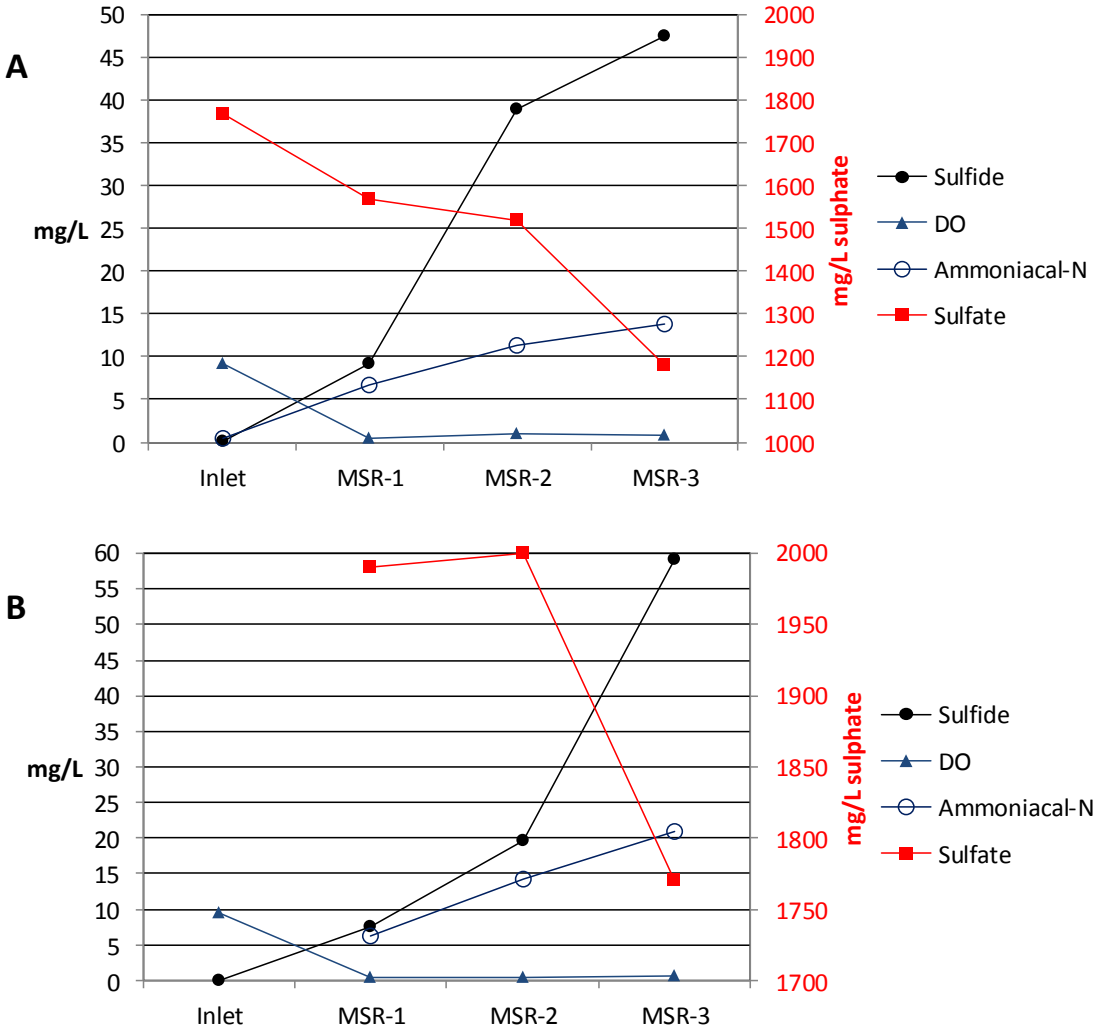

Figure 3 Sulfur species, DO, and ammoniacal nitrogen through treatment system. **A** HRT of 56 hours. **B** HRT of 95 hours. MSR-1, mussel shell reactor 1; MSR-2, mussel shell reactor 2; MSR-3, mussel shell reactor 3

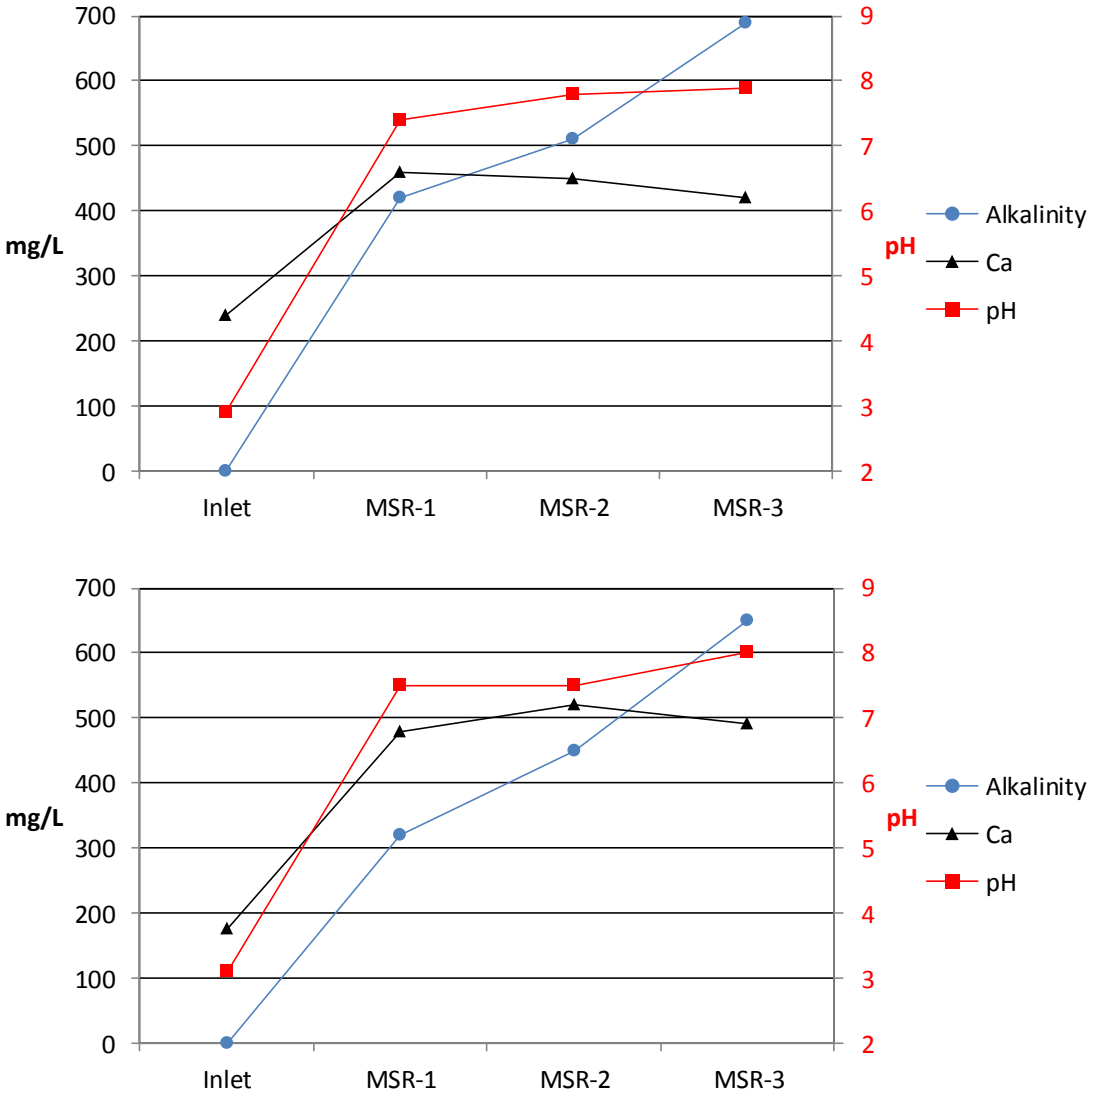

Figure 4 Alkalinity, calcium, and pH through treatment system. **A** HRT of 56 hours. **B** HRT of 95 hours. MSR-1, mussel shell reactor 1; MSR-2, mussel shell reactor 2; MSR-3, mussel shell reactor 3

Preliminary genomic DNA and RNA-Seq molecular analysis of the substrate shows a succession of bacterial communities through the three reactors. In the first reactor, the microbial community is comprised of bacteria (90 %) and archaea (10 %). The bacteria community is dominated by SRB (such as *Desulfotomaculum* and *Desulfovibrio*) but also contains many methanotrophs (methane-oxidizing bacteria). The second reactor contained some SRB but no methanotrophs. Compared to the first reactor, the SRB only comprised a minor proportion of the entire community. The third reactor did not contain any SRB or methanotrophs, but rather had very generic species such as bacterial halophiles of marine origin, and Firmicutes, such as soil bacteria of the Clostridia class (obligate anaerobes).

After the systems had operated for several months, precipitates were noted on the surface of the water in all three reactors (Figure 5). In the first two, this precipitate exhibited a vein-like and

crystalline-like texture with various colors of grey and tan. In the third reactor it was dominated by yellowish-white crystalline and amorphous material.

Figure 5 Precipitates on the water surface of mussel shell reactors

DISCUSSION

Neutralization of the AMD and generation of bicarbonate alkalinity is likely occurring through both dissolution of the mussel shells and sulfate reduction by SRB. Almost all of the metal removal by the systems and pH increase is accomplished in the first reactor, with the exception of Mn which shows removal (albeit minimal) in the second and third systems. Changes in dissolved oxygen, ammoniacal nitrogen, and sulfate show that reducing conditions are established in the first reactor, and are enhanced in the second and third reactors, suggesting that the transition metals Fe, Ni, and Zn are likely being removed as sulfides. The presence of SRB in the first two reactors confirms that sulfate reduction is occurring. The presence of methanotrophs in the first reactor show that methane is being produced, which only occurs under strong reducing conditions with an Eh below -150 mV (Wang et. al., 1993).

Aluminum, however, does not form a sulfide in these systems, but rather precipitates as a hydroxide. Manganese also does not form a sulfide in these systems, but rather can precipitate as oxides, hydroxides (Stumm & Morgan, 1996), and carbonates (Bamforth et al., 2006) and can be removed through adsorption onto iron hydroxides. It is unlikely that manganese oxides are forming under these reducing conditions and unlikely that Mn is being adsorbed onto iron hydroxides if most of the Fe is being removed as sulfide. It is possible that the minimal removal of Mn through these systems is occurring through the formation of manganese carbonates, similar to rhodochrosite ($MnCO_3$) or kutnahorite ($CaMn(CO_3)_2$. The formation of these minerals typically requires a pH of greater than eight, which is approached in the third system.

In the second and third reactors, additional alkalinity is produced, the pH is raised slightly higher, and sulfate concentrations are lowered significantly while dissolved sulfide concentrations increase. Minimal dissolution of mussel shells occurs in the second and third reactors, as evidenced by relatively stable, and even decreasing, Ca concentrations. Therefore, the increase in bicarbonate alkalinity in the second and third systems may be due in part to sulfate reduction by SRB. The presence of SRB in the second reactor confirms that sulfate reduction is occurring in that cell,

however, no SRB were detected in the third reactor. The microbiological samples were collected near the top of the reactors. It is possible that SRB may be present in the third reactor at depth.

The precipitates forming on the surfaces of the reactors may be elemental sulfur, since more sulfate is removed from these systems than can be accounted for by dissolved sulfide and the formation of metal sulfides. It is also possible that gypsum is forming on the surfaces, which could explain the decrease in both Ca and sulfate in the third reactor.

The construction of these three systems in series creates a true plug flow reactor (Schmidt & Lanny, 1998). Although short-circuiting is possible within each individual component, short-circuiting through the entire system train is prevented by having three distinct parts to the system. Since sampling can be conducted between each component of the system, the performance and removal mechanisms in each component can be analyzed separately and extrapolated to the potential performance of a full scale system. Construction of trial passive treatment systems in series can provide useful information on treatment performance and metal removal mechanisms.

The up-flow configuration likely contributes to the successful establishment of reducing conditions and likely will lead to minimal formation of iron hydroxides. It is preferable to avoid the formation of iron hydroxides, as this would lead to a decrease in permeability with time, as was noted in a large-scale mussel shell reactor constructed at Stockton Mine, West Coast, New Zealand (Crombie et al., 2011).

Additional up-flow mussel shell reactors have been constructed at the Bellvue abandoned coal mine AMD site on the West Coast of New Zealand (West et al., 2013). Along with mussel shell reactors, a bioreactor containing compost, bark chips, post peel strips, and mussel shells is operating at the Bellvue site to compare the performance of mussel shells with and without an organic matrix. The results from Bellvue and from this study will be used to optimize mussel shell reactor design for other sites in New Zealand.

Future work on mussel shell reactors includes permeability studies, biogeochemical investigations, and installation of full-scale systems. The permeability studies currently underway aim to measure the change in permeability in down-flow reactors as hydroxides accumulate. Biogeochemical investigations are currently underway for both up-flow and down-flow reactors, and several full-scale system are planned to be installed at AMD sites using both techniques.

CONCLUSIONS

1. Three small-scale mussel shell reactors were constructed in series at an active coal mine to treat AMD. Unlike previous mussel shell reactors, these were constructed in an up-flow configuration.
2. Inlet water chemistry to the system train had a pH of 2.9 to 3.1, and metal concentrations as follows: Fe (108 mg/L), Al (28 mg/L), Mn (24 mg/L), Zn (6.3 mg/L), and Ni (1.4 mg/L). Sulfate concentrations were 2100 mg/L.
3. Residence times in each of the three reactors ranged from 14 to 232 hours, over an operating period of 141 days.
4. The pH increased to 7 through the first reactor and near 8 through the second and third reactors and the effluent water had net alkalinity.
5. Metal removal rates were as follows: Fe (96 to >99 %), Al (>99 %), Ni (95 to >99 %), Zn (98 to >99 %), and Mn (0 to 22 %). With the exception of Mn, these metals were mostly removed in the first reactor.

6. Sulfate concentrations were lowered by up to 500 mg/L, dissolved sulfide increased by approximately 60 mg/L, DO concentrations decreased from near saturation to less than 1 %, and ammoniacal nitrogen increased through the systems, all suggesting that reducing conditions were achieved in the systems by means of SRB.
7. Sulfate-reducing bacteria were present in the first two reactors, confirming that sulfate reduction is occurring.
8. It is likely that Fe, Zn, and Ni were removed in the system as sulfides, Al as hydroxides, and Mn as carbonates.
9. A crystalline and amorphous precipitate forming on the surface of the reactors may be elemental sulfur with or without gypsum.
10. An up-flow configuration through mussel shell reactors may help to establish and maintain reducing conditions and remove Fe as sulfides rather than hydroxides, thereby maintaining permeability and extending the longevity of these systems.

ACKNOWLEDGEMENTS

This research was financed by the Ministry for Business, Innovation and Employment, Contract CRL1202. The mussel shells were donated by Sanford Limited, Christchurch. We acknowledge the anonymous mining company which allowed the systems to be constructed at their mine site. Preparation of graphs was completed by Patrick Turner of CRL Energy.

ABSTRACT

Japan Oil, Gas and Metals National Corporation (JOGMEC) has been researching a low-cost microorganism-based passive treatment system for acid mine drainage (AMD). This system consists of the aerobic reactor and the following anaerobic one that utilizes iron-oxidizing bacteria and sulfate-reducing bacteria, respectively.

The aerobic reactor is filled with iron scales including iron-oxidizing bacteria from the aqueduct of drainage treatment facilities, and iron ions have been oxidized by iron-oxidizing bacteria and removed as iron oxides. In the anaerobic reactor, which is filled with rice husk, limestone, soil, and rice bran, various metal ions (copper, zinc, lead, cadmium, etc.) have been removed as sulfides by the action of sulfate-reducing bacteria. The materials used to be filled in the reactors are either free or very inexpensive to be got in Japan.

Since 2013, the field tests have been carrying out at abandoned mine site. The concentrations of solved metals in the targeted AMD are 35–40 mg/L iron, 18 mg/L zinc, and 8 mg/L copper, and the value of pH is 3.5. The results of field tests showed that 80% of the iron ion has been removed with the retention time of approximately 2 hours in the aerobic reactor, while almost of the other metal ions have been removed with the retention time of 50 hours in the anaerobic reactor. The tests have been running for approximately a year until at present, June 2014. The metals have been continuously removed without another maintenance and addition of materials and reagents during the test period. Moreover, in the reactors, which were not temperature-controlled, the metals continued to be removed even in winter, although the internal temperature dropped to approximately 5°C during the winter.

It is expected that this passive treatment system for AMD can be scale-upped and realized to be a cost-saving and energy-saving treatment system.

Keywords: Passive treatment, Sulfide reducing bacteria, Acid mine drainage, Iron-oxidizing bacteria

INTRODUCTION

Japan Oil, Gas and Metals National Corporation(JOGMEC) has conducted research on the passive treatment of mine drainage since 2007, and has focused on drainage treatment methods that remove metal ions as sulfides using sulfate reducing bacteria (SRB). For neutral pH mine drainage, field tests have been carried out using an anaerobic bioreactor filled with "rice husk" as an organic carbon source. The successful removal of metal ions had continued for approximately 1100 days under the appropriate conditions (retention time: 50 h, water temperature: over 15 °C). For acid mine drainage, with pH 3.0, containing several types of metal ions, the field tests are being performed using an anaerobic bioreactor filled with "rice bran" and "rice husk" as the organic carbon sources.

In many cases, acid mine drainages contains iron ions, which are difficult to be removed as sulfides because of their relatively high solubility. Therefore, in these field tests, iron oxide bacteria were employed separately to remove the iron ions from the mine drainage, prior to removing the non-ferrous ions as sulfides.

In this paper, the results of these tests are presented.

METHOD

Equipment

A prefabricated testing hut was built on the premise of the mine-drainage treatment plant of the mine site. Test equipment was installed in the prefabricated room. The aqueduct for mine drainage was introduced into the prefabricated hut to guide the drainage to the test apparatus.

Apparatus

A schematic diagram of the bioreactors used for the tests is shown in Fig. 1. For the test apparatus, an aerobic (iron oxidation-removal) bioreactor (left, Fig. 1) and an anaerobic bioreactor (center and right, Fig. 1) were prepared. A multistage process was configured to remove iron in the mine drainage by an aerobic bioreactor, and other metal ions by an anaerobic bioreactor. Both bioreactors are made of vinyl chloride. The iron oxidation-removal bioreactor is a rectangular parallelepiped with a bottom area of 900 cm^2 and a height of 45 cm. The anaerobic bioreactor is a cylinder with a diameter of 25 cm and a height of 110 cm. For the anaerobic bioreactor, four sampling ports (called the 1st, 2nd, 3rd, and 4th ports) were provided, in addition to an output port.

The iron oxidation-removal bioreactor was filled with approximately 15 kg in wet weight of iron scales that had been precipitating in, and sticking to the drainage aqueduct from the mine drainage treatment plant on the mine site (provided free of charge). Once filled with iron scales, the bioreactor was further filled with 20 L of mine water.

The anaerobic bioreactor, on the other hand, was filled with the following materials. Soil collected from the surface layer around the mine site was used as a source of bacteria, including SRB. Rice husk was used as a base material of the column and as a carbon source for bacteria. In addition, rice bran was added because it is more easily decomposed by bacteria than rice husk, due to its high levels of protein and lipids. Limestone (5 to 10 mm) was used as a structural material for securing cavities and for buffering the pH value. These materials are either free or very inexpensive to obtain in Japan and were easily collected. The column was filled with these materials to a height of 100 cm.

The weight of each material is as follows: approximately 4.5 kg of rice husk, approximately 1.5 kg of rice bran, 1 g of soil, and 18 kg of limestone. In this case, rice husk, limestone, and soil were combined and evenly distributed throughout the entire column. Rice bran, on the other hand, was filled intensively in the upper portion of the column (described later). The capacity of the column, to a height of 100 cm, is 50 L, and the volumetric composition of the content was approximately 95% rice husk, 3% limestone, and approximately 2% rice bran. In conjunction with the volume of solids, 35 L of mine water was used to fill the water level to 100 cm.

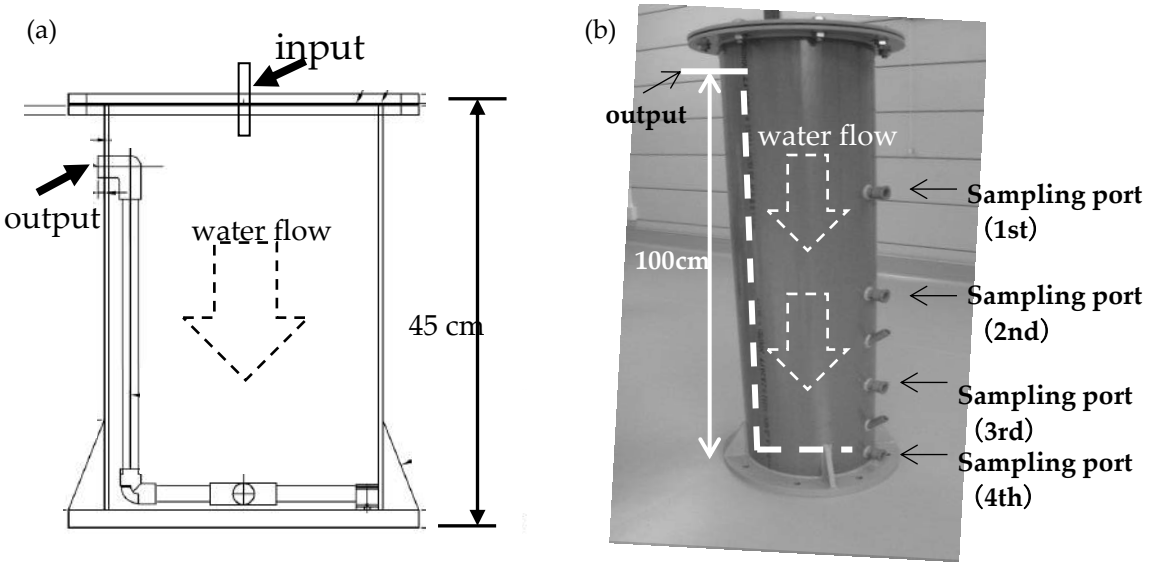

Figure 1 Bioreactor equipment.
Iron oxidation-removal reactor, (b) anaerobic bioreactor

Process

Acclimation of SRB in the anaerobic bioreactor

The anaerobic bioreactor was filled with the above-mentioned mixture of rice husk, limestone, and soil to the height of 100 cm. The contents were water sealed with 35 L of mine water as the sulfate ion source, and the SRB were acclimated under room temperature for approximately 10 days. In this case, rice bran was added to the top of the anaerobic bioreactor after acclimation of the SRB, and immediately before continuous feeding of the mine water. This was done because in laboratory tests it was observed that if bacteria are acclimated with added rice bran, microorganisms other than SRB ferment excessively, and eventually the sulfate reduction activity of SRB becomes non-detectable. Approximately 10 days after starting acclimation, the SRB became active, and the oxidation-reduction potential (ORP) of the water in the bioreactor became approximately -200 to -300 mV.

Water feeding method

After acclimation of the SRB, mine water was gravity-fed to the iron oxidation-removal bioreactor, with the flow rate adjusted to approximately 125 ml/min. Air was fed into the iron oxidation-removal bioreactor with an air pump so that the concentration of dissolved oxygen was

approximately 3 to 4 mg/L. The mine water passing though the iron oxidation-removal bioreactor was guided to the upper part of the anaerobic bioreactor with a pump. The flow rate was adjusted to 11.7 ml/min so that it passed through the anaerobic bioreactor as gravitational flow.

Quality of treated water

The mine drainage for the continuous test was sampled at the abandoned mine in Akita Prefecture, located in the northern part of Japan. The concentrations of zinc, copper, and iron in the drainage are shown in Table 1. These values exceed the national effluent standard; therefore, the drainage was selected as the sample in this investigation. Most of the iron was removed from the drainage after passing through the iron oxidation-removal bioreactor, and contained only 6 to 8 mg/L of iron (almost all the volume is ferric), while the pH value decreased to about 3.0. The concentrations of other metal ions in the mine water did not change after passing through the iron oxidation-removal bioreactor.

The temperature of treated water did not fluctuate very much throughout the year; it exited at a temperature of 12 to 14 °C.

Table 1 Water quality of the drainage and the national effluent standard values.

	pH	**Zn (mg/L)**	**Cu (mg/L)**	**Fe (mg/L)**	**SO_4^{2-} (mg/L)**
Mine drainage (min–max)	3.3–3.8	15–18	3–10	33–38	350–400
National effluent standard	5.8–8.6	2.0	3.0	10	

Analysis of items

Samples were collected periodically from the raw mine water, the treated water of the iron oxidation-removal bioreactor, as well as from the outlet and water sampling holes at each height of the anaerobic bioreactor. The samples were subjected to analysis, which included temperature, pH, ORP, metal ion concentrations (iron, copper, zinc, and cadmium), sulfate ion concentration, sulfide ion concentration, and COD. Concentrations of metal ion were determined using ICP and sulfate ion was determined using ion chromatography. Sulfide ion concentration was colorimetrically measured as hydrogen-sulfide ion and COD value determined titration method.

Retention time

The retention time for the raw mine water to pass through the iron oxidation-removal bioreactor was adjusted to approximately 1.5 to 2 h. The time to pass through the anaerobic bioreactor was set to 50 h.

Temperature conditions

Neither of the bioreactors was subjected to temperature control with a heater or air conditioner. Although no heating or cooling was applied, minimal heat insulating material (glass wool) was used to protect the test equipment from the elements, thus ensuring that the tests were conducted under natural temperature conditions. In addition, in the prefabricated hut, air conditioning was not employed, but minimal ventilation and lining of walls with heat insulating material was applied.

RESULTS AND DISCUSSION

Iron oxidation-removal bioreactor

Figure 2 shows the changes in the concentration of iron (total iron concentration, T-Fe) from the raw mine water (input) to the water that was treated with the iron oxidation-removal bioreactor (output) during the field test. The iron ion concentration in the bioreactor decreased gradually over the first 20 days, but it became steady at a low concentration after 50 days. The performance of the treatment did not change, even in the winter. Throughout the year, the iron concentration in the treated water was approximately 20% of that in the raw mine water. Moreover, there was no need for maintenance, such as replacement or replenishment of iron scales or other agents.

Anaerobic bioreactor

Changes in temperature in the anaerobic bioreactor

Figure 3 shows the changes of the temperature inside the anaerobic bioreactor in the field test and that of the mine water used for the test. The temperature inside the bioreactor was measured at the lateral center, at a depth of 40 cm from the top of the bioreactor. Figure 3 shows that the mine water used in this test entered at a constant temperature (12 to 14 °C) throughout the year. In contrast, the temperature inside the column exceeded 20 °C in the summer (September) and decreased to approximately 5 °C in the winter.

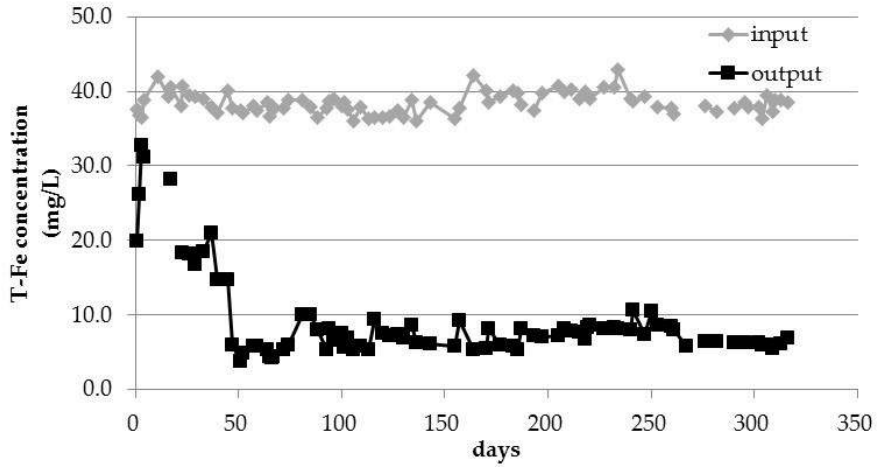

Figure 2 Changes in the concentrations of T-Fe in the mine drainage before and after treatment in the iron-oxidation removal bioreactor.

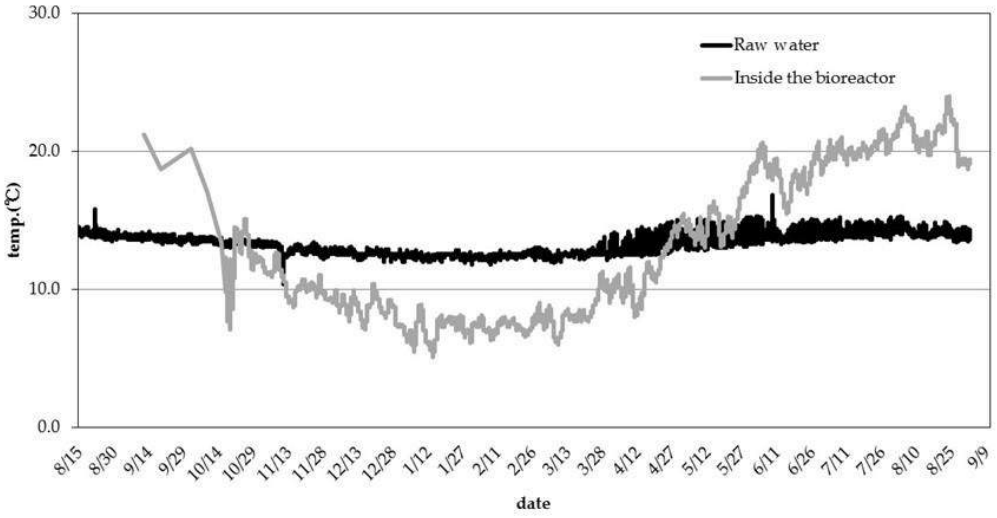

Figure 3 Changes in temperatures of raw mine water and inside the anaerobic bioreactor throughout the year.

Changes in pH and ORP values in the anaerobic bioreactor

Figure 4 shows the changes of the pH values in the anaerobic bioreactor. In the first port (1st) of the bioreactor, although the pH value was slightly lower in the winter, it was raised in the spring due to the rising atmospheric temperature. In the second (2nd) and subsequent (3rd and 4th) ports of the bioreactor, the neutral pH values remained steady, regardless of the fluctuations in the temperature. Figure 5 shows the changes in ORP values in the anaerobic bioreactor. The ORP in the first stage of the bioreactor was slightly unstable in the winter, sometimes exceeding -100 mV. In the second and subsequent stages of the bioreactor, the ORP was stably maintained below -200 mV. It is commonly said that the appropriate ORP for SRB is -200 to -300 mV. Accordingly, the ORP in this process remained within the above-mentioned range for one year after starting the test.

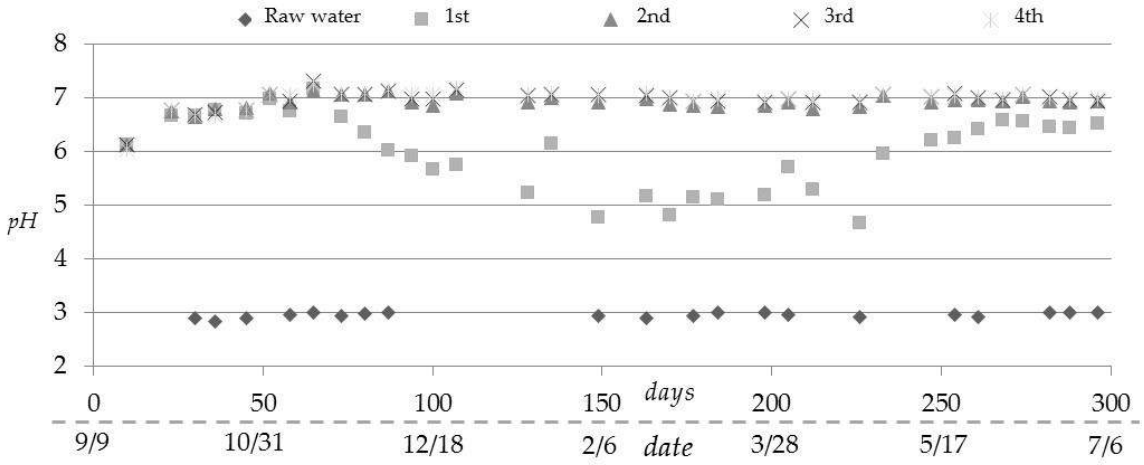

Figure 4 Changes in the pH values over time in the anaerobic bioreactor."1st, 2nd, 3rd, and 4th denote the location at which the sample was drawn"

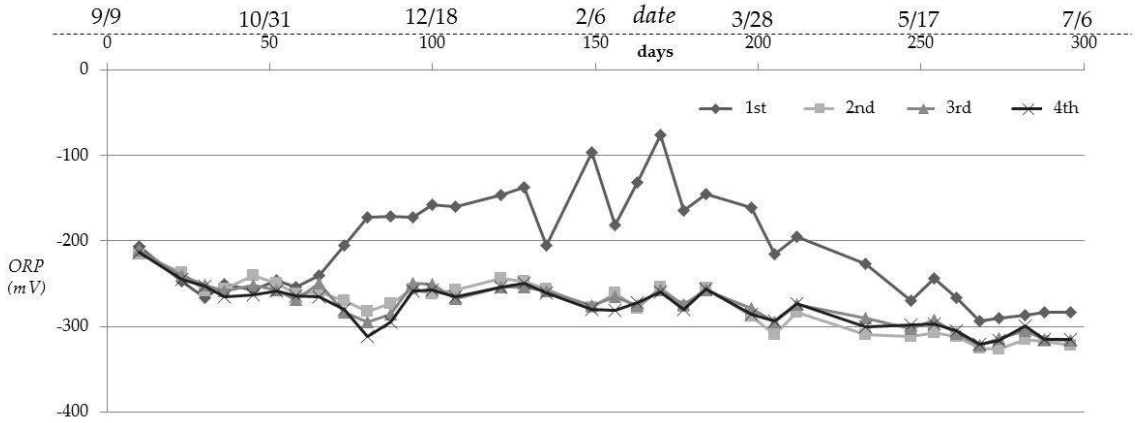

Figure 5 Changes in the ORP values over time in the anaerobic bioreactor.

Removal of metal ions in the bioreactor

Figure 6 shows the changes in the concentration of sulfate ions before and after treatment with the anaerobic bioreactor. In accordance with the fluctuations of the ORP values in Figure 5, the concentration of sulfate ion in the treated water did not be stabilized until 60 days from the start of the water feed. In the spring and summer seasons, after passing winter, the concentration of sulfate ion greatly decreased due to the high performance of sulfate reduction by the SRB in the bioreactor.

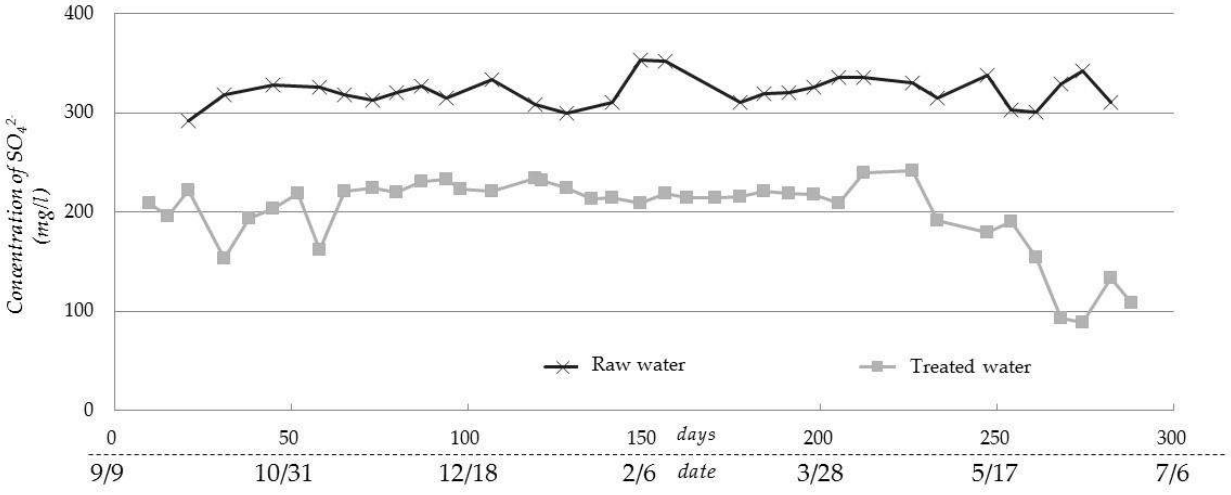

Figure 6 Concentration of sulfate ions in the mine drainage before and after treatment with the anaerobic bioreactor.

Figure 7 shows the changes in the concentration of zinc ions before and after the treatment with the anaerobic bioreactor. The concentration of zinc ions in the raw mine water was approximately 17 mg/L, with no large fluctuations throughout the test period. The water quality therefore always exceeded the national effluent standard in Japan. After the treatment with this process, the

concentration of zinc in the treated water was very low, indicating that the treatment had stably cleared the national effluent standard of 2 mg/L for one year. Other metal ions (copper, and cadmium) were also almost completely removed in the bioreactor. Although the temperature inside the bioreactor was as low as about 5 °C in the winter (as shown in Figure 5), no deterioration of the treatment performance was observed.

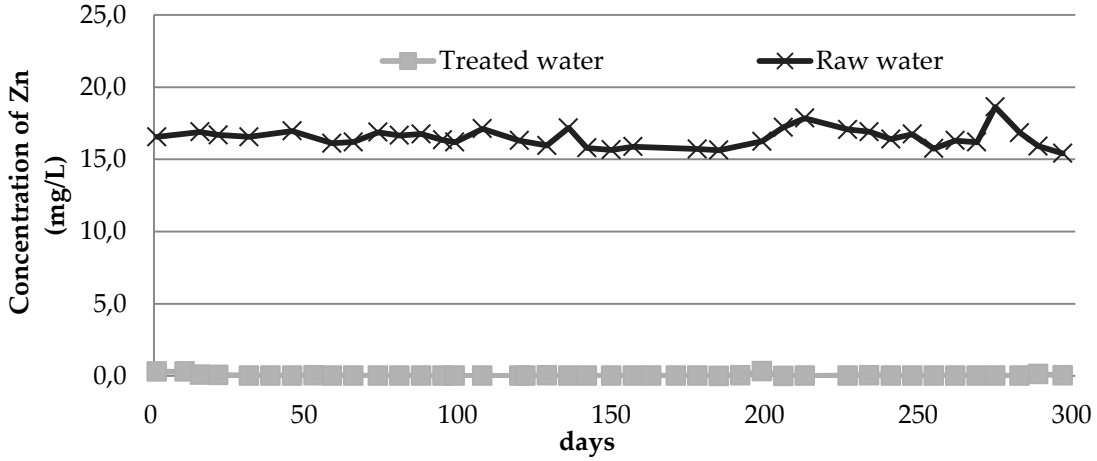

Figure 7 Concentration of zinc ions in the mine drainage before and after treatment with the anaerobic bioreactor.

Degree of pH, ORP, and sulfate ion reduction in the winter

Figure 4 and Figure 5 show that the pH decreased in the 1st stage of the anaerobic bioreactor and the ORP increased in the winter, respectively. The cause of the increase of pH in this process might be considered to be the neutralization effect of limestone and the progress of the sulfate ion reduction reaction of SRB. In the winter, the performance of sulfate ion reduction by SRB in the anaerobic bioreactor was lower than in other seasons, as shown in Figure 6, and so, it could be considered that the pH value in the 1st stage of the bioreactor was lower because the pH increasing effect of the sulfate ion reduction action was weakened. In the 2nd and subsequent stages of the bioreactor, it could be considered that the pH value was maintained stably even in the winter, mainly due to the neutralizing effect of limestone.

In the 1st stage of the anaerobic bioreactor, the observed increase in the ORP during the winter likely resulted from the decrease in activity of SRB due to the drop in the temperature. Moreover, the ORP tended to increase gradually because the raw mine water, which was always in an oxidation environment at the water channel from the mine site, was supplied in the 1st stage of the bioreactor. Therefore, generally the reduction condition was already weakened and the activity of the SRB was decreased, as mentioned above. Then, it could be conjectured that a stable reducing condition was revived in the 1st stage of the bioreactor and the activity of SRB increased again thereafter due to the temperature rise in the spring.

Treatment performance on metal ions (zinc, copper, and cadmium) in the winter

It is generally considered that the capability of sulfate ion reduction by SRB is weakened with a decrease in temperature. However, Figure 7 shows that almost all of the zinc ions contained in the raw mine water was removed after passing through the anaerobic bioreactor. Consequently, it could be considered that a sufficient volume of hydrogen sulfide ions, which were used for

precipitating metal ions in the raw mine water as sulfides, were generated in the anaerobic bioreactor. It was so far confirmed that this test apparatus could remove metal ions stably over a long period at a temperature of 15 °C. Furthermore, it was confirmed in the field test at this time that metal ions could be removed over a long period, even in an environment with low and seasonal temperature changes.

CONCLUSION

During the field tests in approximately one year, at the mine drainage treatment plant, iron was removed with the iron oxidation removal bioreactor, and other metal ions were removed with the anaerobic bioreactor stably and successfully without additional maintenance, such as replacement or replenishment of some materials. The materials used to be filled in both reactors are either free or very inexpensive to obtain.

Although the reaction temperature changed in the range of twenty degrees and it lowered to 5 °C in the winter, the sufficient reduction of sulfate ions occurred and the removal of metal ions continued very stably. This field test suggested that this process was applicable in low temperature environments, as low as approximately 5 °C, and therefore, it was probably applicable in environments with a wide range of temperatures.

For practical use of this passive treatment system, it is important that metal ions are removed stably for a long period, without any maintenance and even in the low temperature conditions. In our field tests, it was confirmed that metal ions were removed over a long period, even in the environment with lower temperatures and changing temperatures. Furthermore, in the case that mine drainage contained iron ions, it was confirmed that placing the iron oxidation-removal bioreactor before the anaerobic bioreactor during the treatment process was very useful. To develop a new cost-saving and energy-saving process, JOGMEC is now continuing the researches to make this multistep bioreactor process (“JOGMEC PROCESS”) more useful and durable.

Antimony Passive Treatment by Two Methods: Sulfate Reduction and Adsorption onto AMD Precipitate

Dave Trumm[1], James Ball[1], James Pope[1] and Chris Weisener[2]

2. *Great Lakes Institute for Environmental Science, University of Windsor, Canada*

ABSTRACT

Two different passive water treatment methods to remove antimony from mine water were tested in field trials at a gold mine in New Zealand. In one method, antimony was removed through adsorption onto iron oxyhydroxides. The oxyhydroxides were collected from precipitate within an acid mine drainage discharge at a nearby coal mine. In the other treatment method, antimony was removed through precipitation as antimony sulfide (stibnite) in a sulfate-reducing bioreactor. Each system consisted of a 1000 liter plastic tub, filled with the treatment media. The loading ratio of iron oxyhydroxide in the adsorption chamber was 253 grams of precipitate per liter of water. The bioreactor contained equal parts of post peel, bark and compost. Inlet antimony concentrations ranged from 0.3 to 2.3 mg/L. Hydraulic residence times ranged from three minutes to 14 hours (adsorption chamber) and two hours to 30 hours (bioreactor). Removal rates in the adsorption chamber were 14 % at residence times of only three minutes and were up to 95 % at residence times greater than 2.5 hours. As the experiment progressed, removal rates by the adsorption chamber decreased over time, suggesting that adsorption capacity was being approached. Removal rates in the bioreactor were greater than 80 % at residence times above 15 hours. The greatest removal rate was 98 % at a residence time of 30 hours. Quantitative analysis using a scanning electron microscope confirmed the presence of stibnite in the bioreactor. Bioreactor performance continued to improve over time when compared to the adsorption chamber. This difference is possibly due to multiplication of sulfate-reducing bacteria. These results show that passive treatment can be a successful treatment method for antimony at gold mine sites, and that treatment through sulfate reduction and precipitation as stibnite is a favorable long-term treatment method over a treatment method using adsorption onto iron oxyhydroxides.

Keywords: Antimony, Passive Treatment, Adsorption, Sulfides

INTRODUCTION

The metalloid antimony (Sb) is often associated with gold mines, typically in the form of the sulfide mineral stibnite (Sb_2S_3) (Nesbitt et al., 1989; Williams-Jones & Normand, 1997). Removal techniques for Sb from solution are similar to those for arsenic (As) and include coagulation with ferric chloride, ion exchange, membrane filtration, and adsorption onto ferric hydroxide (Kang, 2003; Cumming et al., 2007; Klimko et al., 2008; Nokes, 2008). Other workers have documented potential removal of Sb through sulfate reduction and formation of stibnite. Biswas et al. (2009) conducted an experiment in a test tube to show that Sb can be removed as a sulfide in the presence of sodium sulfate. Wilson & Webster-Brown (2009) suspected that precipitation of stibnite could be occurring naturally at the bottom of Lake Ohakuri along the Waikato River where concentrations of hydrogen sulfide and Sb approach stibnite saturation conditions.

Trumm & Rait (2011) conducted a laboratory column leaching experiment to test removal of Sb from mine water in New Zealand by two different passive treatment methods. In one method, Sb was removed through adsorption onto iron oxyhydroxides. The oxyhydroxides were collected at two different coal mines where precipitate was forming within acid mine drainage (AMD). In the other treatment method, Sb was by removed through sulfate reduction and precipitation as stibnite in a sulfate-reducing bioreactor. Both techniques were effective in reducing the concentration of Sb in the mine water and X-ray powder diffraction analysis of the bioreactor substrate showed that stibnite had formed.

In this work, we extend the results of Trumm & Rait (2011) by installing small-scale passive treatment systems at the OceanaGold Globe Progress Gold Mine near Reefton on the West Coast of New Zealand to field test removal of Sb by two different techniques:

- Adsorption onto AMD precipitates in an adsorption reaction chamber
- Precipitation and formation of stibnite in a sulfate-reducing bioreactor

METHODS

Two passive treatment systems were constructed using 1000 L plastic tubs (standard intermediate bulk containers) with PVC piping, alkathene piping, and associated valves. The adsorption chamber was filled with a mixture of gravel and AMD precipitate from a nearby abandoned coal mine, composed primarily of goethite and ferrihydrite (Rait et al., 2010). The loading ratio of iron oxide in the adsorption chamber was 253 g precipitate per liter of water. The bioreactor was filled with equal proportions of post peel, bark chips, and compost. Each system was constructed in an up-flow configuration, such that the inlet was at the base of each system and the water flowed upwards through the treatment media driven by sufficient hydraulic head (Figures 1 and 2).

The systems operated for a period of 71 d. Flow rates were varied to determine Sb removal for different hydraulic residence times (HRTs). Inlet and outlet samples were collected approximately three times per week from each system, or more often for very short HRTs, and analyzed for dissolved As, dissolved Sb, and sulfate by inductively coupled plasma mass spectrometry using APHA method 3125-B (for metalloids) and by ion chromatography using APHA method 4500-PG (for sulfate) (APHA, 2005). Solid samples were collected from the top 10 cm of the bioreactor for mineralogical analysis by scanning electron microscopy (SEM) with energy dispersive X-ray spectrometer (EDS) and also for microbiological analysis.

Figure 1 Adsorption chamber prior to being filled with treatment medium

Figure 2 Adsorption chamber (on left) and bioreactor (on right) prior to being filled with water

RESULTS AND DISCUSSION

Adsorption chamber

Inlet concentrations to the adsorption chamber ranged from 0.3 to 2.3 mg/L. The system removed as much as 95 % of the inlet Sb concentrations (to as low as 0.09 mg/L) (Figure 3). The greatest percentage removal was noted at the beginning of the experiment, with removal effectiveness decreasing over time. A drop in treatment effectiveness with time likely indicates that adsorption capacity of the treatment media was being approached. Since HRT varied, it is possible to analyze the effectiveness of similar HRTs over the duration of the experiment. In general, the effectiveness of each HRT dropped with time (Figure 4). This suggests that if a consistent removal rate is required, HRT must be increased over time.

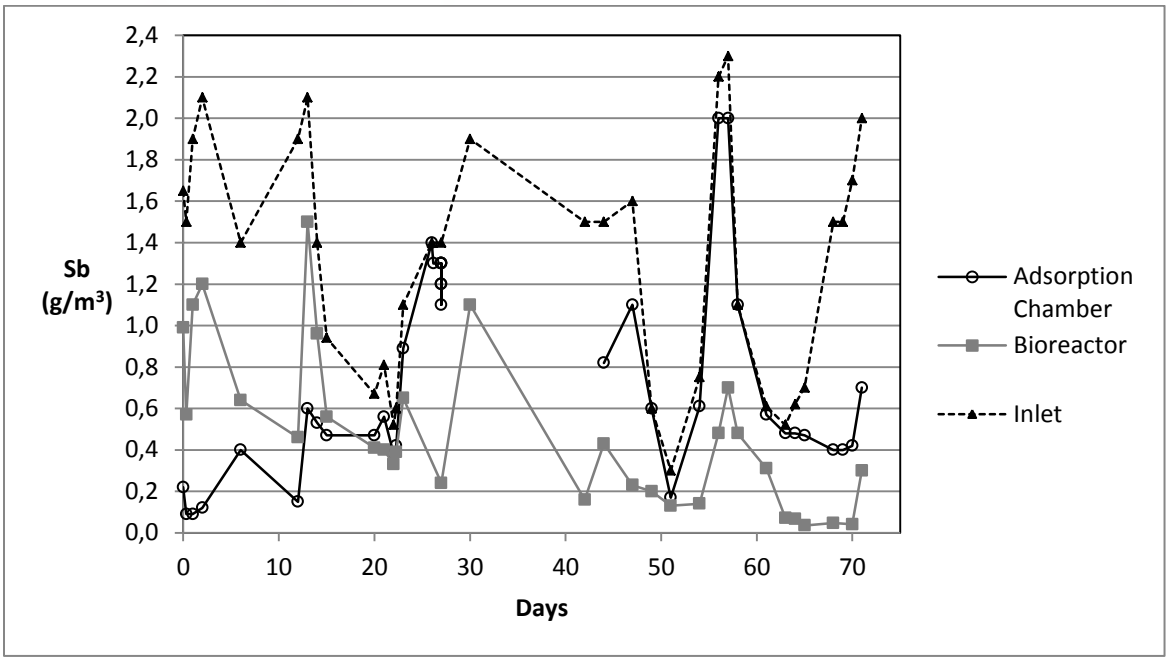

Figure 3 Inlet and outlet Sb concentrations for adsorption chamber and bioreactor over the duration of the field trials

At the very short HRT of 3 min, Sb removal in the adsorption chamber was 14 %, lowering Sb concentrations from 1.4 to 1.2 mg/L (Figure 5). Removal increased to 95 % at an HRT of 2.4 h (lowering Sb concentrations from 1.9 to 0.09 mg/L). For HRTs longer than 10 h, however, Sb removal was only 65 to 75 %. This is likely because Sb removal at these low flow rates were tested at the end of the experiment, after much of the adsorption capacity of the material had been exhausted and removal efficiency had declined.

Bioreactor

Antimony removal in the bioreactor was as low as 29 % near the beginning of the experiment, increasing to 98 % at the end of the experiment (Figure 6). Unlike the adsorption process where removal was initially good and decreased with time, Sb removal in the bioreactor was lower initially and improved with time, possibly due to growth and establishment of the sulfate-reducing bacteria population.

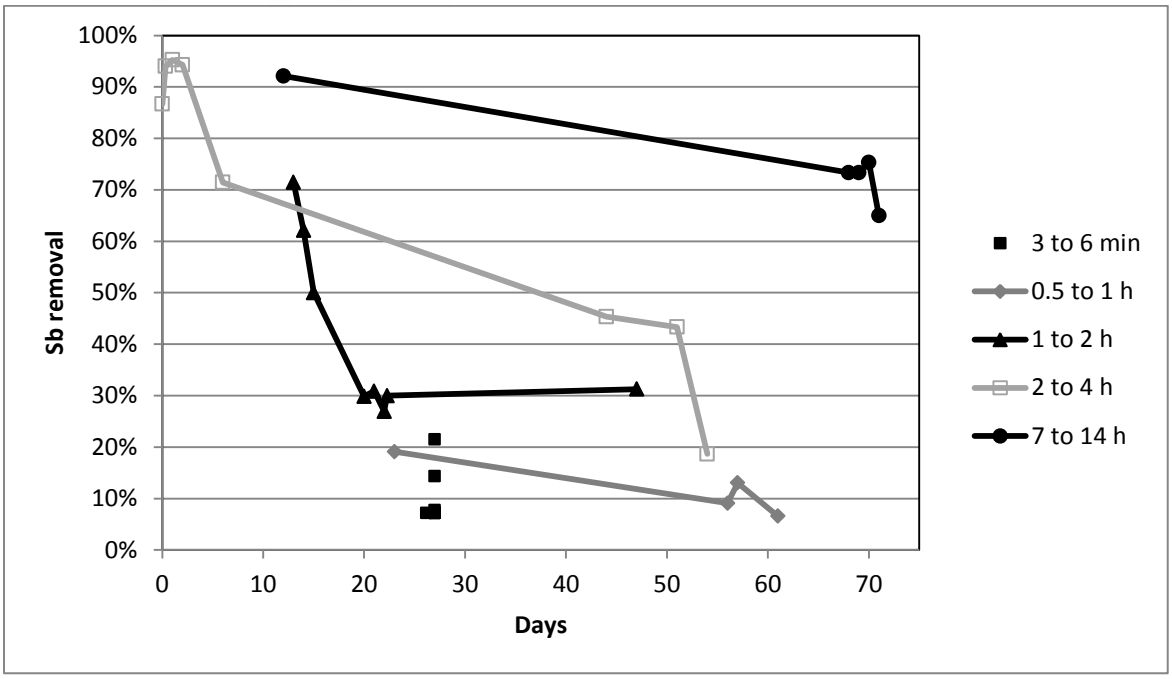

Figure 4 Antimony removal by adsorption chamber grouped according to HRT in the system to show trends

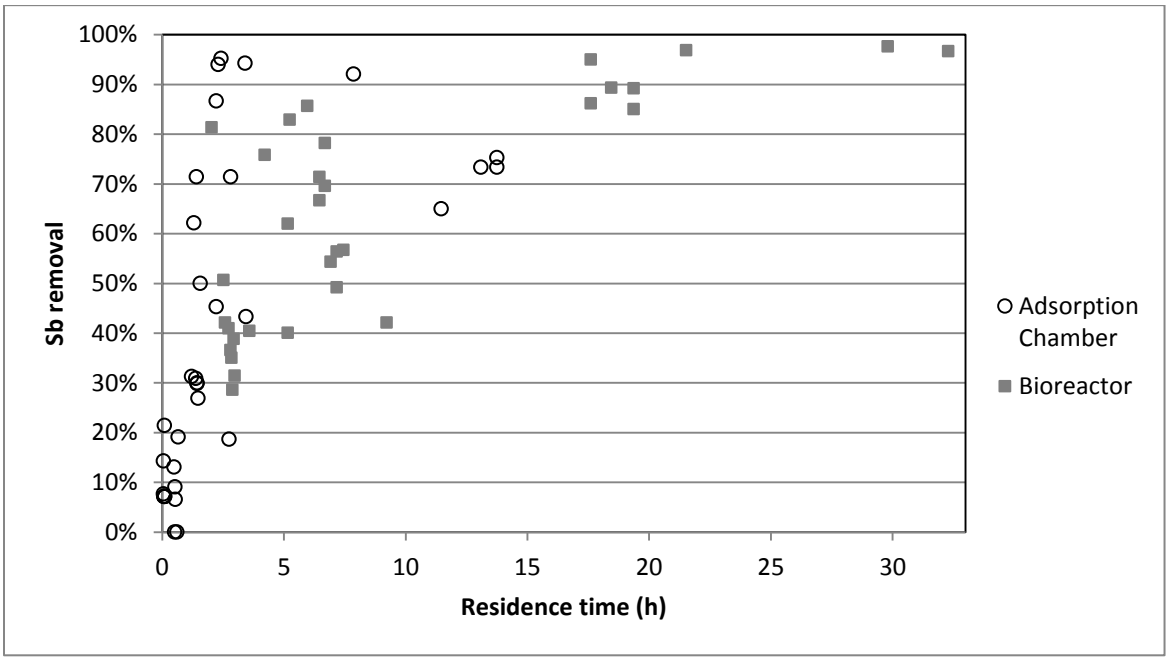

Figure 5 Antimony removal by adsorption chamber and bioreactor according to HRT

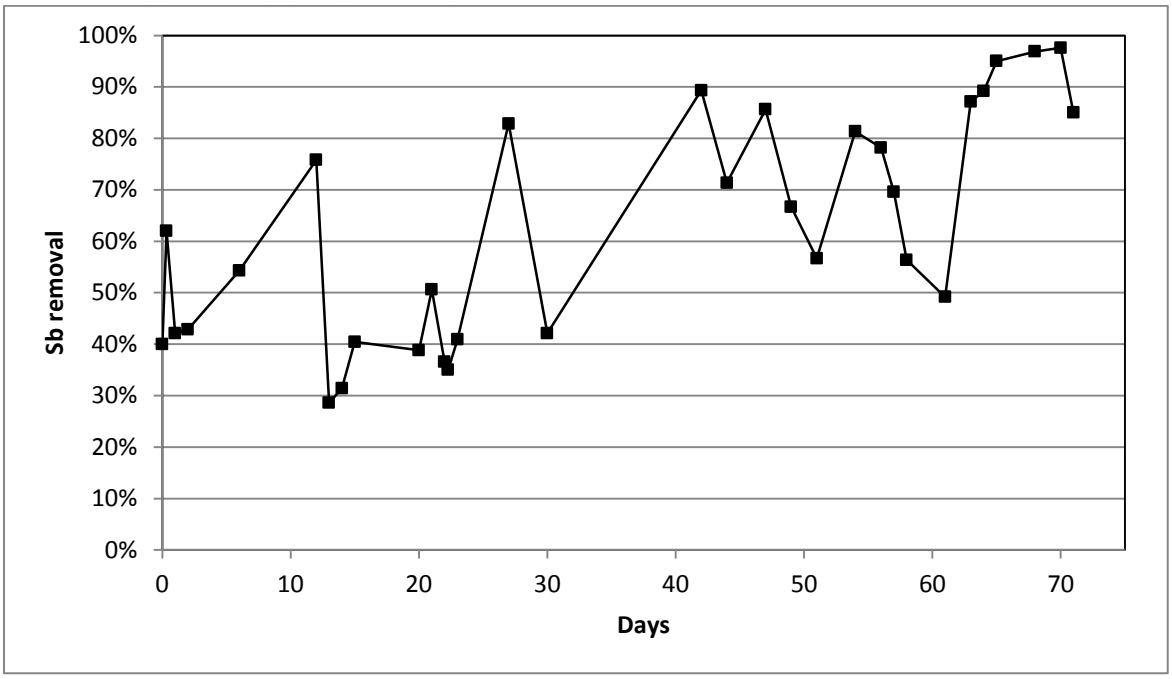

Figure 6 Antimony removal by bioreactor over the duration of the field trials

At HRTs below ~5 h, Sb removal was ~40 %, and at HRTs between 20 and 30 h, Sb removal was up to 98 % (Figure 5). Antimony removal rates ranged from 0.002 moles/m^3/d to 0.034 moles/m^3/d and are correlated with HRT. Solid samples from the bioreactor analyzed by SEM with EDS confirmed the presence of stibnite, suggesting *in situ* sulfate reduction was occurring (Figure 7). Preliminary genomic DNA and RNA-Seq molecular analysis of the substrate shows a complex community of sulfate-reducing bacteria along with species capable of metabolizing intermediate sulfur compounds, such as *Dethiosulfovibrio peptidovorans.*

Removal of Sb with a sulfate-reducing bioreactor may be a better long-term treatment technique than removal through adsorption onto iron oxyhydroxide precipitate. Preliminary work here shows that for similar sized systems, a bioreactor will outperform an adsorption chamber over time.

It should be noted that the duration of this experiment (71 d) was relatively short, and that the bioreactor had likely not reached steady-state conditions. It is possible that, over time, bacteria may reach a rate-limiting phase due to a condition such as complete lignocellulose hydrolysis (Brown, 1983) which could then compromise performance. To determine long-term performance of a bioreactor removing Sb (as well as long-term performance of an adsorption chamber), both systems were restarted and have been operating continuously for nearly two years. Complete data analysis will be presented in another publication, however, preliminary results show generally good performance over this time (Figure 8). Poor performance between days 124 and 162 and between days 405 and 483 coincide with cold winter conditions, which could affect the activity of sulfate-reducing bacteria.

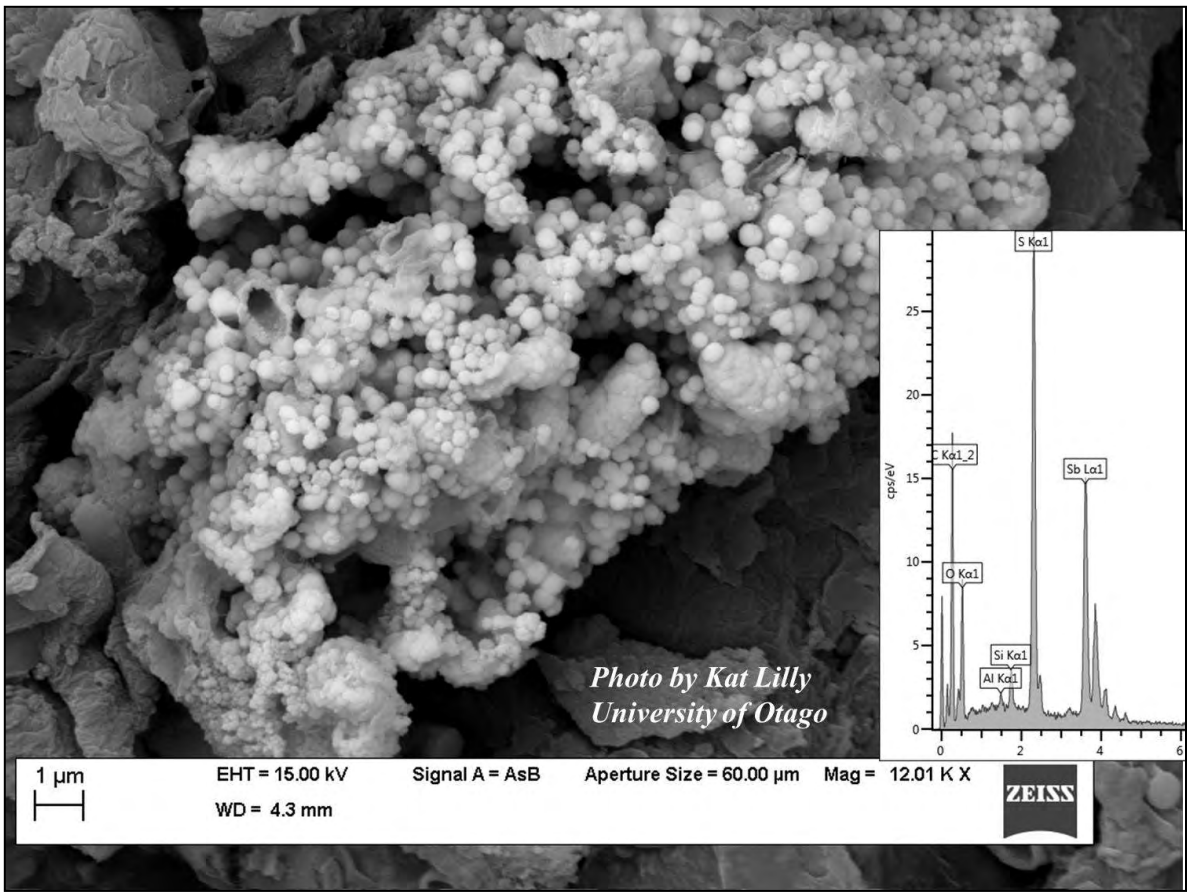

Figure 7 SEM microphotograph and EDS scan of antimony sulfide (stibnite) in substrate from the bioreactor

CONCLUSIONS

These results show that Sb dissolved in mine water can be removed through adsorption onto ferric hydroxide precipitates sourced from coal mine AMD. This study also shows that Sb can be removed through sulfate reduction in a sulfate-reducing bioreactor. For treatment by adsorption, Sb concentrations can be lowered by 14 % at HRTs of only 3 min and by 95 % at HRTs above 2.5 h. Performance declines in an adsorption chamber as the adsorption capacity of the treatment media is approached, therefore, HRT must be extended over time to compensate.

In a bioreactor, treatment of Sb occurs through sulfate reduction and formation of stibnite. Antimony concentrations can be lowered by 81 % at HRTs of only 2 h and by 98 % at HRTs above 20 h. Treatment performance increases with time as the microbial population expands and sulfate reduction improves. Therefore, HRTs should be longer initially and can be lowered as treatment performance improves.

Although this trial was only 71 d in duration, a second trial is underway (now nearly two years in duration) to measure long-term performance of a bioreactor and to determine if a rate-limiting phase may develop as steady-state conditions are approached. Preliminary results show good performance except during cold winter months when biological activity may be suppressed.

ABSTRACT

Acid mine drainage (AMD) generation is one of the greatest challenges for mine water management and treatment. An alternative treatment for AMD is the application of passive systems that include the use of sulfate-reducing bacteria. This study aimed to evaluate the applicability of anaerobic bench-scale reactors to remove the presence of aluminum in the effluent from a waste pile of a gold exploration. Five anaerobic reactors were applied in parallel with different proportions of substrates composed by limestone, sugar cane bagasse, a leguminous species, manure and sawdust. A source of iron was also added into two of the studied reactors. The results suggest an aluminum removal higher than 99 % for all reactors. The pH of the reactors effluents was naturally kept over 6.0 during the whole study.

Keywords: AMD effluent treatment, anaerobic reactors

INTRODUCTION

Jacobina mine is a complex of underground gold mine located in the town of Jacobina in Bahia state Brazil and it belongs to YAMANA GOLD INC. Now a days this mine process 6,500 tons of ore per day in activated carbon pulp processing plant, this production started in 2005.

The occurrence of acid mine drainage (AMD) has been reported in the extraction of commodities such as gold, coal, copper, zinc and uranium. Sulphide minerals are formed under reducing conditions and therefore in the absence of oxygen. These minerals, when exposed to atmospheric oxygen due to excavation and deposition of tailings, they can become unstable and oxidize.

AMD is therefore the result of natural oxidation of sulphide minerals such as pyrite (FeS_2) and pyrrhotite ($Fe_{(1-x)}O$) when exposed to water and oxygen, and this chemical reaction action can be accelerated in the presence bacteria. AMD usually has a low pH (1.5 to 3.5) and high levels of dissolved sulphate and metals.

The passive treatment systems refer, in general, processes which do not require human intervention to regulate the activities of operation. Such systems are usually constructed from locally found materials (soils, clays and rock fragments), natural materials (crop residues such as straw, wood shavings, manure) to promote the growth of natural vegetation or to promote an environment where effluent treatment can occur through microbial activity.

Typically passive systems can be characterized by promoting water flow by gravity, by having long operation years without demanding equipment that requires electrical power supply.

The passive treatment has been applied to the detriment of several alternatives due to their low cost of deployment and maintenance processes. However, passive wastewater treatment is only possible to be applied in cases where the triad, effluent quality, flow and availability of area allows your application with greater probability of success.

The aim of this study is to present the results of the implementation of a passive system of anaerobic bench scale, applied to the treatment of acid mine water produced in the waste dump known by the name of João Belo and located at Jacobina Mining Corporation (JMC) that belongs to Yamana GOLD INC.

METHODOLOGY

Study area

The study area is comprised by the JMC mine, located in the town of Jacobina in Bahia State Brazil and belongs to YAMANA GOLD INC. The experimental apparatus is located downstream from the waste dump João Belo after the flooded area formed by the drain from the battery.

Characterization of DAM and early treatment

The characterization of the effluent from the mine waste dump was obtained from a sampling campaign conducted in August 2011, where the chemical of interest for treatment were determined. The mine effluent results were compared with the maximum concentration limits (MCL) of Brazilian water surficial water quality criteria (CONAMA 357/2005) for class 2 over the limits for effluent discharge.

Table 1 presents the results of this campaign, which also reports the results of detection, the legal concentration limit of the Brazilian regulation CONAMA 357/2005 for Class 2 water bodies and the analytical method employed. All components were dissolved and analyzed for their overall shapes.

Table 1 Characterization of acid drainage from the waste dump.

(3) Maximum Concentration Level for Water Bodies Class 2 According to CONAMA 357/2005.
(4) ICP-AES: Inductively Couple Plasma – Atomic Emission Spectroscopy
(4) Ion chrom: Ion Chromatograph

As noted, the main constituents of interest were those whose concentration is found above the legal limits for class 2 rivers, especially aluminum, whose concentration was 20 mg / L or approximately 1.0 x 10^{-3} mol / L.

The principle of treatment is guided by the fact that 0.3 moles of sulfide will be produced per cubic meter per day in the reactors. Each reactor contains about 150L to 200L of substrate and, consequently, each reactor should be capable of generating 0,045 moles of sulfide according to the following reaction.

$$2\ H^+ + SO_4^{=} + 2\ \text{“}CH_2O\text{”} \dashrightarrow H_2S + 2\ HCO_3^- \quad (1)$$

In the reaction, "CH2O" generically represents the organic matter present in the reactors. The contaminants are removed by two geochemical mechanisms. The H_2S generated by the reaction above reacts with Fe, Zn, Cu, Cd and Pb metals generating precipitated sulfides (secondary sulfides).

$$H_2S + Zn^{2+} \dashrightarrow ZnS + 2\ H^+ \quad (2)$$

Furthermore, HCO_3 increases the pH and form metal hydroxide precipitates, which will be important process for removing aluminum and chromium.

$$Al^{3+} + 3\ HCO_3^- \dashrightarrow Al(OH)_3 + 3\ CO_2 \quad (3)$$

According to the reactions as shown and the aluminum concentration found in the effluent, 2 moles of HCO_3^- are released for every mole of H_2S and 3 moles of HCO_3^- are necessary to 1 mol of aluminum be removed. Consequently, 0.045 mol of sulfide is generated in the reactors 0.030 mole of aluminum can be removed. Thus, 30L of water a day can be processed in reactors containing 150L to 200L of substrate, which corresponds to a rate of 20,5mL / min.

Experimental apparatus

The passive system deployed on the site consists of five anaerobic pilot scale with volume of 250L, which in turn receive the effluent from the mine waste dump. The effluent distribution system consists of a feed tank of 1,000L which forwards the effluents by gravity to five tanks/ of 50L, which in turn feed the reactors. The feed rate of each reactor is 30L / d. Figure 1 below shows a schematic of the system implementation.

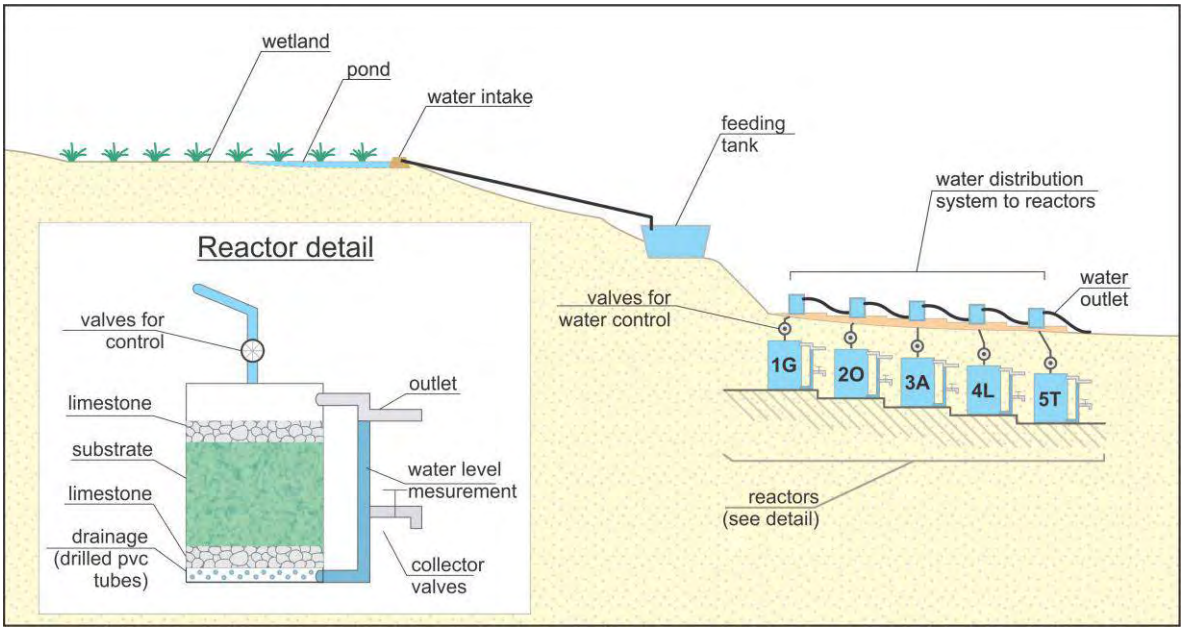

Figure 1 Bench scale passive treatment system developed in the Jacobina mine, belonging to Yamana Gold

The five reactors were sized to receive a limestone layer disposed on top of the substrate and a layer on the bottom of the reactor. The composition of the substrate comprises carbon sources, nitrogen, and an inoculum (manure), and a source of iron was added in two reactors. Table 2 below shows the composition of the substrates used in each reactor. The percentage of substrate used is relative to the working volume of the reactors (150L).

Table 2 Materials used for the substrate filled in each reactor.

Substrate	Reactors				
	1 G	2 O	3 A	4 L	5 T
Wood dust	40%	20%	30%	35%	40%
Limestone	30%	30%	25%	30%	30%
Sugarcane bagasse	-	10%	10%	15%	20%
Legume vegetation	20%	15%	15%	10%	-
Steel dust	-	10%	10%	-	-
Manure	10%	10%	10%	10%	10%

Monitoring and start-up system

After the implementation of the reactors on the site, the substrate was inserted into each reactor composition as indicated in Table 2. The start-up of the system was performed by maintaining the water level of the reactor above the substrate for a period of one week, so that the community of sulfate-reducing bacteria could be established in the system. For monitoring system, samples of effluent from the waste dump and effluents from the treatment of the five reactors were collected monthly between the months of October 2011 to March 2012. The monitored parameters were: temperature, pH, electrical conductivity and alkalinity. For monitoring the efficiency of the system, the concentrations of sulfate and metals aluminum, manganese and iron, in its dissolved form, were analyzed. The parameters of interest were analyzed according to Standard Methods for the Examination of Water and Wastewater. Metal concentrations in the influent and effluent of the system were analyzed through atomic emission spectrometry (ICP-AES) techniques.

RESULTS AND DISCUSSION

Table 3 shows the results of the concentrations of dissolved aluminum dissolved iron dissolved manganese sulfate, and pH from monitoring the influent and effluent produced by the five reactors.

Table 3 Results in mg/L of passive monitoring system for treatment of AMD.

Parameter	Average concentration (Parameter reduction - %)					
	In take	1G	2O	3A	4L	5T
Al	20,7	0,02 (99,9)	0,02 (99,9)	0,02 (99,9)	0,02 (99,9)	0,03 (99,8)
Fe	1,44	0,01 (99,6)	0,05 (96,4)	1,41 (2.17)	0,32 (77,3)	0,01 (99,3)
Mn	1,95	2,21 (25.1)	2,23	3,15	2,48	1,26 (35,5)
SO_4	209.21	75,7(63.8)	32,4 (84.5)	27,9 (86.6)	23.07 (88.9)	134,5 (35.7)
pH	3,03	7,47	7,14	6,89	6,98	7,39

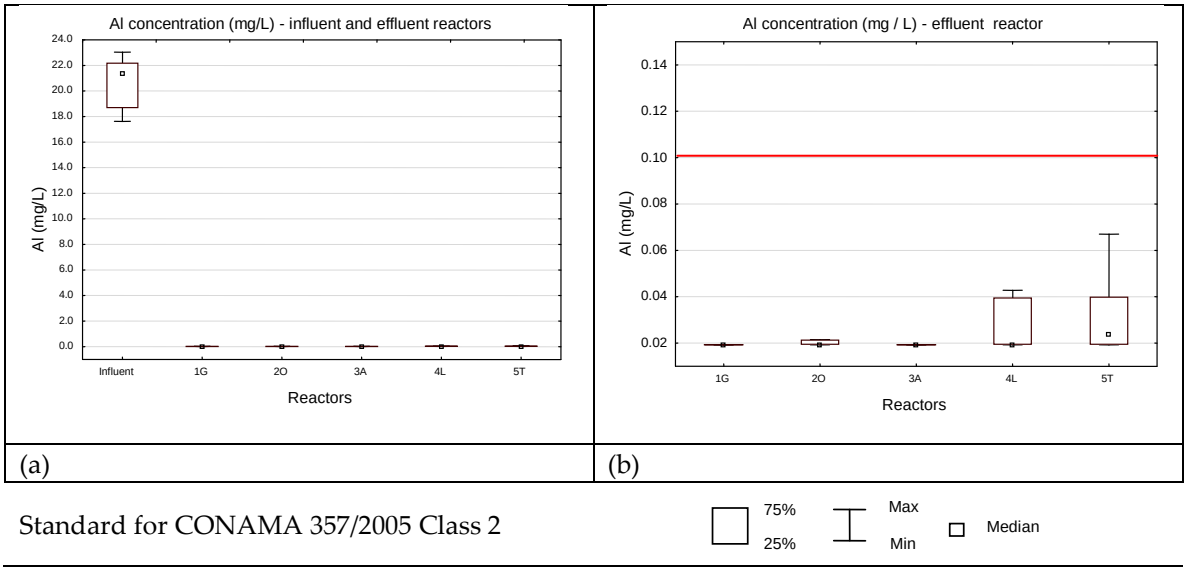
As noted in Table 3, the average concentration of aluminum in the tributary system is 20,7mg / L and the effluent of the reactors yielded concentrations below 0.04 mg / L. The average efficiency for all reactors was greater than 99.8% removal of aluminum.

In the characterization of AMD produced on site, the main element of interest was the treatment of aluminum metal. The iron was introduced into the substrate only to promote coprecipitation of metal, so the high concentration observed in the effluent of reactor 3A is a consequence of the removal of iron present in the substrate. As noted, 10% by volume of the reactors of the substrate 2O and 3A is constituted of iron filings. Although the same amount of iron has been added in the substrate from both reactors, the reactor effluent showed 2O average concentration of 0.05 mg / L, and the effluent from the reactor had an average concentration 3A iron 1,41mg / L. Regarding other reactors, lower average concentrations to 0.4 mg / L was observed.

As noted, the increased manganese concentrations in the effluents of the reactors. The average concentration of manganese was 1,95mg / L and the influent was noted that the effluent from the reactors had concentrations above the value observed for influent. Due to the fact that manganese may be present in the crystal structure of carbonate minerals (e.g., rhodochrosite - $MnCO_3$), the increase in the average concentration in the effluent of the reactors can be attributed to solubilization of manganese present in the limestone.

With respect to pH, it was noted that the composition of the substrate was able to raise the pH of the effluents from all reactors. The average concentration of the effluent was pH 3.03 (in take) and the average concentrations of the effluent of the reactors were maintained pH between 6 and 8.

Efficiency in removing sulfate above 60% for all reactors except reactor 5T, whose average efficiency was 35.7% although the goal of treatment has not been the removal of sulfate, this was observed.

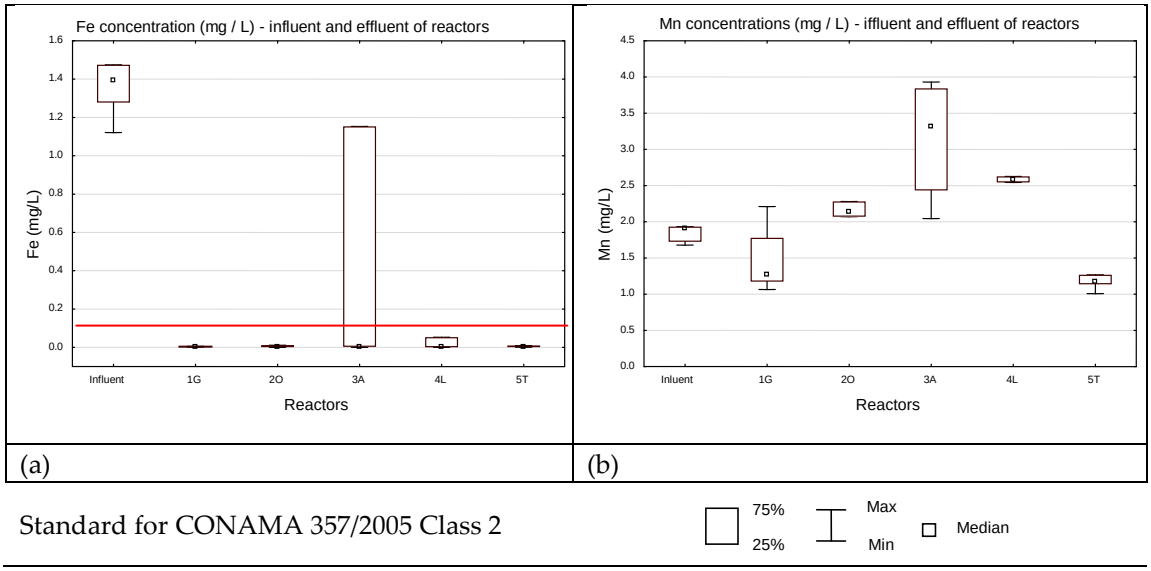


Graph 1 Concentrations of aluminum in the influent and effluent of the reactors.

The graphs (Figure 1) show the different aluminum concentrations in the influent and effluent of the reactors. Plot (a) shows the inflow concentrations compared to the effluent quality of the system. The graph (b) shows the effluent concentrations of the reactors and the limit for aluminum according to CONAMA No. 357 of 2005 for class 2 [4] water bodies.

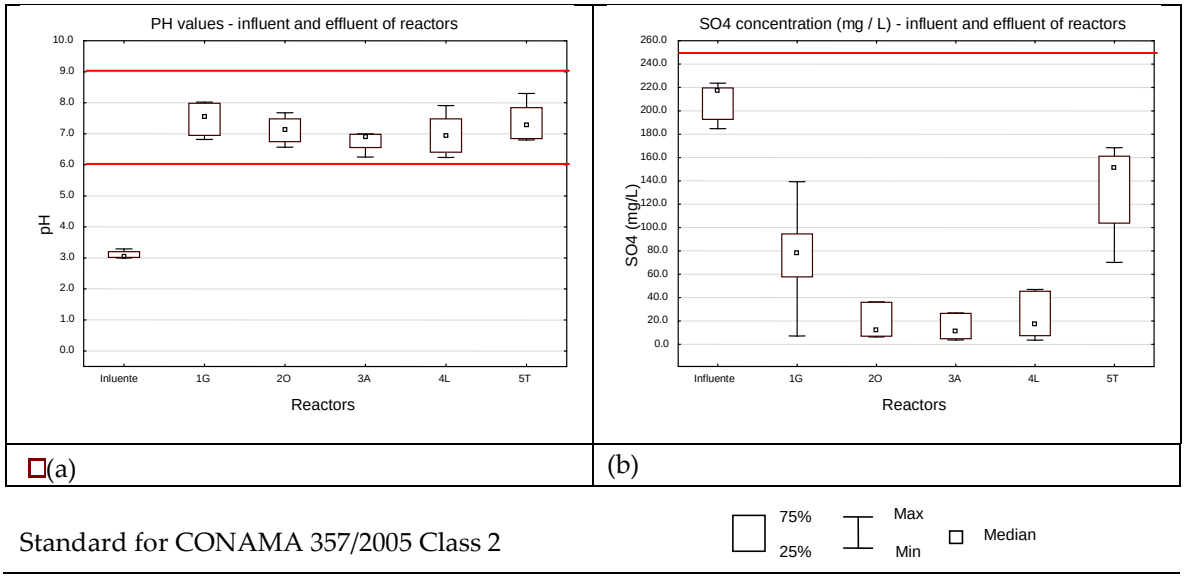
It is observed that the average aluminum concentration in the influent of the reactor is between 20 and 22 mg / l. For effluent concentrations, we note that the maximum, minimum and median values have little variability for 1G, 3A and 2O reactors, while for the other reactors, 4L and 5T, concentrations were more variable, with maximum values exceed 0.04 mg / l. In fact, the effluent concentrations of aluminum were often below the detection limit of the analytical method in order to justify the stability of the observed values. It is seen that the concentrations of the effluent from reactor consistently met the threshold practiced 0.1mg / l.

Chart 2 below shows the concentrations of iron and manganese influent and effluent of the reactors.



Graph 2 Concentrations of iron (a) and manganese (b) in the influent and effluent of the reactors.

The graphs show the concentrations of iron (a) and manganese (b) in the influent and effluent of the reactors. The iron concentration in the influent have a median value of 1.4mg / l and the effluent have median values below 0.1 mg / l. As previously mentioned, the source of iron present in the substrate may have contributed to the increase in concentration in the reactor effluent 3A. With respect to the concentrations of manganese, there is greater variability in the distribution of concentrations from reactor 3A, whose median was approximately 3,4mg / L.



Graph 3 Values of pH (a) sulfate and (b) in the influent and effluent of the reactors.

As noted, the pH values consistently complied with the environmental laws, whose values should be between 6.0 and 9.0. Given that the median pH of the influent was approximately 3.0, the limestone used as the substrate alkalinity produced by anaerobic activity in the system was able to elevate and maintain the pH of the reactors to values above 6.0.

According to the graph (b) of the figure, we note that the sulfate median concentrations in the reactors 2O, 3A and 4T, were below 20,0mg / L. In comparison with the inflow concentrations, the removal of sulfate in the reactor was 63.4%, 84.5%, 86.6%, 88.9% and 35.7% for the 1G 2O, 3A, 4L reactor and 5T respectively. It is also noticed that the effluents did not exceed the maximum concentrations of 250 mg / L of sulfate, as pointed out by environmental legislation.

Regarding other metals characterized in acid drainage from the waste dump of João Belo, it was noted that their concentrations were below the detection limit of the analytical method used in all analyzes.

CONCLUSIONS

In accordance with the observed results, it can be concluded that all reactors are capable of complying with the procedure outlined for treatment of acid drainage from the waste dump John Belo, mine JMC main objective. It was observed that all reactors were able to reduce aluminum concentrations below the limit of 0.1 mg / l recommended by law. The mechanism for aluminum reduction is due to the precipitation of this metal as hydroxides, as it was mentioned before.

The production of alkalinity caused by anaerobic activity, as well as limestone applied to the substrate, greatly increased the pH of all reactors applied in passive treatment so that the effluent met the minimum and maximum limit recommended by law.

With respect to iron and manganese in the effluent of the reactors analyzed, it was noted that their concentrations exceeded the limits prescribed by law due possibly to the fact that these metals are present in the chemical composition of the substrate applied.

Considering the low cost of the ingredients and this stage of this effluent treatment study it was not necessary to develop cost estimation among the different reactors for a full scale implementation. Once this project moves to the next phase, a cost evaluation for the implementation of the different reactors will be developed. So the mine company would have the best cost / return ratio for this effluent treatment system.

ABSTRACT

Before tailings pond water can be discharged to the environment it must meet the very stringent local water quality requirements. In British Columbia, selenium must be below 1μg/L and sulfate, depending on the hardness of the receiving water, must be as low as 100mg/L. To meet this challenge, in anticipation of future mine expansion, Mount Polley Mine commissioned a pilot-scale passive treatment system to remove selenium and sulfate from their tailings pond water. The design was based on laboratory column tests with wood chips and hay that verified removal of selenium and sulfate to the required levels. This paper describes the design and construction of a sub-surface flow wetland and its evolution over several years into a passive remediation system. Regular monitoring and troubleshooting led to upgrades and modifications that improved performance. The subsurface layer of woodchips, hay and manure provides microorganisms with carbon sources. As part of a genomics project, material from this layer was shown to contain many different species of sulfate-reducing bacteria. Additional carbon inputs come from plants and filamentous algae that are beginning to populate the periphery and surface of the wetland. The genomics work also showed that planktonic algae were plentiful in the water column. This pilot-scale process shows that passive remediation can be used to improve the water quality of mine tailings pond water.

Keywords: Biochemical reactors, metals, mining, bioremediation, microbial ecology, selenium, sulfate

INTRODUCTION

The mining industry in British Columbia was valued at C$8.3billion in 2012 (The Mining Association of Canada, 2012) and is therefore a great contributor to employment and prosperity in the Province. Almost every mine has a tailings storage facility into which process effluents consisting of finely ground rock and water are placed. These are very large (squares of kilometers in size). Mount Polley had been investigating several ways of treating their tailings pond water so that they could discharge some of it so as to ease the demand for additional storage capacity. One of the approaches under consideration included a passive treatment process for metal and sulfate removal.

Passive treatment means that natural biological and geochemical processes are harnessed in specially constructed sub-surface and/or surface flow wetlands. The purpose of each cell in the process is to provide the best environmental conditions to encourage the growth of biological organisms that promote metal immobilization and, in cases where needed, sulfate reduction. Since some engineering is usually required they are more accurately referred to as biochemical reactors (BCRs), and a variety of configurations have been used at mine sites to successfully remediate metal-contaminated water (Khoshnoodi et al., 2013; Mattes et al., 2011; Blumenstein and Gusek, 2008; Gusek, 2008).

The main constituents of interest that needed to be reduced in the Mount Polley tailings water in order to meet discharge requirements were sulfate, selenium, copper, molybdenum, phosphorus and nitrate. Sulfate can be reduced by sulfate-reducing bacteria, which are anaerobic organisms that grow in most natural terrestrial and oceanic sediments devoid of oxygen. Sulfate replaces oxygen as an electron acceptor in respiration of these organisms thereby producing the product sulfide. Metal removal occurs concomitantly as metal ions such as Cu^{2+} combine with S^{2-} to make sparingly soluble metal sulfide precipitates (Jalali, 2000). Metalloids such as selenate and selenite can be reduced directly by bacteria to produce elemental forms that precipitate and are immobilized (Stolz et al., 2006;Baldwin and Hodaly, 2003). To achieve metal and sulfate removal the microbes involved are encouraged to grow by being provided with nutrients and anoxic conditions. In BCRs this is achieved through using organic materials obtained from forestry, agricultural and other wastes available nearby the mine site. Within close proximity of the Mount Polley Mine, wood chips, hay and cattle feed lot manure were obtained and shown to support growth of sulfate-reducing bacteria in proof-of-concept laboratory reactors that successfully removed sulfate and selenium to below the required concentrations. Based on these results, a pilot-scale BCR was constructed at the mine site in 2009. This paper describes the configuration of this BCR, the results of water quality and microbial community monitoring carried out over the ensuing years and subsequent modifications that were made to improve performance.

METHODOLOGY

Proof of concept laboratory experiments

Plexiglas columns (I.D.: 11.43 cm, Length: 50.8 cm) with a mixture of 50%dw hay, 20%dw woodchips and 30%dw cow manure were used as up-flow BCRs. These organic materials were pre-soaked in water overnight and adjusted to pH 8.0 before being added to the columns together with laboratory cultures of sulfate-reducing and cellulose-degrading bacteria as inocula as well as

crushed limestone for pH control. For the first few weeks, the columns were fed with a Postgate-B growth medium (Postgate, 1983) to allow a healthy sulfate-reducing bacteria population to build up. Thereafter, simulated tailings water containing 600mg/L sulfate and 15µg/L selenium, plus 52mg/L Iron (Fe) and sources of nitrogen (N), phosphorus (P) and potassium (K) was fed to the BCRs. Iron was required as a source for excess sulfide precipitation. Accumulation of sulfide in the BCR would have inhibited the bacteria from growing, and therefore it had to be removed. The columns were set up so as to prevent any oxygen from getting in (since sulfate-reducers are obligate anaerobes). Over the period of operation, concentrations of sulfate and selenium were measured in the effluent using the turbidimetric barium sulfate American Water Work Association method 4500-SO_4^{2-}, and inductively coupled plasma mass spectroscopy (ICP-MS), respectively. Dissolved oxygen, pH and oxidation-reduction potential were monitored regularly so as to check that optimal conditions were being maintained in the BCRs.

Construction of the field-based pilot-scale BCR

A field-based pilot-scale BCR was constructed at the mine site in December 2009. After experimenting with smaller scale systems, a 100 gallon per minute sub-surface flow BCR with a water cover was constructed using the same organic material mixture composition as was used in the laboratory column experiments. The Figures below show the BCR during construction and immediately after commissioning.

Figure 1 Construction of the field-based BCR showing the perforated feed pipes, organics (brown) and rock (right-hand side) layers.

Figure 2 View of the completed BCR looking down from the top of the tailings storage facility.

Water from the tailings storage facility toe drain flows into the bottom of the BCR through a series of parallel, perforated pipes, percolates upwards through the organic material and then flows out. A layer of rocks on top of the organics keeps them in place. A 3-4m deep water cover acts as an oxygen barrier. The treatment area is approximately 50m by 70m. An island was included in the centre of the pond for aesthetics.

BCR monitoring

Water quality data were collected regularly from the influent and effluent to determine the effectiveness of metal and sulfate removal. The inside of the BCR was sampled once a year by the University of British Columbia team. Since samples from within the organic matrix could not be accessed easily due to the rock layer covering them, water samples from just above the

sediment/water interface were taken. If the BCR was performing as expected then the water percolating out of the sediments into the water column would be anaerobic with evidence of sulfide as an indication of active sulfate-reducing bacteria in the sediments. The microbiology of the water just above the sediments was assessed to see if any sulfate-reducing bacteria were entrained by the water flowing out of the sediments, and to see what other microbes were colonizing the water column. Microbiological analysis was done by extracting DNA and subjecting it to sequencing of the small subunit ribosomal ribonucleic acid (SSU rRNA) gene, which is a barcode that is used to identify microbes. In 2012, the BCR was shut down and drained. At this time, solid samples were taken from within the organic matrix and frozen to preserve the microbial community for later analysis. The BCR was modified based on monitoring results, adding a berm to increase hydraulic retention time and replenishing with fresh organics. Further modifications in 2013 included installation of booms to reduce wind mixing so that anaerobic conditions could be better maintained. One year after reconstruction (August 2013), samples taken from the sediment layer were used for metagenomics, which is a new technique for measuring both the microbes present as well as their function.

RESULTS AND DISCUSSION

Proof of concept laboratory experiments

Even though the pH was adjusted to 8.0 before starting the BCRs, additional NaOH needed to be added to maintain the pH above 6.5. Organic acids leaching from the wood, or produced due to fermentation of organic matter, contributed to pH decrease. Since the desired bacteria require a circum-neutral pH in which to grow, pH adjustment was needed. The pH of the laboratory BCR feed was 8.0, similar to that of the Mount Polley effluent. After 114 days, the pH stabilized above 6.0 and it was only necessary to add NaOH sporadically thereafter. Throughout their operation, conditions remained optimal for sulfate-reducers with dissolved oxygen below 1mg/L except until day 374, when it suddenly increased to 4.7-5.7mg/L. The ORP was below -300mV and the pH was steady between 6.0 and 7.0. Sulfide levels inside the BCR were always below 100mg/L, which is much lower than those known to cause inhibition of sulfate-reduction (Utgikar et al., 2002).

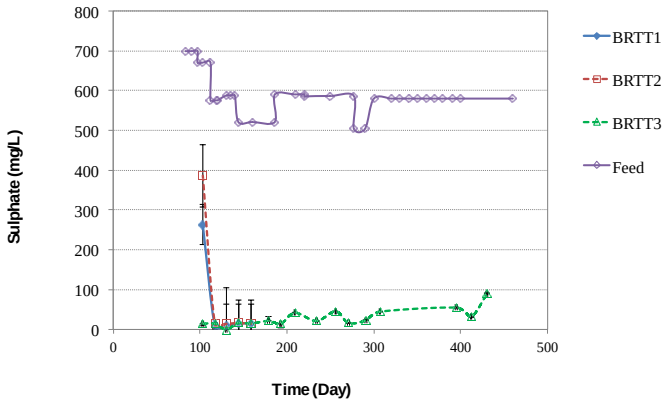

Figure 3 Plot of sulfate concentration versus time for the influent and effluents from all three of the laboratory BCRs. BRTT1, BRTT2 and BRTT3 are triplicate columns run under identical conditions. Sulfate concentration measurements were performed in triplicate with the average values plotted and the whiskers representing the standard deviation.

Two of the BCRs were stopped after approximately 100 days after starting feed of the simulated tailings pond water so as to examine the nature of the microbial population associated with successful performance. The third BCR was run for a total of 430 days to see if and when it would fail. Performance was consistently successful for the entire period (Figure 3). For all BCRs the sulfate concentrations in the effluent were below 100mg/L, the level desired for discharge. The selenium concentrations in the effluent were below the detection limit (< 0.0001mg/L). The proof-of-concept experiment demonstrated that sulfate and selenium can be removed from the Mount Polley tailings water to the required levels using these organic materials in a BCR, provided that the pH is maintained near neutral, no oxygen is allowed to enter the bioreactor and that enough metal ions be present to keep sulfide levels low.

Initial performance of the field-based pilot-scale BCR

Initially, the field-based BCR successfully removed nitrite- plus nitrate-N and selenium to below detection levels (Table 1). Twenty three percent of the sulfate coming in was removed, but the final sulfate concentration was still well above the desired concentration of 100mg/L. Molybdenum concentrations decreased slightly and copper concentrations increased a little. During the 17 June 2010 field trip, 1-3mg/L sulfide was found at the sediment water interface of the BCR at all of the four locations sampled. This indicated that sulfate-reducing bacteria were active in the sediments as expected. Over the course of the following year, performance of the BCR was similar with the exception that sulfate-reduction was less. During the second University field trip in August 2011, no sulfide was detected at three of the sampling locations in the BCR. Some, 4.3mg/L, was measured at only one of the locations, indicating that only parts of the BCR were active for sulfate-reduction. Also, at that time, the sulfate concentrations at the sediment/water interface (464-599mg/L) were not significantly different from those in the influent.

Microbial community analysis from 2010 to 2012

Samples taken during the first two field trips in 2010 and 2011 from the sediment/water interface were analysed for microbial community composition, and in particular the types of sulfate-reducers present was determined (Figure 4). Sulfate-reducers were detected in the BCR in 2010 consistent with presence of sulfide, but they were absent from the sediment/water interface in 2011. Even though sulfate-reducers were not detected just above the sediment surface, they may still have been present inside the organic matrix. Nevertheless, the lack of detection of sulfate reducers coincided with declining performance of the treatment system (Table 1). In 2012, the BCR was drained and it became possible to take samples directly from the organic matrix. When these samples were analysed for microbial community composition, many sulfate reducers were found (Figure 4). The presence of sulfate-reducers suggested that the organic matrix and conditions inside the BCR were suitable for hosting these organisms. But, contrary to expectations, sulfate-reduction rates through the BCR were low. One possible explanation was that sulfate may be reducing to sulfide within the organics, but low metal ion concentrations were not enough to precipitate all soluble sulfide and it was re-oxidized to sulfate upon contact with oxygen diffusing down through the water column. Such a phenomenon was observed in the laboratory bioreactors before Fe^{2+} was added to the column bioreactor feed (Mirjafari et al., 2011).

Performance since 2012 modifications

Recharging of the BCR organics and increasing of the retention time resulted in improved performance (Table 1). The BCR was again visited in August 2013 and sampled for microbial community analysis.

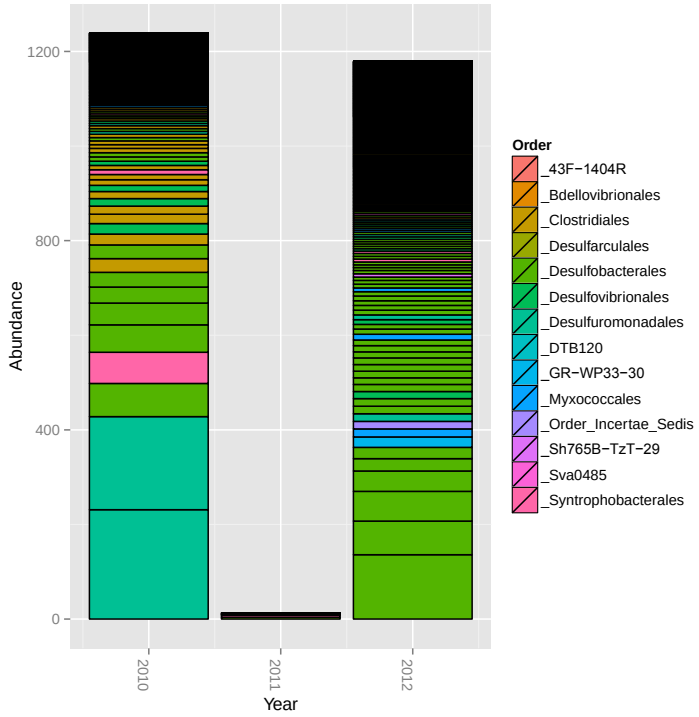

Figure 4 Sulfate-reducing micro-organisms detected in the BCR. Each bar on the plot represents one type of microbe. They are colored according to the Order in which they are classified. Bacteria are classified in taxonomic groups at different levels: Phylum;Class;Order;Family;Genus;Species. Abundance refers to the number of sequences out of a total of 12000, 8000 and 12000 for samples taken in 2010, 2011 and 2012, respectively.

Microbial community composition in 2013

A new technique was used called metagenomics. Instead of amplifying the SSU rRNA gene, which introduces possible biases, whole DNA was sequenced. From this we identified genes involved in sulfate metabolism, such as sulfate-reduction, and the types of bacteria that they came from, thus tying function to taxonomy. The results revealed that a psychrophilic organism, *Desulfotalea psychrophilia*, was the most prevalent sulfate-reducer in the BCR. Interestingly, this type of sulfate-reducer was first found in permanently cold Arctic marine sediments (Rabus et al., 2004), and even can survive at temperatures below 0°C. As before, the *Desulfobacterales*, *Desulfovibrionales* and *Desulfuromonadales* were sulfate-reducing bacteria taxa that were present in the BCR sediments. Presence of a healthy population of sulfate-reducers and detection of sulfide at the sediment/water interface (Table 2) coincided with active sulfate reduction and metal removal; although final sulfate concentrations were not meeting the 100mg/L discharge requirement.

A very interesting phenomenon was noted by the operators during the colder months of 2013, when the BCR was covered with ice and snow. Higher concentrations of sulfide and lower concentrations of BCR effluent sulfate were measured in Spring than in Summer (Table 2). This suggested that sulfate-reduction was active even though temperatures of the BCR water were between 2.1 and 7.7°C. The cover of ice and snow on the surface of the BCR prevented oxygen from getting into the water layer as dissolved oxygen profiles with depth revealed (Figure 5). Improved anaerobic conditions correlated with improved sulfate-reduction. The average BCR influent sulfate

concentration in 2013 was 498mg/L. Sulfate-reduction was highest (35%) in April. Metal removal was also greatly improved in the Spring compared with the rest of the year (percent removal: Se (86%); Cu(56%); Mo(44%)). Presence of cold-adapted sulfate-reducers in the BCR, and active sulfate-reduction and metal removal supports the use of biological treatment in cold climates

Table 2 Sulfate and sulfide concentrations measured in the BCR effluent over 2013

Parameter	14-Mar-13	4-Apr-13	1-May-13	6-Jun-13	10-Jul-13	8-Aug-13	5-Sep-13	3-Oct-13	5-Nov-13	3-Dec-13

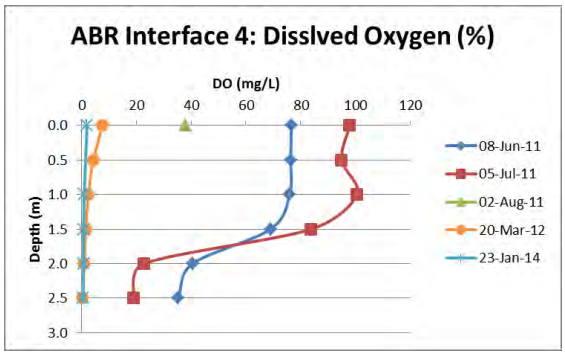

Figure 5 Dissolved oxygen concentrations versus depth below the BCR water surface during winter and summer months.

The BCR in 2014

During the most recent (26 August 2014) sampling of the sediment-water interface in the BCR, sulfide concentrations were higher than were measured in 2013 (August) (Table 2). The locations with higher sulfide concentrations coincided with lower sulfate concentrations. The North East side of the BCR (locations 3 and 4) was more active in terms of sulfate-reduction. Influent sulfate concentrations were 509mg/L. An extimated 15.6% sulfate is being reduced by the system.

Table 2 Concentrations of sulfate and sulfide in the Mount Polley BCR in 2013 and 2014.

	2013		2014	
Location	SO_4^{2-} (mg/L)	S^{2-} (mg/L)	SO_4^{2-} (mg/L)	S^{2-} (mg/L)
1	458	5	471	0
2	458	5	451	60
3	395	9	400	180
4	453	9	426	40-50
Average:	441		437	

Plants (*Typha latifolia*) and filamentus algae successfully colonized the sides and surface of the BCR (Figure 5). At other sites algae have been found to host many microbes, such as sulfate-reducers, and their presence adds organic carbon to the BCR plus they can directly improve water quality (Das et al., 2009;Larratt et al., 2007). Sequencing revealed many types of unicellular algae, such as *Dunaliella*, in the water column. Sub-aqueous plants could be seen growing on the bottom near the edges (Figure 6).

CONCLUSION

A laboratory proof-of-concept test demonstrated that removal of sulfate and selenium to below the required levels for discharge was possible. The field-based BCR constructed at Mount Polley Mine using a woodchip, hay and manure organic mixture was found to successfully support an active sulfate-reducing microbial community and some removal of nitrite/nitrate, metals and sulfate was occurring. The system worked best immediately after the addition of fresh organics but thereafter appeared to decline in performance. Rapid depletion of readily available organic material may be a limiting issue for passive treatment and is it recommended that an upstream surge pond be included in future designs into which fresh organics can be added. The BCR was more successful in the colder months when ice and snow covered the water and improved anaerobic conditions inside the BCR. Thus, addition of a more impermeable cover may improve performance throughout the year.

ACKNOWLEDGEMENTS

Genome British Columbia, the Natural Sciences and Engineering Research Council of Canada, Imperial Metals and Teck are acknowledged for providing funding for this work. Mine personnel are thanked for their assistance with the fieldwork and sampling.

ABSTRACT

Mining and metallurgical industries are critical to world's economy; however, their socio-environmental impacts are not negligible. Often, they have to deal with acid mine drainage (AMD), which is generated by sulfide oxidation in waste following the prolonged exposure to oxygen and water, if neutralizing minerals are insufficient. The AMD is characterized by low pH and high concentrations of dissolved metals and sulfates.

Environmental impacts of AMD can be minimized by passive treatment systems such as constructed wetlands (CWs). They represent an interesting approach, from technological, economic, environmental and regulatory points of view, for the efficient treatment of AMD impacted waters.

Wetlands have the capacity to increase pH and alkalinity, to remove dissolved iron and other metals, and to reduce sulfate concentration in AMD. Water treatment is accomplished by various physical (e.g. sedimentation, flocculation), chemical (e.g. sorption) and biological processes (e.g. sulfate reduction, phytoextration) acting independently, in some cases, or interactively, in others. However, cold climate could be challenging for CWs efficiency.

For the purpose of the present study, small-scale laboratory tests using cattail (*Typha latifolia*) were designed and carried out in 0.2 m^2 reactors filled with reactive mixtures, including substrates. The AMD, pH 4.2, contained an average 38.0 mg/L Fe, 2.6 mg/L Mn, 0.4 mg/L Ni, and 9.0 mg/L Zn, at pH 4.2. The AMD flow rate is 1.5ml/min.

CWs efficiency was evaluated during a 3 months period. Water chemistry analysis, as well as sequential extraction procedure (SEP) and microwave digestion of solids and plants were performed. Removal efficiency of Fe and Zn after treatment was up to 99%, at neutral pH. However, the removal of Mn and Ni, as well as of sulfate was negligible. The results of SEP performed on solids proved to be efficient tools for assessing metal fractionation and their potential mobility.

Keywords: Constructed wetlands (CWs), acid mine drainage (AMD), metal fractionation.

INTRODUCTION

Acid mine drainage (AMD) is one of the most significant environmental challenges faced by the mining industry worldwide. Its low pH and the high concentrations of dissolved metals and sulfates can severely impact surface and ground water making it harmful to human and aquatic life (Champagne *et al.*, 2005). AMD is formed by a series of complex biogeochemical reactions that occur when sulfide minerals are oxidized in the presence of water and oxygen to form acidic, sulfate- and metal-rich drainage (Neculita *et al.*, 2008; Genty, 2012). Passive systems, such as constructed wetlands (CWs), represent an interesting approach for the efficient treatment polishing of AMD. The CWs for secondary treatment of effluent are engineered systems specially designed to employ natural processes (vegetation, soil, and microbial activity), in order to treat the AMD (Vymazal, 2010). These systems are low-cost and low-maintenance, and are capable of removing heavy metals, nutrients, organic matters, and micropollutants (Neculita et al., 2007; Rötting *et al.*, 2008; Yeh, 2009;). The CWs increase pH and alkalinity, remove the dissolved metals, and reduce sulfate concentration in AMD.

Water treatment is accomplished by a variety of physical (sedimentation, flocculation), chemical (oxidation, hydrolysis, reduction) and biological (sulfate reduction, phytoextration) processes acting independently, in some cases, or interactively, in others (Matagi *et al.*, 1998; Stottmeimeister *et al.*, 2003). However, the mechanisms governing the removal of metals (plants versus reactive mixture) are not well understood, hence the need to elucidate these processes in order to ensure treatment effectiveness and system sustainability (Stottmeimeister *et al.*, 2003). In CWs, metals could exist in various particulate or dissolved forms (which can absorb onto particles), as complexes with inorganic and organic ligands or as free ions in water (Yeh et *al.*, 2009). The toxicity of a given trace metal is largely controlled by its speciation, thus evaluation of metal partitioning (operational speciation), as well as the becoming and availability under conditions simulating natural processes (e.g. pH variation, reduction and oxidation) is crucial (Ryan *et al.*, 2008). Sequential extraction procedure (SEP) is an important and widely applied tool for gaining information on potential mobility (hence, potential bioavailability and toxicity) of toxic elements in the environment (Bacon and Davidson, 2008). Basically, the ranking of metal mobility in SEPs is based on their concentrations in the water-soluble and exchangeable fractions, as well as the fractions that are reducible, bound to carbonate, and bound to organic matter or sulfides (Neculita *et al.*, 2008). Assuming that bioavailability of heavy metals decreases with each successive extraction step in the SEP, consistent with the decreasing order of solubility, then the following ranking is obtained: water soluble > exchangeable > carbonate bound > Fe-Mn oxides bound > organic matter/sulfides > residual (Jong and Parry, 2004). In fact, bioavailability is a complex and evolving concept, but has recently been defined as the degree to which chemicals present in the soil may be absorbed or metabolized by a human or ecological receptor or is available for interaction with biological systems (Bacon and Davidson, 2008).

The main objective of this study is to design a CW, which can be used in the polishing step of a multi-units passive system for the treatment of AMD contaminated by Fe, Mn, Ni, and Zn. The evaluation of removal mechanisms and of metal speciation in the reactive mixture and the plants of the CW is also performed. For this purpose, small-scale laboratory tests were carried out. The overall results improved the understanding of the processes governing the treatment and the evaluation of design criteria for a CW. This knowledge would allow the transfer of this technology on active, closed or abandoned mine sites, contaminated by the AMD. The research focuses also on hydrology, effect of plants, substrate or filter media that should not be neglected, since they are key elements, especially in a northern climate such as Abitibi-Témiscamingue.

METHODOLOGY

Bench-scale testing of CWs for AMD treatment

Bench-scale CWs were built in polypropylene (48 x 33 x 33 cm). Two different support media and two configurations (vertical and horizontal flow) were tested. Limestone (up to 20 mm in size) was

placed on the bottom of the vertical flow cells and was covered then with a mixture of gravel (8-16 mm) and peat, whereas free surface flow cells were filled with a mixture of sandy soil (0-4 mm), cattle manure, peat and granular dolomitic limestone. Once filled with the reactive mixture, 45 five month old *Typha latifolia* (cattail) were planted in tested wetland modules at a density of 2,84/m^2.

In parallel, unplanted CWs (control) were also set-up. The testing was carried out for a 3-month period (July to October, 2013).

Tap water was added to the plants for 3 weeks, before starting the artificial AMD feed. Continuous flow of AMD was then applied to the CWs, at a flow rate of 1.5ml/min, for a 5-day retention time. The artificial AMD, at pH 4.2, was constituted with Fe, Mn, Ni and Zn sulfates salts, at average concentrations of 38.1, 2.6, 0.4 et 9 mg/l, respectively.

Water sampling and analysis

Influent and effluent samples were collected from each wetland daily for the 3 months duration. The following parameters were measured in the laboratory: pH, redox potential (Eh) and sulfate. For the dissolved metal analysis, 10 ml of filtered samples were preserved using 2 % (by volume) of 70 % nitric acid and then analyzed (ICP-AES type: Vista AX CCO Simultaneous ICP-AES - Palo Alto) with detection limits of 0.39, 0.006, 0.004 and 0.008 mg/l, for Fe, Mn, Ni and Zn, respectively.

Media sampling and analysis

In addition to water samples, solid media from the top (0-5 cm) and middle (15 cm, for vertical-flow only) layers were collected from each CWs, toward the end of the testing. Sediments (solid media) were dried in an oven at 70 ºC and digested (0.200g) via microwave digestion by HNO_3:HCl (7:1) solution for the analysis of total metal concentration. The fractionation of heavy metals was evaluated using the SEP developed by Jong and Parry (2004), which is based on the classical method of Tessier *et al.* (1979). The SEP was performed to evaluate the partitioning of four heavy metals (Fe, Mn, Ni and Zn) into six operationally defined fractions. Dried sediment samples were used for the separation of the following metal fractions: soluble (extracted with water), exchangeable (extracted with 1 M $MgCl_2$, pH 7.0), carbonate bound (extracted with 1 M NaOAc buffered with HOAc, pH 5.0), reducible or bound to Fe–Mn oxides (extracted with 0.04 M NH_2OH-HCl in 25% (v/v) HOAc), oxidable or bound to organic matter (digested by HNO_3, H_2O_2, and 3.2 M NH_4OAc in 20% (HNO_3), and residual fraction (dissolved by acid attack with HNO_3 and HCl).

The SEP was conducted with 1 g of solid accurately weighed in 50 mL polypropylene centrifuge tubes. Between each two extraction steps, the supernatant was separated from the solid-phase residue by centrifugation (Thermo Scientific Sorvall ST-16) at 1000 rpm for 30 min. The supernatant was then carefully removed, filtered through a 0.45 μm filter and preserved in 50 mL vials. The remaining residue was washed twice with 8 mL deionized water, centrifuged for 30 min, and the filtered supernatant mixed with the initial extract and stored at 4°C before analysis for metal concentrations by ICP-AES.

RESULTS AND DISCUSSION

Evolution of pH and sulfate concentration

Results showed the effectiveness of CWs for increasing the pH, all along the 3-month testing period (Fig. 1). The data indicate that there was a significant increase in the pH at the outlet of both configurations. The effluent had, in average, pH of 8.0, for vertical-flow, and pH of 7.6 for surface-flow wetlands. The processes responsible for pH increase were probable (1) the dissolution of carbonate substrate materials, which generate alkalinity and consume protons, and (2) bacterially-mediated sulfate reduction producing carbonate alkalinity in anoxic conditions (Mayes *et al.*, 2009).

As a result, SO_4^{2-} concentration in VSS-flow planted and unplanted and HS-flow CWs halved over the time (292-138; 377-193; 309-146 mg/l), excepting for HS unplanted one (320-301 mg/l). It is reasonable to assume that SO_4^{2-} were released from the substrate material after the start-up (Zagury et al, 2006; Song et al., 2012).

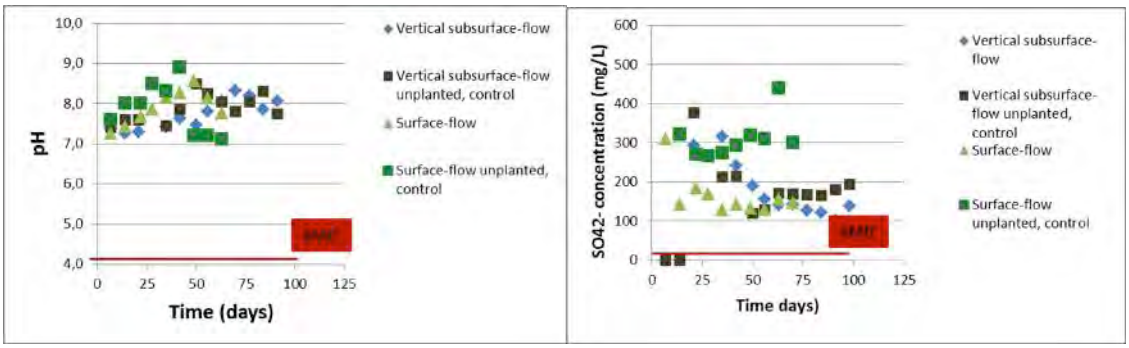

Figure 1 Evolution of pH and sulfate concentration over time in CWs

Metal removal efficiency

Results on bench-scale testing showed that CWs are efficient for Fe and Zn removal in AMD, with values up to 98.6%. The VSS-flow were more efficient than the HS-flow wetlands for contaminant removal (probable due to larger surface of contact), as well as the planted test cells. However, the removal of Mn and Ni was negligible, especially for HS-flow wetlands. Noteworthy, Mn is among the most difficult metals to remove due to the complexity of the interactions governing its solubility (Karathanasis *et al.*, 2009; Song *et al.*, 2012). Kinetics of Mn chemical oxidation are slow, whereas due to the high reduction potential of Mn(IV), parallel reactions, such as organic matter and Fe^{2+} oxidation, induce excessive oxidant consumption. Therefore, iron removal is required prior to manganese oxidation (Sylva *et al.*, 2010).

Table 1 Removal of Fe, Mn, Ni and Zn in AMD by CWs

Wetland design	Removal of metals (%)			
	Fe	Mn	Ni	Zn
Vertical subsurface-flow planted	98.6	75.5	88.5	96.7
Vertical subsurface-flow unplanted	92.7	23.1	46.4	95.7
Horizontal surface-flow planted	89.8	-20.3	58.1	96.3
Horizontal surface-flow unplanted	86.9	-35.2	-6.0	91.2

Fractions that contain most of Fe (5.01-5.04 mg/l) and Zn (1.01-4.43 mg/l) in planted and unplanted subsurface were bound to Fe-Mn oxides, whereas most of the Mn (0.84-0.47 mg/l) and Ni (0.28-0.27 mg/l) were found bound to carbonates. In surface-flow wetlands substrate, Fe was concentrated mostly to Fe-Mn oxides (4.43-3.95 mg/l) and residual fraction (6.57-6-40 mg/l) in planted and unplanted cells respectively, Zn to organic matter and sulfides (0.01-0.01 mg/l), Mn was found bound to carbonates (1.16-0.47 mg/l) and in the residual fraction (0.39-0.39 mg/l) and Ni was essentially found in the residual fraction (0.97-1.31 mg/l). These results indicated that metals were successfully immobilized in the microcosms. However, the availability of heavy metals within sediments can change over time, as a result of changes in redox potential, pH, organic material content (Yeh et al., 2009). Low pH could increase metal solubility, while low redox potential (more reducing conditions) could dissolve iron and manganese oxides, resulting in the mobilization of oxide-sorbed metals. On the contrary, increasing the redox potential (more oxidizing conditions) could mobilize metals by oxidation of metal sulfides (Hodda and Alloway, 1998).

CONCLUSION

The efficiency of bench-scale laboratory CWs was evaluated during a 3-month period for the treatment of AMD contaminated by Fe, Mn, Ni, and Zn. Results showed that the wetland test cells have the capacity to increase pH, to remove Fe and Zn, whereas they proved inefficient for Mn and Ni treatment. However, metals were immobilized in the substrate of CWs. The findings of the study include also the fact that the design and the substrate have no significant influence on the treatment effectiveness in laboratory.

Results from microcosm experiments must be interpreted with care due to edge and container effects but they are especially useful in determining broad patterns and investigating mechanisms. In order to investigate the "patterns" found in this bench-scale study and to understanding the processes governing the treatment of AMD, the overall results will be used to evaluate landscape-scale design criteria.

This knowledge would allow the transfer of this technology on active, closed or abandoned mine sites, contaminated by the AMD.

Stability of metal precipitates and their potential mobility

As mentioned, the SEPs are currently used to assess the geochemical fractionation of metals in soils (Claff *et al.*, 2010). Partitioning patterns of heavy metals in CWs are shown in Table 2.

Table 2 Partitioning of Fe, Mn, Cd, Ni, and Zn in spent reactive mixtures from bench-scale CWs

ABSTRACT

The Campbell Complex (Goldcorp Inc.), located in northwestern Ontario, Canada, has been the site of gold-ore milling operations since 1949. As part of water management measures for the site, an engineered surface-flow wetland was commissioned in 2002 to facilitate final polishing of neutral-pH effluents prior to discharge. The wetland is 16 ha in area, accommodates flows of ~10,000 m^3/day, and affords a mean hydraulic retention time (HRT) of 6-7 days. Vegetation consists predominantly of transplanted cattails (*Typha spp*.) with substrates comprised of inert mining waste-rock overlaid by organic topsoil containing *Typha* rootstock and native flora. The system operates during the ice-free period only (May through October), and serves as the final point of discharge for the mine. The wetland serves as a net sink for ammonia (NH_3), cyanide (CN), arsenic (As) and copper (Cu). Over the period 2011-2013, NH_3-N showed a pronounced decrease in concentration through the wetland, from a mean influent value of ~11 mg/L to a mean of 1.2 mg/L in the wetland discharge (overall reduction of 89% by mass). Over the same period, CN exhibited a mean loading reduction of 78%, with average influent and effluent concentrations of 0.14 mg/L and 0.07 mg/L respectively. Arsenic (primarily as dissolved species) showed a mean loading reduction of 56%, with concentrations being reduced from approximately 0.09 to 0.04 mg/L through the wetland system. Cu loading reductions averaged 33% (2011-2013), with values decreasing from a mean influent concentration of 0.01 mg/L to an outflow mean of 0.007 mg/L. In contrast to Cu and As, Ni shows evidence of remobilization within the wetland complex, with concentrations in the outflow (mean = 0.065 mg/L) exceeding those at the inflow (2011-2013 mean = 0.047 mg/L). Factors likely to contribute to variations in wetland performance include seasonal changes in HRT, redox-controlled processes, metal-CN complexation, and temporal variability in influent chemistry. Overall, the data demonstrate that constructed wetlands can be used effectively for the treatment of gold-mill effluents in cold-interior climates. This is particularly relevant for mine sites that have sufficient water storage capacity upstream of the wetland to allow for seasonal treatment during the warmer months when wetland performance is maximized.

Keywords: bioremediation, *Typha*, ammonia, arsenic, copper

INTRODUCTION

The use of bioremediation in the form of constructed wetlands for the treatment of mine-influenced wastewater has been widely used since the 1980's (Hammer, 1992). The potential utility and performance of constructed wetlands depend on several factors, including climate, the parameters of interest, parameter concentrations, vegetation type, wetland substrate, and the physical characteristics of the wetland itself, such as surface area, water depth, and hydraulic retention time (HRT). The following paper examines a surface flow constructed wetland in northwestern Ontario, Canada, designed for the bioremediation of effluents at an operating gold mine. This study specifically examines the data for the 2011, 2012, and 2013 treatment seasons, which extend from May to October in each year. The primary objectives of this paper are to: (a) quantify the magnitude of contaminant removal, (b) delineate the biogeochemical controls governing contaminant removal within the wetland complex, and (c), provide a general prognosis for the use of wetlands for the treatment of gold mill effluents in cold-interior climates.

SITE SETTING

The Campbell Complex (51º03'43"N and 93º44'40"W) comprises part of Goldcorp's Red Lake Gold Mines, and is located in Balmertown, Ontario, 7 km northeast of the town of Red Lake. The mine has been in continuous operation since 1949, following discovery of the deposit in the 1940's gold rush in the region. The project is located within the cold-interior region of North America, with mean monthly temperatures ranging from -19.3°C (January) to 18.3°C (July) (annual daily temperature of 0.9°C). The site receives an average of 644 mm of precipitation per year, with rainfall accounting for approximately 73% of the total. Snow cover generally persists from November until late March.

Ores are processed using a combination of grinding, flotation, pressure oxidation and carbon-in-pulp processing. Tailings slurry is sent to an SO_2/Air treatment circuit for CN destruction prior to discharge to the Main Pond. From the Main Pond, water is recycled back to the process plant and treated with lime to further precipitate dissolved metals. The treated effluent is then conveyed to the Settling/Polishing Ponds which afford 750,000 m^3 of storage for the polishing of treated effluent from the Main Pond. During warmer months (May through October) this polished effluent is conveyed to a 16 ha constructed wetland, which allows for further removal of NH_3, CN and trace elements. The wetland complex is divided into 34 cells, separated by internal dykes to maximize the length of the flow path and water retention time. All cells host transplanted cattails (*Typha spp*.) in a substrate composed of inert waste rock overlain by *Typha* rootstock, organic matter, and soil/loam. Water depths range from 15 to 70 cm (mean ≅ 45 cm). A mean flow of 10,000 m^3/day, a total surface area of 16 ha, and a mean water depth of 45 cm, translate to a HRT of ~7 days.

Effluents from the Polishing Pond are conveyed to two distinct inputs to the wetland (WET-IN and WET-IN2). These flows are treated in parallel wetland circuits, with the flows merging prior to discharge to Balmer Lake. The discharge from the wetland to Balmer Lake (WET-OUT) serves as the final point of discharge for the mine, and where Ontario compliance standards apply with regards to water quality and toxicity. The system of water management and storage upstream of the wetland facilitates the removal of total suspended sediments (TSS) prior to entry into the wetland (TSS <3 mg/L in wetland inflow). Accordingly, the performance of the wetland relies solely on processes

that remove dissolved species from solution. Inflows to the wetland are circumneutral in pH (6<pH<7).

METHODOLOGY

This study focuses on the treatment seasons of 2011, 2012 and 2013. These years correspond to the period of maximum wetland area (expanded to 16 ha in early 2011) and implementation of a new SO_2/Air treatment system (commissioned in late 2010). The latter had a significant effect in reducing the concentrations of CN and trace metals in inflows to the wetland complex. The 2011 and 2013 treatment seasons extended from late May to the end of October in each year. A shorter treatment season was implemented in 2012 (May through August).

This paper focuses on parameters (NH_3, CN, As, Cu, and Ni) although other parameters were examined to elucidate contaminant behaviour (*e.g.*, Fe, Mn, Se and U). Temporal resolution of the data varies by location and parameter. At WET-OUT, samples of all five major parameters as well as sulfate, were collected three times per week through the treatment period. In contrast, influent data (WET-IN) were collected once per week for NH_3, As, Cu, Fe, and Ni, and once per month for CN and sulfate. Flows are measured continuously at WET-OUT using an OCM III Ultrasonic flow meter. For loading calculations, inflow rates to the wetland were assumed to be equal to those at WET-OUT. Specifically, the influences of precipitation and evapotranspiration were assumed to be negligible given the magnitude of flow through the wetland system. HRT was calculated based on wetland dimensions and flow, and supported with analysis of lag times inferred from the timing of water quality changes between WET-IN and WET-OUT.

To provide additional insight in the role of redox controls within the wetland, high-resolution vertical profiles of dissolved oxygen (DO), temperature, pH, ORP and conductivity were collected from 7 locations within the wetland (July 2014). At these same 7 sites surface (0-3 cm) sediments were collected and analyzed for grain size, organic carbon, major elements and minor elements.

RESULTS AND DISCUSSION

Hydrology and Retention Time

Mean daily flow rates through the wetland for 2011, 2012 and 2013 were 11,200 m^3/day, 10,600 m^3/day and 7,200 m^3/day (Figure 1), translating to total volumes of 1.9 million m^3, 1.1 million m^3, and 1.1 million m^3, respectively. Wetland HRT typically varied between 6-7 days depending on the discharge rate from the Polishing Pond, with an overall 2011-2013 mean of 6.4 days. Estimates of HRT are supported by lag times observed between WET-IN and WET-OUT for changes in concentration of conservative parameters such as sulfate.

Water Quality

Ammonia

NH_3 originates from the degradation of CN compounds (*e.g.*, cyanate hydrolysis) as well as from the leaching of residual blasting residues used in underground mining. Influent concentrations of NH_3-N were variable, with values typically ranging between 10 and 15 mg/L (Figure 2). Concentrations at WET-OUT were greatly reduced compared to WET-IN, with the majority of

values in 2012 and 2013 being <0.5 mg/L. Removal rates ranged from 60 to 1,200 mgN/m²/day (2011-2013 mean = 482 mgN/m²/day), with mass removal showing a general decrease from 2011 to 2013 (overall mass removal efficiency of 89%)

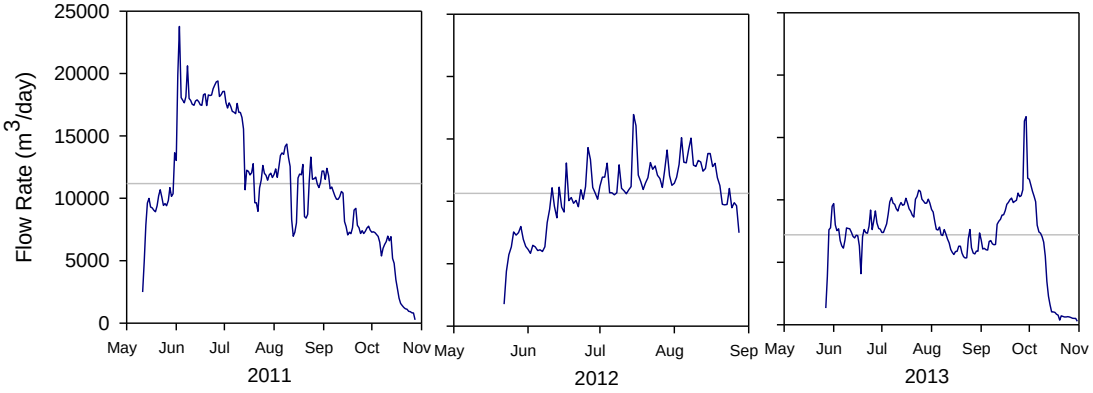

Figure 1 Daily flow rates (measured at WET-OUT) for the 2011, 2012 and 2013 wetland treatment periods.

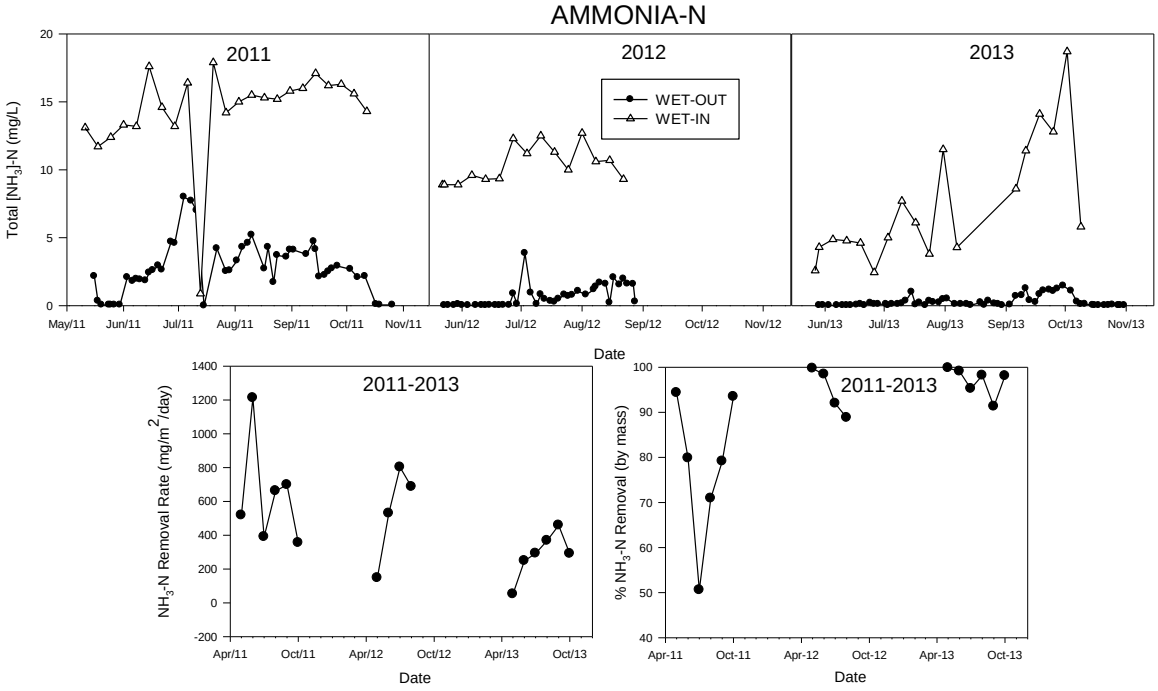

Figure 2 (Top) Time-series of NH_3-N concentration in the influent (WET-IN) and effluent (WET-OUT) of the wetland complex (May to October of 2011, 2012, and 2013). (Bottom left) Wetland removal rate for NH_3-N as monthly means for May to October of 2011, 2012, and 2013. (Bottom right) NH_3-N percent removal efficiency (by mass) as monthly means for May to October of 2011, 2012, and 2013.

(Figure 2). The decrease in removal rate from 2011-2013 is largely due to the general decline in influent NH_3 concentration over the study period. In contrast, removal efficiency generally increased over time, with % removal in 2013 ranging from 91 to 99% (Figure 2). Mechanisms of NH_3 removal include biological uptake (macrophytes, algae), adsorption to substrates and microbially-mediated nitrification (oxidation to nitrate). At the influent pH range (6<pH<7)

ammonia will be predominantly present as ammonium (NH_4^+); therefore, volatilization of $NH_3(g)$ is not predicted to be significant (Reddy and Patrick, 1984).

Wetland removal efficiency for NH_3 was seasonal, with maximum efficiency observed at the beginning of the treatment season, and efficiency decreasing to minima in July/August. Comparison of removal efficiency (by mass) as a function of HRT suggests NH_3 percent removal is dependent on flow rate to some degree (Figure 3). Specifically, NH_3 removal efficiency shows an asymptotic relationship with HRT, whereby the two parameters show a positive correlation up to a HRT value of 10 days, beyond which removal efficiency does not improve. The decrease in removal efficiency during the warmer months may also be linked to the remobilization of NH_3 associated with the degradation of organic matter within the wetland, which is expected to be at a maximum during the warmer period. Increased temperatures and rates of organic matter decomposition are also more likely to sustain low oxygen conditions in the water column, which are more conducive to the persistence of NH_3. Indeed, dissolved oxygen (DO) measurements in the wetland at the end of July 2014 revealed zones of low DO, with values as low as 1 mg/L at some locations. Dunne *et al*. (2013) also showed that releases of NH_3 were greatest during warm periods, and liked this to anoxia in the water column due to increased temperatures and rates of organic matter decomposition.

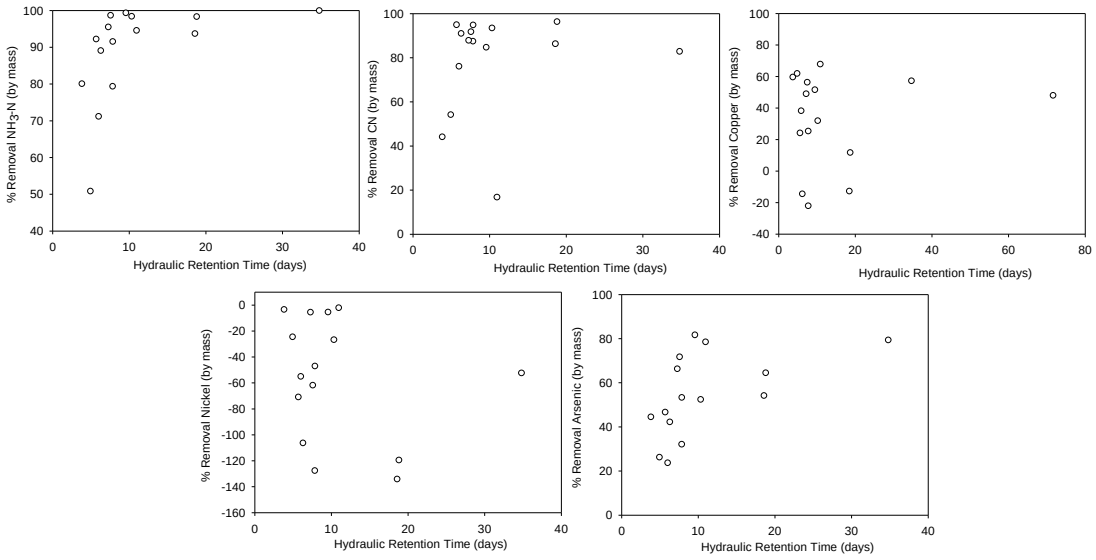

Figure 3 Wetland removal rates for NH_3-N, CN, Cu, Ni and As (as monthly means) as a function of hydraulic retention time (monthly means) for the period 2011-2013.

Cyanide

CN originates from the use NaCN in gold extraction during ore processing. Treatment using SO_2/Air methods reduced CN to values well below compliance limits prior to entry into the wetland. Values for total CN in the wetland inflow were low and variable (0.02 to 0.1 mg/L) (Figure 4). CN levels were reduced through the wetland system, with most values at WET-OUT in 2012 and 2013 being <0.01 mg/L. Such concentration reductions equate to a mean removal rate of 2.8 mg/m^2/day (range from 0.2 to 6.4 mg/m^2/day). Rates of CN removal are variable (17 to 95%; 2011-2013 mean = 78%), and increase over the course of each treatment season in 2011, 2012 and 2013 (Figure 4). For 2012 and 2013, the increases over time in removal efficiency can be explained by the

progressively increasing CN values at WET-IN in combination with the low and invariant values at WET-OUT. Similar to NH_3, CN removal efficiency shows a weakly-positive relationship to HRT (Figure 3), suggesting flow rate also affects CN removal efficiency.

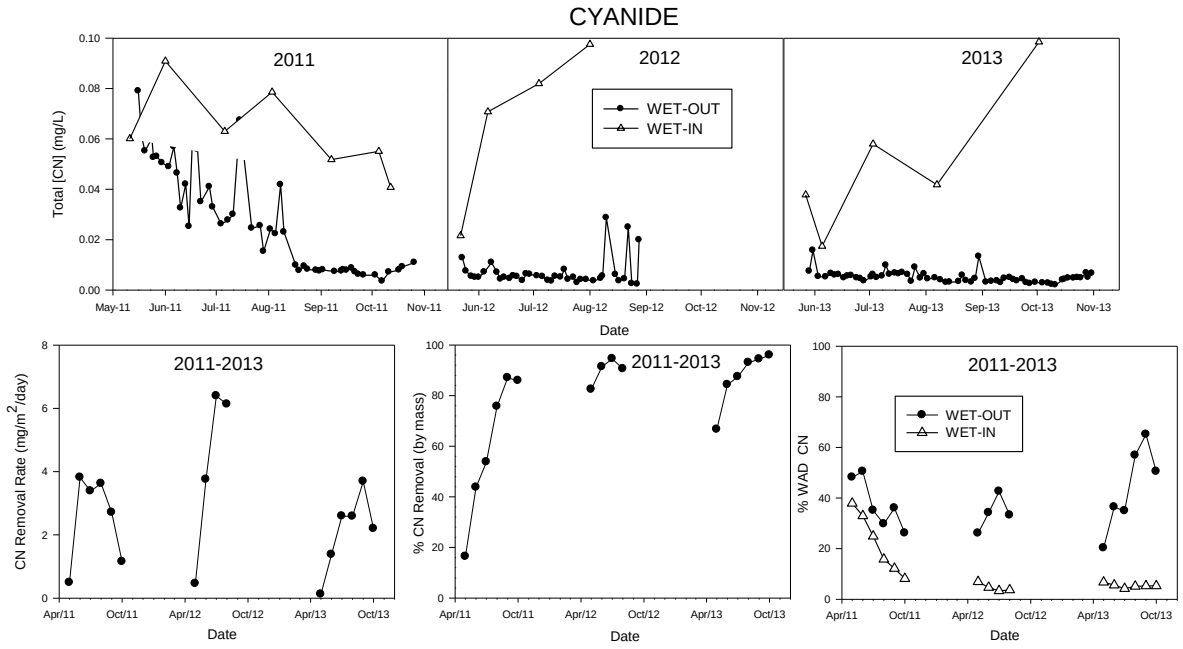

Figure 4 (Top) Time-series of total CN concentration in the influent (WET-IN) and effluent (WET-OUT) of the wetland complex (May to October of 2011, 2012, and 2013). (Bottom left) Wetland removal rate for total CN as monthly means for May to October of 2011, 2012, and 2013. (Bottom centre) CN percent removal efficiency (by mass) as monthly means for May to October of 2011, 2012, and 2013. (Bottom right) Ratio of WAD CN to Total CN in influent (WET-IN) and effluent (WET-OUT) as monthly means for May to October of 2011, 2012, and 2013.

Mechanisms for CN removal in wetland systems may include volatilization of HCN, UV-catalyzed oxidation, hydrolysis to NH_3 and precipitation of insoluble metal-CN complexes (Gasper and Beck, 1983). Insight into CN behaviour can also be garnered from the proportion of weak-acid-dissociable (WAD) CN in the wetland inflow and outflow (Figure 4). Specifically, in both 2012 and 2013, the %WAD-CN at WET-OUT increases during each treatment season, while the %WAD-CN in the inflow remains constant. These data indicate that either: 1) strong acid dissociable CN compounds (*e.g.*, ferri/ferro CN complexes) are preferentially removed within the wetland complex; and/or 2) WAD-CN complexes are increasingly remobilized into solution over the treatment period. These considerations also have relevance to the interpretation of Ni and Cu behaviour (discussed below).

Copper

Total Cu concentrations in the wetland inflow were variable, ranging from 0.001 to 0.022 mg/L (mean = 0.011 mg/L) (Figure 5). Over the course of each treatment season, inflow Cu concentration generally declined, which reflects processes occurring upstream in the tailings management area (TMA). Concentrations of Cu were significantly reduced by the wetland, with a mean outflow value of

0.0065 mg/L (range of 0.001 to 0.02 mg/L) (Figure 5). Cu removal rates range from -0.12 to 1.5 mg/m²/day.

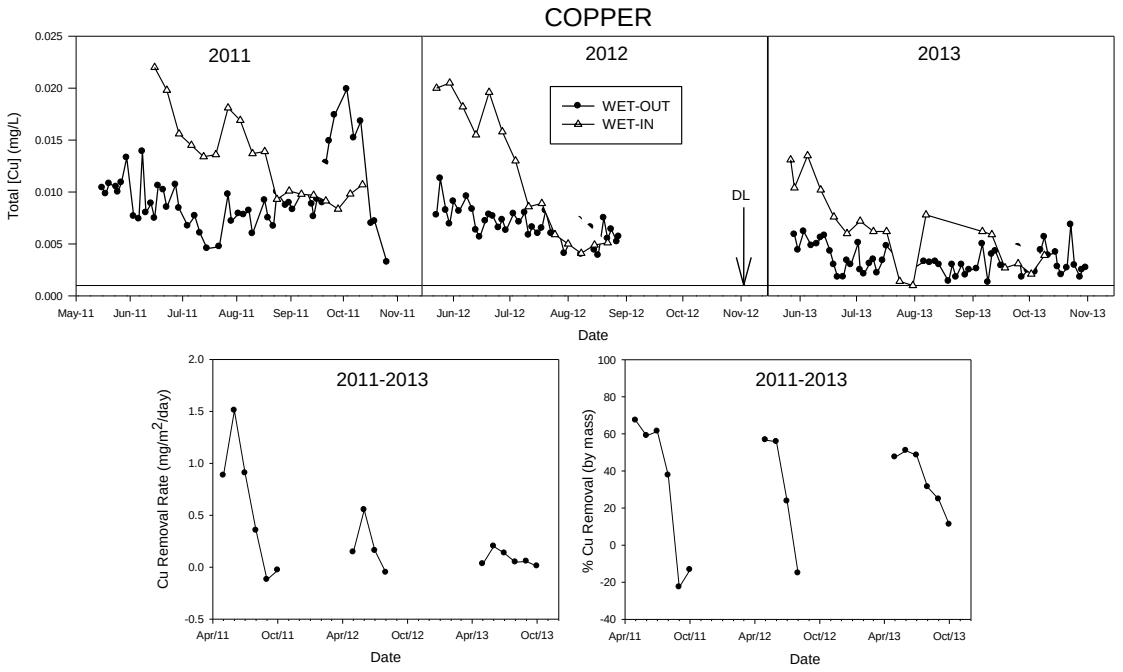

Figure 5 (Top) Time-series of total Cu concentration in the influent (WET-IN) and effluent (WET-OUT) of the wetland complex (May to October of 2011, 2012, and 2013) DL = detection limit (0.002mg/L). (Bottom left) Wetland removal rate for total Cu as monthly means for May to October of 2011, 2012, and 2013. (Bottom right) Total Cu percent removal efficiency (by mass) as monthly means for May to October of 2011, 2012, and 2013.

Removal rates declined over the course of each treatment season (May – October), possibly related to the decreases that occurred to inflow concentration (*i.e.*, decreased removal efficiency with decreasing influent concentration). Cu removal efficiency ranged between -23% to 68% (mean = 33%), indicating that in some months, the wetland served as a source of Cu rather than a sink (Figure 5). Cu removal efficiency was weakly proportional to HRT, suggesting flow rate is not a dominant variable with respect to percent removal (Figure 3).

Possible sinks for Cu in wetland systems include adsorption (*e.g.*, Fe oxides, organic matter, clays), biological uptake (bacteria, algae, biofilms, macrophytes), and precipitation as secondary phases (*e.g.*, Cu sulfides) (Sobolewski, 1999). As a means to assess the nature of Cu removal, elemental data for the near-surface substrates were examined. Cu concentrations in surface sediments were variable, and ranged from 17 to 504 mg/kg (mean = 136 mg/kg) (Figure 6). Most values greatly exceeded the local background (22 mg/kg) for sediments collected in a nearby reference wetland, demonstrating that the sediments are serving as a pronounced sink for Cu. Sedimentary Cu showed strong correlations (r^2>0.7) with parameters indicative of organic matter enrichment, including T-N and TOC (Table 1). Cu also shows strong correlations with parameters that preferentially accumulate in reducing sediments, including S and Se. In particular, the observation of Se enrichment in zones of high organic carbon provide strong evidence to indicate redox controls are important, given the tendency of dissolved Se to accumulate in organic-rich reducing sediments (Martin *et al.*, 2011). This is also supported by observations of low DO values in the wetland water

column (as low as 1 mg/L in some locations). Overall, the data suggest that Cu accumulation in sediments is in part tied to sedimentary organic matter abundance, which may reflect Cu uptake by macrophytes/algae and/or precipitation of Cu as secondary sulfides.

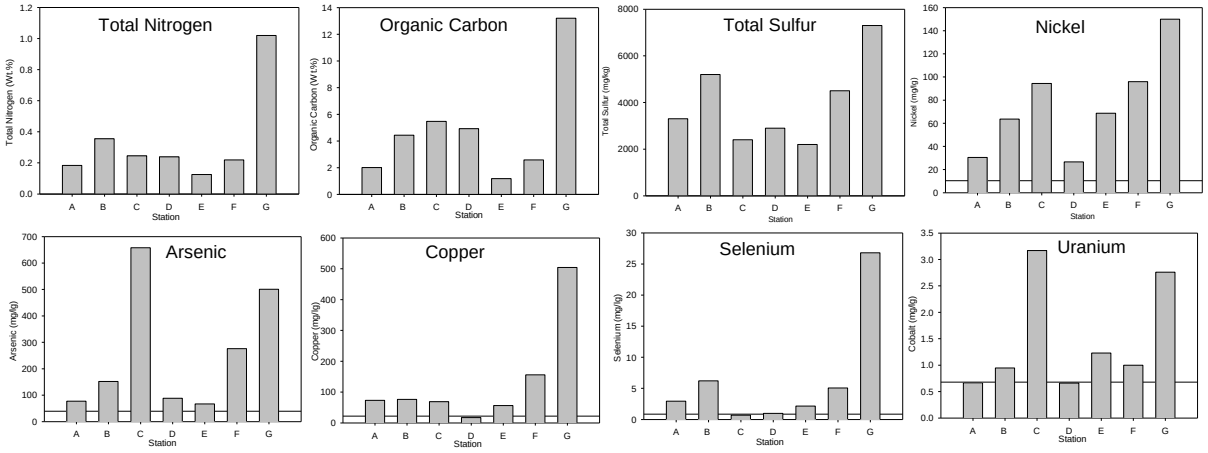

Figure 6 Solid-phase concentrations of total nitrogen, organic carbon, total sulfur and select trace elements (Ni, As, Cu, Se and U) in the upper 3 cm of wetland substrate at seven locations in the wetland complex. Horizontal lines for trace elements represent background values for a control wetland in the local area.

Table 1 Coefficients of determination (r^2) for correlations between total nitrogen (T-N), total organic carbon (TOC), sulfur (S) and select trace elements (As, Cu, Fe, Mn, Ni, Se and U) in the upper 3 cm of wetland sediments (n=7). R^2 values >0.7 are shaded.

Parameter	T-N	TOC	As	Cu	Fe	Mn	Ni	Se	S	U

Nickel

Ni concentrations in the inflow to the wetland showed a strong decline during the 2011-2012 period, from approximately 0.17 mg/L (June 2011) to 0.02 mg/L (August 2012), after which time values remained relatively invariant (Figure 7). This decrease in Ni may in part reflect implementation of a new SO_2/Air CN destruction circuit at the end of 2010, which would be expected to lower Ni solubility in response to reducing the potential for CN-Ni complexation. In contrast to Cu, Ni concentrations at the outflow are consistently higher than those at the inflow, demonstrating that the wetland behaved as a net source for Ni during 2011, 2012, and 2013 (Figure

7). Mean loading to the outflow was 0.9 mg/m²/day (2011-2013), translating to a mean increase of 54% (by mass) over the same period (Figure 7).

The source of Ni within the wetland complex is not clear. Possible reasons include the leaching of Ni from Ni-bearing waste rock used in wetland construction, or more likely, the remobilization of Ni through desorption processes. With respect to the latter, the remobilization of Ni through CN complexation may play a role. As described in the discussion of CN, the removal of CN appears to be linked to the preferential removal/destruction of strong-acid-dissociable species (*e.g.*, Fe-CN). This process may allow for secondary complexation of liberated CN- with other trace elements (*e.g.*, Ni) within the wetland complex. The strong correlation between Ni and Cu removal efficiencies (Figure 7, bottom right) implies that similar factors may apply to Cu.

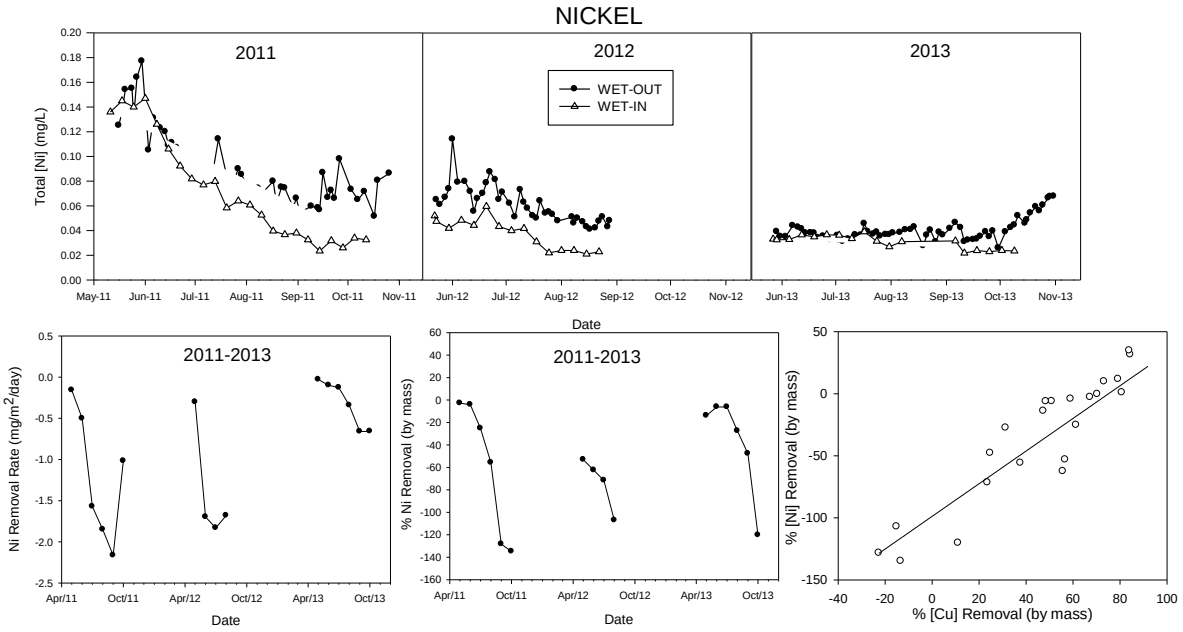

Figure 7 (Top) Time-series of total Ni concentration in the influent (WET-IN) and effluent (WET-OUT) of the wetland complex (May to October of 2011, 2012, and 2013). (Bottom left) Wetland removal rate for total Ni as monthly means for May to October of 2011, 2012, and 2013. (Bottom centre) Total Ni percent removal efficiency (by mass) as monthly means for May to October of 2011, 2012, and 2013. (Bottom right) Relationship between Ni and Cu percent removal efficiencies (regression of monthly means for period 2011-2013).

Alternatively, the remobilization of Ni from within the wetland complex may be related to the decline in Ni influent values during 2011-2012, which was likely the result of improved CN treatment upstream. Specifically, the pronounced decline in Ni concentrations in the wetland inflow may have promoted desorption of Ni from binding sites on particle/organic surfaces. Metal concentrations in solution that are governed by sorption reactions can be described in terms of a distribution coefficient (K_d) (Tessier, 1989), which is the ratio of sorbed metal concentration (expressed in mg metal per kg sorbent) to the dissolved metal concentration (expressed in mg/L) at equilibrium (Equation 1).

$$\square_{\square} = \frac{\square\square\square\square\square\square\ \square\square\square\square\square\ \square\square\square\square\square\square\square\square\square\square\square\square\ (\square\square/\square\square)}{\square\square\square\square\square\square\square\square\square\ \square\square\square\square\square\ \square\square\square\square\square\square\square\square\square\square\square\square\ (\square\square/\square)} \qquad \text{(Equation 1)}$$

According to this equation, if the dissolved metal concentration decreases, the sorbed concentration must also decrease to maintain a constant K_d value. This mechanism, which relies on the assumption of adsorptive equilibrium, provides a possible explanation of the remobilization of Ni from the wetland complex.

Arsenic

In the wetland inflow, As concentration consistently declined between June and October in each of 2011, 2012 and 2013, with values ranging from 0.43 to 0.16 mg/L (mean = 0.095 mg/L) (Figure 8). The decrease in As concentration in the wetland influent within each season likely relates to seasonal redox-related processes in the TMA upstream. Arsenic values were consistently lower at the wetland outflow (mean = 0.039 mg/L), indicating that the wetland served as a sink for dissolved As. Mean monthly As removal rates ranged from 0.6 to 6.9 mg/m2/day (mean = 2.3 mg/m2/day), translating to a mean removal efficiency of 56%. Arsenic removal efficiency showed a positive correlation with HRT (Figure 3), suggesting flow rate affected wetland performance to some degree. Within each treatment year, removal efficiency showed a seasonal decline to minima typically occurring in July or August. Removal efficiency increased late in the season (September) despite the influent concentration continuing to decrease. Such behaviour may relate to redox-controlled processes in the wetland. Specifically, higher rates of Fe-oxide reductive dissolution may be expected during the peak summer period, when rates of bacterially-mediated organic matter oxidation are at a seasonal maximum. This, combined with lower DO values in the water column, may promote the recycling of As into surface waters (Martin and Pedersen, 2002).

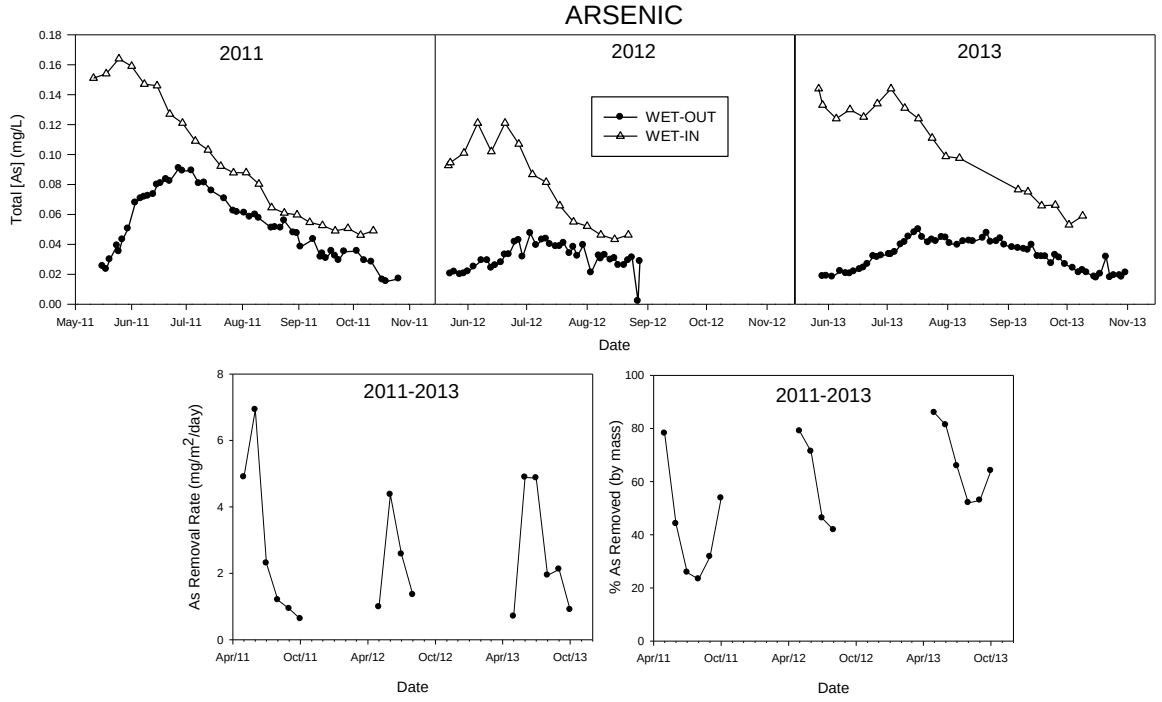

Figure 8 (Top) Time-series of total As concentration in the influent (WET-IN) and effluent (WET-OUT) of the wetland complex (May to October of 2011, 2012, and 2013). (Bottom left) Wetland removal rates for total As as monthly means for May to October of 2011, 2012, and 2013. (Bottom right) Total As percent removal efficiency (by mass) as monthly means for May to October of 2011, 2012, and 2013.

Arsenic showed significant solid-phase enrichment over background values in reference wetland substrates, indicating that the sediments are serving as a sink for As. Possible accumulation pathways include sorption to Fe/Mn oxides, adsorption of arsenite (As^{+3}) to particles, and precipitation of secondary As sulfides. Correlations of As with Fe (r^2=0.31) and Mn (r^2=0.38) are relevant, and suggest some degree of As adsorption with Fe and/or Mn oxides (Table 1). In contrast, As was poorly correlated with S (r^2=0.08), suggesting secondary As-sulfide formation is not a dominant accumulation pathway. Interestingly, As showed the strongest relationship with U (r^2=0.89) (Table 1). Like As, U is redox sensitive and tends to accumulate as discrete U phases in anoxic sediments (Lovely *et al*., 1991). The strong link of As to U, and weak correlations of As with S, Fe and Mn, may suggest that As adsorption as arsenite (*e.g*., to clays and/or organics) may play a significant role in governing As uptake within the wetland complex.

CONCLUSIONS

The results of this study demonstrate the successful utility of constructed wetlands for the treatment of neutral-pH gold mill effluents in cold interior climates, with parameters including NH_3, CN, Cu and As showing robust removal efficiencies. The data suggest that contaminant removal relates to a combination of biological uptake as well as redox-related processes that result in the sequestration of trace elements under conditions of suboxia. The successful application of wetland treatment at the Campbell Complex is strongly tied to the water management system, which facilitiates sufficient storage within the TMA to allow all mine waters to be discharged through the wetland during the ice-free period (May through end of October). The data also illustrate the effect of several processes that can influence wetland performance on seasonal and inter-annual scales, including changes to influent composition, variability in HRT, and biogeochemical processes that may promote contaminant remobilization.

Passive Removal of Iron from AMD Using VFRs

ABSTRACT

This paper presents data on treatment trials of three low pH mine waters and one circumneutal mine water in the UK and New Zealand using Vertical Flow Reactors (VFRs) - mine water treatment systems where mine water is directed through an unreactive gravel bed to encourage metal removal under aerobic conditions. Previous VFR studies have demonstrated their efficacy at iron removal at circumneutral pH; this study demonstrates that significant removal of iron (as high as 85%) can be achieved at low pH (~3), within a practicable treatment area using the VFR system. The iron removal rate varies between the four study sites. The difference is attributed to the mechanism of removal which is suspected to be the agglomeration and filtration of nanoparticulate colloidal-sized ferric iron precipitates in addition to microbial Fe(II) oxidation and heterogeneous precipitation. The use of VFRs represents an inexpensive option for removing the majority of iron from low pH mine water without the requirement for any pH adjustment. The study also confirms the VFR's applicability to iron removal from circumneutral mine water.

Keywords: vertical flow reactors, nanoparticulate iron, filtration

INTRODUCTION

Passive mine water treatment involves a number of physicochemical and microbiological strategies for the removal of dissolved species of concern. Removal of metals is either achieved via harnessing of naturally occurring physicochemical and microbiological processes, for example the manipulation of solubility via changes in pH (e.g. by reaction with limestone) or redox conditions (through contact with organic matter) or through sorption processes. Removal of iron (Fe) is the focus of the present study.

In general, at pH below 9, the divalent Fe(II) species are highly soluble and do not readily form salts or hydroxide precipitates. Fe(III) solubility is such that under oxic conditions numerous Fe(III)-bearing phases precipitate (hereafter termed $Fe(III)_{(s)}$) over the pH spectrum. In acid mine drainage (AMD) environments it is common for the Fe hydroxy-sulfate mineral schwertmannite to form (e.g. Bigham et al, 1996)as well as jarosite-alunite minerals. Ferrihydrite and goethite dominate at higher pH (> 4). It is difficult to predict the exact solubility because of the heterogeneity of mineral products and the corresponding paucity of unanimity in thermodynamic data for Fe in the literature. Fe(II) is meta-stable under acidic oxidizing abiotic conditions due to slow oxidation kinetics but is widely reported to be microbiologically catalyzed (e.g. Kirby et al,1999), with the production of aqueous Fe(III) species or Fe(III) phases depending on the pH.

Iron is often the principal contaminant of concern from coal mine AMD and generally the approach to treatment is to contact the mine water with reagents to raise the pH to circumneutral pH or higher to accelerate Fe(II) oxidation and minimize Fe solubility. The reagents include lime, limestone, caustic soda, slag,. in different configurations depending on whether the treatment is active or passive or semi-passive. In active treatment schemes the resultant particulate Fe(III) will either be removed by polymer dosing and clarification; in passive systems a limestone drain, slag bed or RAPS will be used to raise pH ahead of settling ponds and/or aerobic wetlands which are used to settle and filtrate the suspended particulate Fe(III). In passive systems the rise in pH also accelerates the oxidation of Fe(II) to precipitate $Fe(III)_{(s)}$ and may be augmented by the addition of hydrogen peroxide or other oxidants in semi-passive treatment schemes.

Vertical Flow Reactors

Dey et. al (2003), Sapsford et. al (2008), and Sapsford and Williams (2009) and related publications detail a vertical flow system which operates under aerobic conditions to remove Fe from circumneutral coal mine water by (self)filtration of $Fe(III)_{(s)}$ supported by a gravel support bed and also heterogeneous Fe(II) oxidation and precipitation. This was based on earlier observations in the literature as well as observations from the field concerning the ubiquity of Fe(III) precipitates forming on vertical flow RAPS. There are a number of related publications concerning heterogeneous Fe(II) oxidation harnessed for treatment (e.g. Best and Aikman, 1983, Jarvis and Younger, 2001). Some authors have investigated harnessing low pH microbial Fe(II) oxidation (e.g. Burgos et al, 2004). This paper examines the application of VFRs to AMD. The specific aims of this study are to: (i) present data from field trials of VFRs operating at a low pH abandoned lead (Pb) – zinc (Zn) metal mine site in the UK and two AMD sites and one neutral mine drainage site in New Zealand (South Island), and (ii) to highlight the removal chemistry of iron in these systems.

Study Sites

Cwm Rheidol

The Cwm Rheidol former Pb/Zn mine was operated between 1848 and1917 and is located within the mid-Wales Orefield approximately 12 km east of Aberystwyth north of the river Rheidol. The mine is part of a big mine complex situated just below the village of Ystumteum, on the steep southerly face of the Rheidol Valley which runs ESE to WNW. The AMD issues from two adits. Cwm Rheidol is classified as one of the top 50 polluting metal mines in Wales and put forward as a priority site for remediation in the Metal Mines Strategy for Wales report by Johnston (2004).

Despite this mine complex having been abandoned for almost a century, AMD is still contributing almost half the Zn and Pb loading to the River Rheidol (Edwards and Potter, 2007).

Bellvue Mine

Bellvue Coal Mine is and underground mine located on the West Coast of the South Island of New Zealand approximately 15 km northeast of Greymouth. It operated from 1928 until 1964 and is currently abandoned. The entrance to the mine is on a hillside approximately 100 m above a nearby creek. An AMD water pool at the entrance drains to a cascade which flows down the slope to the creek. The water in the pool is in a reduced state, with the majority of iron as Fe(II) and very low dissolved oxygen (DO) concentrations, and a pH of approximately 2.5. As the AMD flows down the cascade, DO concentrations increase and Fe(II) oxidises to Fe(III) and some Fe hydroxides precipitate. The Fe and aluminum (Al) concentrations are some of the highest recorded at NZ mines.

Active Mine Site with AMD, New Zealand

The second AMD site in New Zealand is an active opencast coal mine. The AMD at the site issues from overburden waste rock dumps and contains relatively high concentrations of Fe, Al, and Mn and low pH.

Active Mine Site with neutral drainage, New Zealand

The neutral drainage site in New Zealand is an underground active coal mine. The neutral drainage issues from an old adit on the site and contains relatively low concentrations of Fe and a neutral pH.

METHODOLOGY

UK VFR

The system (see Figure 1) was adapted from the original design used in initial field trial at the Taff Merthyr site in South Wales (Dey et al, 2003), using a 1 m^3 intermediate bulk container (IBC) adapted to become a VFR treatment tank. A 100 mm gravel bed layer (of unreactive siliceous 5 mm chips), supported by a layer of 30 mm chips of the same material was used in the base of the tank upon which ochre is allowed to accumulate. IBCs have an outlet at the bottom of the tank which has a standard fitting which can be opened and closed manually. Inside the tank, underneath the gravel bed a length of coiled slotted drainage pipe was attached to the outlet valve which allowed the treated water to be collected and directed up through a swan neck outlet. A length of hose was fitted to that outlet valve to act as a swan neck mechanism so that the driving head within the container could be adjusted; the head was set to 200 mm. Monitoring of the influent and effluent mine water was conducted as follows: Samples for total iron (Fe-Tot) including suspended particulate Fe and dissolved Fe were taken directly from the mine water using a disposable Plastipak syringe and stored in a sample bottle and acidified with 0.1 ml of 20% (v/v) HNO_3. Samples for filtered Fe (Fe-Filt) were taken in the same way except that first they were filtered using disposable 0.2 µm syringe filters. These samples were analyzed by ICP-OES. Samples for Fe(II) were either measured in the field using a portable Merck SQ NOVA60 spectrophotometer with appropriate Spectroquant® Fe test cells or acidified with HCl and placed immediately into a dark cool box and stored at 4° C until analysis in the laboratory by the 2'2-bipyridyl solution method using a Hitachi U1900 spectrophotometer. All field pH/DO measurements were taken using Hanna combination meters, calibrated at each site visit. Influent and effluent flow measurements were taken by timing the length of time to fill a measuring cylinder.

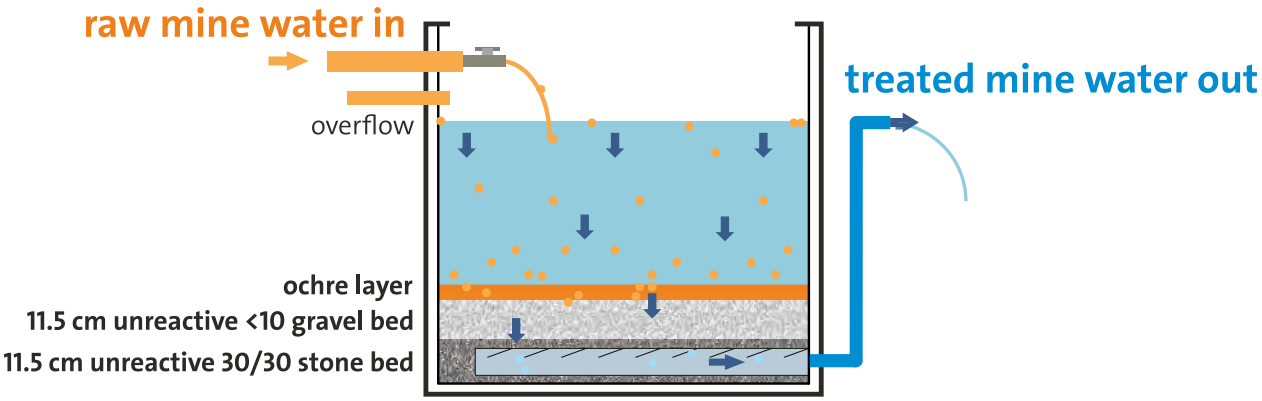

Figure 1 Schematic of Cwm Rheidol VFR

New Zealand VFRs

The systems installed in NZ used the same configuration as the one installed at Cwm Rheidol in the UK. Monitoring of the influent and effluent for the systems was conducted as follows: Samples for total iron (Fe-Tot) including suspended particulate Fe and dissolved Fe were taken directly from the mine water using a disposable Plastipak syringe and stored in a sample bottle and acidified with 0.1 ml of 20% (v/v) HNO_3. Samples for filtered Fe (Fe-Filt) were taken in the same way except that first they were filtered using disposable 0.45 µm syringe filters. These samples were analyzed by ICP-OES. Samples for Fe(II) were measured in the field immediately upon collection using Hach Method 8146 (1,10 Phenanthroline Method) and concentrations determined through absorbance using a Hach DR/2400 Portable Spectrophotometer. All field pH/DO measurements were taken using a portable YSI 556 multi-probe system, calibrated against known standards in the field. Influent and effluent flow measurements were taken by timing the length of time to fill a measuring cylinder.

RESULTS AND DISCUSSION

The results for iron removal are given in Figures 2 – 5. Further explanation of the bar charts presented is required with respect to the meaning of the reported breakdown of iron. Fe-Tot (total iron) is the sum of dissolved iron (both $Fe(II)_{(aq)}$ and $Fe(III)_{(aq)}$) + particulate iron suspended in the water. Fe-Filt (filtered iron) is the concentration of iron in all its forms that has passed a 0.2 μm filter (0.45 μm for New Zealand data) and Fe(II) is the spectrophotometrically determined aqueous Fe(II) concentration. Presented in the stacked format it can be seen what proportion of the total iron exist in each category, and how each form of iron is changing through the VFRs. Images of the VFR beds are given in Figure 6.

UK VFR

The Cwm Rheidol (UK) VFR was monitored 21 times between August 3, 2011 and July 4, 2012; of this data, ,Fe(II) analyses were included 11 times, and so the data set presented here is for these 11 monitoring occasions. For these times the mean data (± Stdv) was as follows: flow rate = 0.34 ± 0.29 L/min; Influent pH = 2.97 ± 0.63; Effluent pH = 2.98 ± 0.67; Influent DO = 7.69 ± 1.34 mg/L; Effluent DO = 6.45 ± 1.39 mg/L. The mean total Fe removal was 70% with a high of 85% and a low of 36%. The mean Fe removal rate was 30 g/m^2/d with a high of 87 g/m^2/d and low of 3.7 g/m^2/d. Iron accumulated on the VFR bed after 11 months of continuous operation is shown in Figure 6 (a).

A summary of the Fe removal (in various forms) is given for the Cwm Rheidol VFR in Figure 2. It can be seen that there is always Fe removal observed in the VFR, but the first thing to note is that removal of particulate Fe > 0.2 μm is not solely responsible for the observed removal of Fe in the system, nor is there a substantial change in pH which would explain Fe removal. Where Fe(II) is

present in the influent it is seen to dramatically decrease on passage through the VFR indicating the presence of active acidophilic Fe(II) oxidizers (this was in fact confirmed by a concurrent microbial study by Prof B Johnson, Bangor University, UK) which probably oxidize Fe(II) and precipitates the resultant Fe(III) as schwertmannite. However, it is interesting to note that on all occasions (except for '1') the decrease in Fe(II) between inlet and outlet is not sufficient to explain the observed decrease in Fe-Filt.

Excluding $Fe(II)_{(aq)}$ which is accounted for analytically, the other species that could be reasonably expected to be present and pass a 0.2 μm filter are $Fe(III)_{(aq)}$ and nanoparticulate $Fe(III)_{(s)}$. The definition of what is truely 'dissolved' and 'particulate' is largely operationally defined, but Waychunas et al (2005) have reported nanoparticles in mine water. The removal of dissolved/nanoparticulate Fe seems to be occurring within the VFR. PHREEQC modelling (not shown) indicates that a range of Fe(III) minerals (including schwertmannite) are oversaturated and able to precipitate. It is possible that the residence time (mean 39 hrs) in the VFR allows time for kinetically constrained hydrolysis of Fe(III) to occur, however, according to Combes et al., (1989) precipitation of Fe can be viewed as Fe(III) phases forming from solution begining as small clusters of octahedral $Fe(O, OH, OH_2)_6$ units that evolve into larger polymeric units with time, eventually reaching colloidal sizes. It is also feasible that heterogeneous nucleation is important in the VFR system.

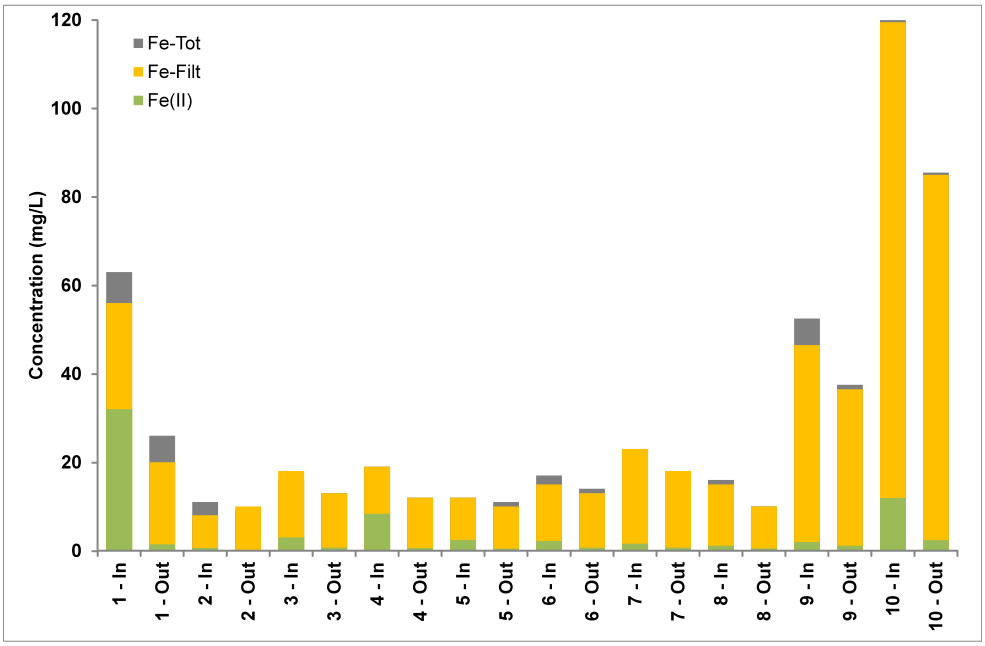

Figure 3 Active mine site with AMD (NZ) iron concentration data for VFR influent (in) and effluent (out) on sampling occasions 1 – 10

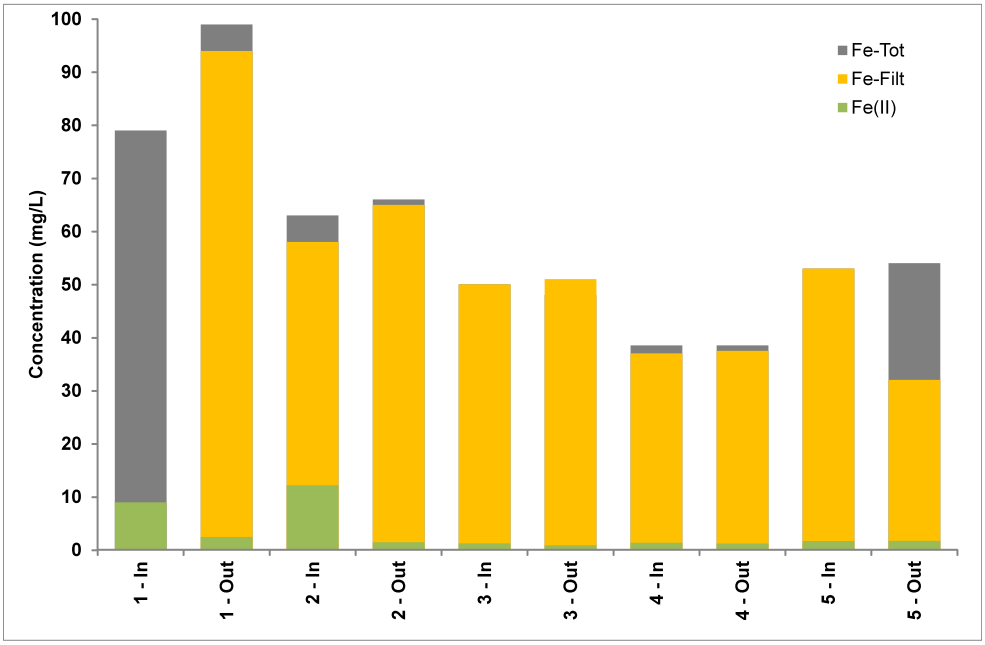

Figure 4 Bellvue (NZ) iron concentration data for VFR influent (in) and effluent (out) on sampling occasions 1 - 11

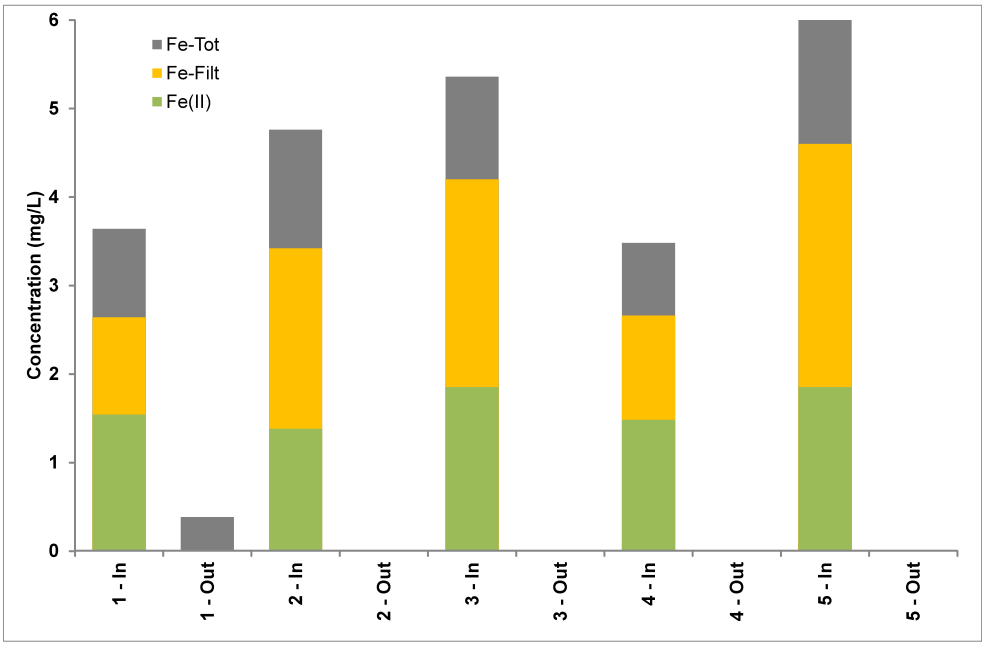

Figure 5 Active mine site with neutral mine drainage (NZ) iron concentration data for VFR influent (in) and effluent (out) on sampling occasions 1 – 10

Regardless of the removal mechanism (which warrants further research) the data show that the VFR is effective at removing a large proportion (70%) of the iron from the discharge. The full mine water discharge at Cwm Rheidol is circa 10 L/s. Based on an average flow of 0.34 L/min going through the 1 m^2 bed of the VFR, a VFR of 1765 m^2 (e.g. dimensions 50 m x 35 m) could remove circa 70% of the iron from the full discharge continuously for at least one year without the need for maintenance.

New Zealand VFRs

Active mine site with AMD

The VFR at the active mine site with AMD was monitored on 10 occasions between April 30, 2014 and September 11, 2014. The mean data (± Stdv) was as follows: flow rate = 0.47 ± 0.06 L/min; Influent pH = 3.19 ± 0.14; Effluent pH = 3.06 ± 0.11; Influent DO = 8.03 ± 0.66 mg/L; Effluent DO = 8.77 ± 0.89 mg/L. The mean total Fe removal was 28% with a high of 59% and a low of 8.3%. The mean Fe removal rate was 8.2 $g/m^2/d$ with a high of 26 $g/m^2/d$ and low of 8.3 $g/m^2/d$. Iron accumulated on the VFR bed after six months of continuous operation is shown in Figure 6 (b).

Despite being a slightly higher pH mine water than Cwm Rheidol in the UK, the Fe removal is consistently less for this VFR, however significant Fe removal is still occurring Figure 3. Fe(II) is generally a small proportion of the influent Fe, meaning that the Fe-Filt is likely either Fe(III)(aq) or nanoparticulate to colloidal $Fe(III)_{(s)}$. As with the Cwm Rheifol VFR, Fe(II) when present is seen to decrease through the VFR indicating the presence of active Fe(II) oxidizing microbes.

Unlike Cwm Rheidol, the decrease in Fe(II) through microbial oxidation and precipitation could explain the overall decrease in Tot-Fe between in and out for many of the observed sampling occasions, but not always, suggesting that there is another mechanism responsible for removing Fe-Filt as was observed at Cwm Rheidol. All of the removal could be accounted for by accumulation of particulate and nanoparticulate Fe(III). The pH at here is higher than at Cwm Rheidol, yet removal is lower suggesting the controls on Fe solubility are slightly different between sites. In summary

despite these differences with Cwm Rheidol the VFR at the New Zealand active mine site with AMD is effective at removing a proportion (28%) of the Fe from the discharge.

Bellvue

The Bellvue VFR was monitored on five occasions between May 7, 2014 and September 2, 2014. The mean data (± Stdv) was as follows: flow rate = 0.46 ± 0.06 L/min; Influent pH = 2.58 ± 0.06; Effluent pH = 2.57 ± 0.03; Influent DO = 8.55 ± 3.22 mg/L; Effluent DO = 9.98 ± 1,07 mg/L. It can be seen from Figure 4 that removal of Fe was not observed in this VFR. Figure 6 (c) shows that after four months of operation the gravel showed no signs of ochre build up (Note 1-In data for Fe-Filt is missing). Interestingly, it can be seen that despite the lack of removal of Fe, Fe(II) decreases across the VFR indicating, as with the other sites, an active Fe(II) oxidizing microbial community, although in this case the resultant Fe(III) is clearly not precipitating in the VFR.

New Zealand active mine site with neutral mine drainage

The VFR at the New Zealand active mine site with neutral mine drainage was monitored on five occasions between June 27, 2014 and September 1, 2014. The mean data (± Stdv) was as follows: flow rate = 0.46 ± 0.05 L/min; Influent pH = 7.46 ± 0.03; Effluent pH = 7.52 ± 0.10; Influent DO = 10.56 ± 0.19 mg/L; Effluent DO = 10.51 ± 0.38 mg/L. The mean total Fe removal was 98% with a high of 100% and a low of 90%. The mean Fe removal rate was 1.2 $g/m^2/d$ with a high of 5.3 $g/m^2/d$ and low of 2.0 $g/m^2/d$. Note that these are seemingly low but actually these are relatively high given the very low Fe concentration.

Overall Fe removal was excellent. Note that the pH is circumneutral and as such, Fe(II) should be rapidly oxidized either homogeneously or heterogeneously within the VFR and particulate Fe(III) removed by filtration/accretion. This observed performance is in line with earlier VFR studies (see references above) conducted at circumneutral pH. It is noteworthy in Figure 5 that Fe(II) ≠ Fe-Filt, despite the circumneutral pH suggesting that colloidal Fe(III) precipitates are passing the filter. On four of the five sampling occasions Fe was removed to below the detection limit of the spectrophotometer. This demonstrates that the VFR can be used to polish Fe levels down to very low levels as a last stage in treatment, and can replace wetlands in this function, which has the commensurate benefits for waste management of the arising ochre.

(c) Bellvue VFR, 4 months operation, note no precipitate in evidence.

Figure 6 Photographs of gravel bed after operation of the VFRs

CONCLUSION

In conclusion, the findings of this study were as follows:

- Where Fe is present as particulate Fe(III) it can be effectively filtered out in a VFR. Even at a low pH of circa pH 3, depending on the phase controlling Fe solubility, significant proportion of Fe can be in particulate form (albeit nanoparticulate) and/or supersaturated and able to be removed in a VFR where (self)filtration and precipitation occurs. This means that for many acid mine waters, significant removal of the principal contaminant can be achieved by a simple filtration-type system. This is of particular significance to coal mine AMD where Fe is the principle contaminant. Even slight pH change should be enough to remove much of the Fe.
- The precipitate and/or the gravel substrate hosts Fe(II) oxidizing microbes resulting in demonstrable Fe(II) oxidation. The activity of Fe(II) oxidizers is important in AMD treatment, but the data presented here shows removal of what appears to be 'dissolved' Fe may not always be due to Fe(II) oxidizers.
- An example scale up for the Cwm Rheidol mine water suggests that 70% of the Fe from the full discharge at that site of 10 L/s could be treated continuously for at least one year without removing the precipitate by a VFR of 42 m × 50 m.

ACKNOWLEDGEMENTS

The authors wish to thank the Coal Authority and the EPSRC for funding the UK part of this research and to CRL Energy Ltd for assisting with the research on the mine water in New Zealand.

Characterization of Passive Treatment System Substrates and Potential for Zinc Recovery

Matthew Bailey, Adam Jarvis and Catherine Gandy
School of Civil Engineering and Geosciences, Newcastle University, United Kingdom

ABSTRACT

Treatment of mine drainage, during operation and following abandonment, can represent a substantial cost to mine operators and governing authorities. Recovery of valuable metals from mine drainage as part of the treatment process may offset costs, yet this is rarely seen in practice. Industrial-scale metal recovery from mine waters are the preserve of active treatment systems, where reactor conditions are carefully controlled to ensure consistent quality of product. In many circumstances passive treatment is the preferred approach, but close process control is not feasible in these systems. Analysis of substrate from a pilot-scale compost-based passive treatment system, which operated for two years, has been conducted. The treatment system, which harnessed bacterial sulfate reduction to remove metals as their sulfides, showed that under UK regulations used substrate was within the worst-case 'hazardous' category due to accumulated zinc, and required pre-treatment due to high total organic carbon. Typical costs for disposal are estimated at 1104 US$/tonne, excluding removal and transport. The majority of zinc accumulates in the upper substrate layer. Greatest zinc concentration of 14,050mg/kg (1.4%w/w) was observed in the 0–230mm depth layer; whereas in the corresponding lower layer, 230–460mm, zinc was 808mg/kg (0.08%w/w). This suggests that selective 'harvesting' of upper substrate layers may reduce waste volumes generated, and higher zinc concentrations may be more amenable to metal recovery. Batch-scale leaching tests have also been undertaken, demonstrating recovery in excess of 83 - 96% of zinc from the upper-layer substrate, depending on acid strength used (20; 100; 500mol/m^3 sulfuric acid), within a 100 hour leach test. The results are discussed in the context of the possible economic benefits of metal recovery for passive treatment systems at larger scale.

INTRODUCTION

Pollution of surface waters by drainage from long abandoned metal mines, often sourced from orphan sites, is extensive in the UK (Mayes, Potter and Jarvis, 2010). A national programme of remediation has recently been embarked upon, funded by the UK Government. The programme has the focus of improving water quality in both an effective and cost efficient way. Recovery of metals may offer a way to both reduce costs of waste disposal, and generate revenue for treatment system operators.

Active mine water treatment systems may be amenable to metal recovery, producing potentially valuable metal ores rather than the comparatively voluminous wastes of passive treatment alternatives (Johnson and Hallberg, 2002; Johnson *et al.*, 2006). However, the capital and operational costs of active treatment are high, and they may be visually intrusive. In many cases in the UK, abandoned metal mines are located within centres of significant heritage and ecological importance, and in areas of high recreational amenity, such as the Lake District National Park. In these settings, passive treatment systems, harnessing natural processes and having a minimal impact upon the landscape, tend to be favoured. For the removal of divalent metals such as zinc, the most prevalent contaminant in UK metal mine waters, bacterial sulfate reduction based systems have been shown to be effective (Gandy and Jarvis, 2012; Jarvis *et al.*, 2013). In 2014 the first large-scale metal mine water treatment system of this type (a Vertical Flow Pond; VFP) was built in the UK (see: Jarvis *et al.*, In press). The compost substrate of such VFPs is the main reactive ingredient, providing the reducing conditions and nutrients required to sustain bacterial communities. Sulfate reducing bacteria provide a critical role within the systems, converting dissolved sulfate to sulfide, which reacts with metal ions to form insoluble metal sulfides. This process has been cited as an important mechanism for metal removal within compost-based treatment systems (Machemer and Wildeman, 1992; Jong and Parry, 2004; Pereyra *et al.*, 2008), although some studies suggest that this is not always the case (Matthies, Aplin and Jarvis, 2010).

While there is a significant body of research into the performance of passive treatment systems, there has been little work considering the character of wastes generated, and their amenability to resource recovery. In a review of resource recovery options for passive treatment systems, Gray, Gandy and Jarvis (2012) suggest that further research should be conducted to characterise wastes from treatment systems, and to investigate processes to recover metals from them. In particular, the use of chemical and biological leaching processes should be considered.

METHODOLOGY

Study site

Mine water treatment trials came to an end at Nenthead in Cumbria, UK, in August 2012 after two years of operation. Here, a flow of circum-neutral mine water with zinc concentrations of 2 – 2.5mg/l was treated within a pilot-scale VFP system, as depicted in Figure 1 (photo taken during spring 2012). The system comprised a tank 2.5m x 1.5m x 1.0m (height) configured so that mine water passed vertically down through a 500mm deep substrate of mixed compost (45% v/v); wood chips (45%v/v); activated sewage sludge (10%). Below the substrate, a 200mm deep layer of limestone gravel facilitated underdraining. The compost substrate was completely submerged in water, with water level controlled by the invert height of the raised outlet pipe.

Sample collection

Compost samples were collected at the time the system was decommissioned in August 2012. Figure 2 shows the sample positions within the treatment tank in plan. The system was uncoupled from the mine water feed and allowed to partially drain, such that substrate samples could be collected from just below the water surface. Compost samples were collected from two layers: upper layer (approximately 0 – 230mm depth below compost surface) and lower layer (approximately 230 – 460mm, the base of the compost), which were denoted with postscripts A and

B. For example, a compost sample from the upper layer at position A2 (Figure 2) would be denoted A2A. Bulk samples were immediately placed into sealed polyethylene bags before being transported to Newcastle University where they were stored at -20°C until analysis.

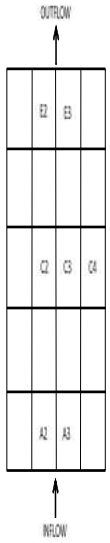

Figure 2 Sample plan of pilot tank

Geochemical analysis of VFP substrate

Relationship between particle size and zinc content

Wet and dry sieving of substrate was conducted on a single sample (C4B), followed by sequential extraction procedures of sieved and bulk samples, in order to determine the relationship between particle size and metal speciation and concentrations. Compost samples were removed from frozen storage and allowed to defrost within their airtight sample bags at room temperature. They were then quartered to obtain suitable subsamples which were oven dried overnight at 105°C, excepting one quartile for wet-sieving. Sieves of 2mm and 212μm were selected, as these provided a relatively even split between particle sizes during preliminary sieving of a test sample. In order to assess the impact of the use of a deionised water flush for wet sieving, compared to dry sieving, the two methods were conducted on quartiles of sample C4B. De-ionised water wash was sampled to determine any solubilised metal. Additional extractions in triplicate were conducted on the remaining two quartiles of the bulk sample in order to test reproducibility of results. Sieved and un-sieved fractions were all ground to less than 212μm and subsampled for sequential extraction. Figure 3 illustrates the quartering and sieving sample preparation procedure.

Spatial distribution of zinc

In addition to determination of the metal distribution in relation to particle size from a single sample location (and the impact of sieving methods on results), investigations were also conducted to assess the spatial variation in metal availability throughout the treatment system. The following twelve samples were investigated from the upper substrate layer: A2A, A3A, C2A, C3A, E2A, E3A; the lower substrate layer: A2B, A3B, C3B, E2B, E3B; plus a blank sample of substrate which had not been exposed to mine water.

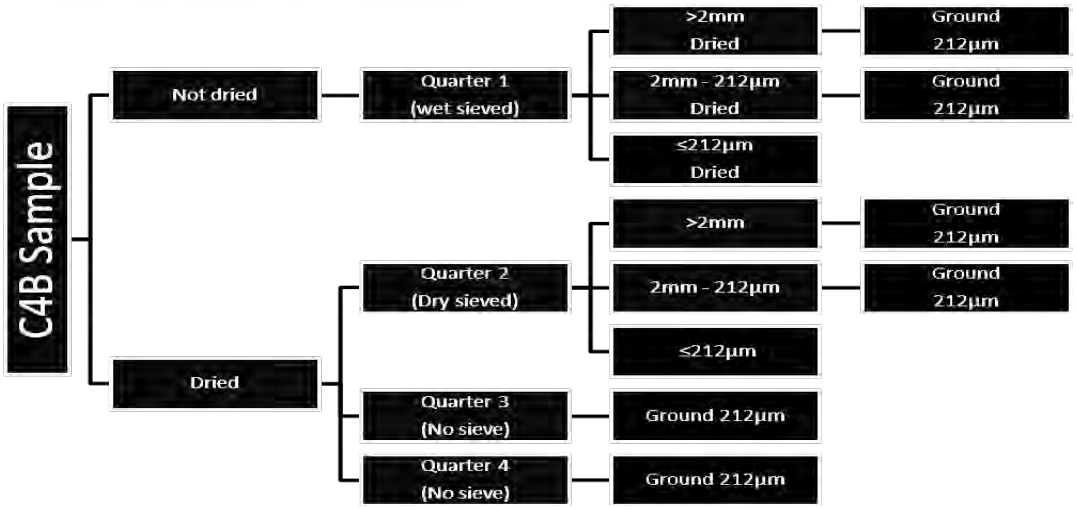

Figure 3 Flow chart showing sieving process

Masses of sieved fractions from sample C4B quartiles were determined and are specified in Table 1.

Table 1 Mass of compost fractions following sieving

Sample	Mass (g)
≤0.212mm dry sieved	1.17
2mm - 0.212mm dry sieved	4.58
>2mm dry sieved	7.04
Dry sieved total	**12.79**
≤0.212mm wet sieved	4.56
2mm - 0.212mm wet sieved	3.05
>2mm wet sieved	5.11
Wet sieved total	**12.72**

Sequential extraction procedure

Sequential extractions using procedures developed by Tessier, Campbell and Bisson (1979) were performed on 1.00g of homogenised sample, sieved to ≤212μm. The method (herein referred to as the 'Tessier' method) consists of five operationally defined extraction steps performed in the following order: 1: Exchangeable; 2: Bound to carbonates; 3: Bound to Fe and Mn oxides; 4: Bound to organic matter and 5: Residual. Solutions were recovered following each step by centrifugation for 30 minutes at 10,000rpm and removed using a glass pipette. Between the five steps, samples were washed with 8ml of deionised water, agitated and separated within the centrifuge for 30 minutes. The wash fluid was then discarded. All reagents were made up either from salts or concentrated solutions, diluted with 18.2MΩ/cm deionised water. Samples from step 1 were acidified with one drop of concentrated nitric acid to preserve metals in solution.

Analysis of extraction solutions was undertaken for iron, zinc, lead, manganese, cadmium, copper, cobalt and nickel in accordance with the Tessier method, although only zinc data are presented here.

Acid leaching of VFP substrate

Substrate used for the acid-leach tests was a composite of the upper layer samples from the treatment system (A2A, A3A, C2A, C3A, E2A, E3A) which were sieved to remove fragments greater than 2mm, and homogenised. Batch leaching tests were conducted over 100 hours at room temperature, with lixiviant sampling and measurements of pH, Eh, conductivity and temperature undertaken intermittently throughout the first day, then daily for the following four days. Lixiviant samples of approximately 10mL were collected and passed through 0.45μm syringe filters to remove any suspended material. Batch cells were operated in duplicate and comprised 2L plastic bottles containing 1.2L of lixiviant and 22.5g of substrate, providing a pulp density close to 2%. This ratio was experimentally determined to be effective by Bayat and Sari (2010) during similar leach-tests. Lixiviants were made up from analytical grade sulfuric acid (H_2SO_4) and distilled water. Compressed air was injected into the pulp continuously at a rate of 1 L/min (±0.07L) in order to maintain oxic conditions, and to promote mixing of substrate and lixiviant. Table 2 shows the starting pH of the various lixiviants.

Table 2 Batch leach test variables

Lixiviant	Distilled water		20 mol/m^3 H_2SO_4		100 mol/m^3 H_2SO_4		500 mol/m^3 H_2SO_4	
Sample	DWa	DWb	0.02Ma	0.02Mb	0.1Ma	0.1Mb	0.5Ma	0.5Mb
pH at start	6.63	6.75	1.99	1.96	1.37	1.35	0.93	0.84

Following completion of the leach tests, residues were collected, dried, subsampled and subjected to an aqua regia digest procedure in order to determine residual metal concentrations. The British Standard method ISO11466:1995 was adopted in duplicate, with addition of extra nitric acid to account for elevated Total Organic Carbon, (TOC) above 20% (BSI, 1995).

Lixiviant samples and aqua regia solutions were analysed for iron, zinc, lead, manganese, cadmium, copper and nickel, although only zinc data are presented.

All experimentation was conducted using laboratory grade reagents and acid washed glassware. Metals analysis was conducted using a Varian Vista MPX Inductively Coupled Plasma Optical Emission Spectrophotometer (ICP-OES),

RESULTS AND DISCUSSION

Zinc is the sole focus of the discussion, as it is both the most significant contaminant metal in the mine water discharge treated, and it is due to zinc that the substrate from the Nenthead pilot system has been classified as Hazardous Waste by independent laboratory testing. Hazardous Waste requires special treatment under UK waste regulations.

Relationship between particle size and zinc content

Figure 4 depicts zinc data from wet sieved and dry sieved fractions of substrate sample C4B. Note that in addition to a breakdown of the five extraction steps, the amount of zinc lost from the wash solution (included in ≤212μm wet sieved fraction) is depicted on this bar as 'Loss in wash'.

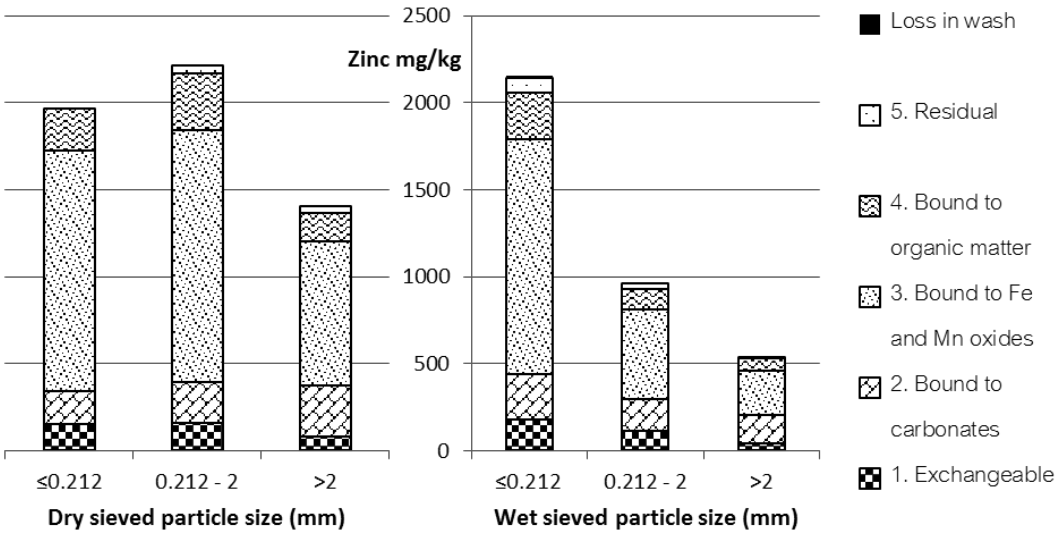

Figure 4 Zinc concentrations in sieved substrate samples

A distinct trend in total metal content was apparent within the wet sieved fraction, with highest zinc concentration in the finest fraction: wet sieved fraction ≤212μm contained 2,158mg/kg of zinc, in contrast to the >2mm fraction that contained just over a quarter of this amount at 541mg/kg. In fact, this trend is apparent for all extraction steps, excepting 2 (bound to carbonates). Dry sieving, however, did not yield such clear results: the ≤212μm fraction contained 2014mg/kg of zinc, in comparison to >2mm which had 1403mg/kg, while the intermediate size fraction contained the greatest amount (2214mg/kg). Such a distinct contrast between sieving methods is thought to be due to the behaviour of materials within the sieves: dry sieved compost, that was pre-dried to remove moisture, was composed of loosely cemented fragments bound to, and together with, fine grained material. Sieving only shows some success in separating these fragments, evidenced in part by the recovery rate of fine grained material (see table 1): just 1.17g passing ≤212μm, compared to 7.04g of material retained on the 2mm sieve. In contrast, 4.56g of material passed the 212μm sieve and 5.11g was retained on the 2mm sieve during the wet sieving operation. From observations during the sieving process, the deionised water wash appeared to aid the separation of compost fragments. It was not unexpected that wet sieving would assist the separation of particles during sieving, but it was recognised that the deionised water wash had the potential to both mobilise weakly-bound metals, and also potentially facilitate geochemical reactions that might alter speciation. Although it was not possible to assess whether metal speciation was influenced by the deionised water, a sample of the deionised water wash solution was analysed by ICP-OES (in parallel with a blank), and revealed that just 13.76mg/kg equivalent of zinc was leached from the compost (see 'Loss in wash' on Figure 4 for relative significance). In order to demonstrate reproducibility of the sequential extraction procedure, triplicate samples were run for the two un-sieved quartiles. Statistically, the standard deviation is less than 7% of the mean for all extraction steps across all sample quartiles, demonstrating good reproducibility.

Spatial distribution of zinc within treatment system

The degree of spatial variation of zinc concentration in the substrate was investigated in a second round of sequential extractions using the methods previously described. Particle size separation was not undertaken as part of these tests, which were conducted to assess the variation (if any) between metal species and their availability throughout different parts of the Nenthead pilot treatment system. Eleven bulk samples in total were analysed, plus a substrate blank. Figure 5 depicts zinc concentrations, and a breakdown of the steps by which they were extracted.

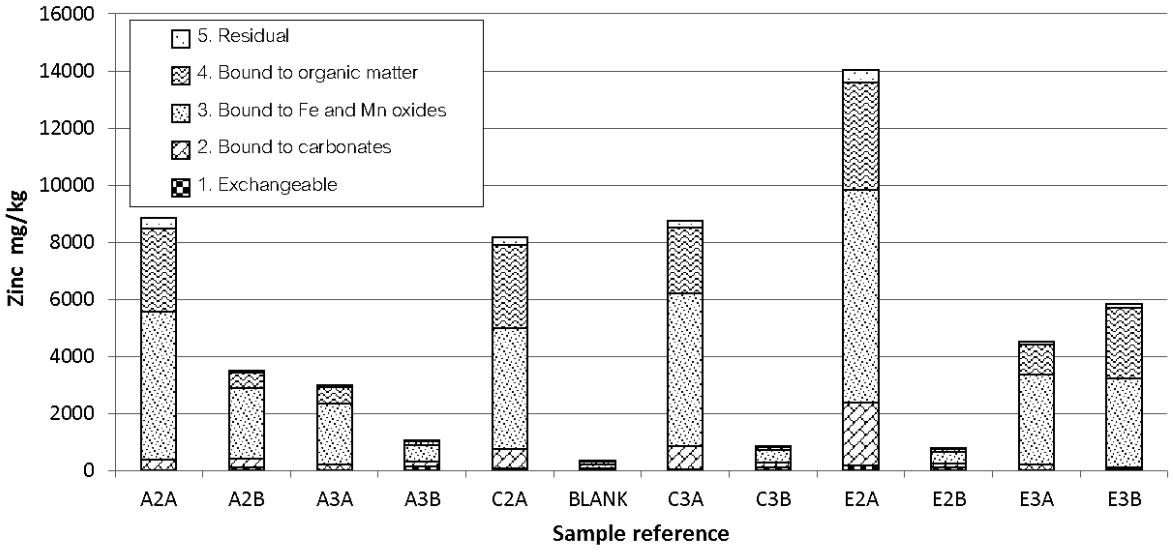

Figure 5 Zinc concentrations from a range of sample locations within the pilot treatment system

In all but one case (samples E3A/B), compost from the upper layer contained substantially more zinc than samples taken from the respective lower layer. Greatest zinc concentration was seen in sample E2A (14,050mg/kg) and the lowest seen in the corresponding lower layer sample (E2B; 808mg/kg). 340mg/kg zinc was measured in the blank substrate. No discernible trend in zinc concentration was evident either laterally or longitudinally.

Exchangeable zinc (step 1) provides perhaps the most pronounced difference between samples, from upper and lower levels, as significant exchangeable zinc is only shown at depth (although it is recognised that this is difficult to see in Figure 5). E3B does not show this clear trend, however this sample was previously identified as a possible outlier. In the upper layer, zinc species are dominated by Fe/Mn oxide and organically bound fractions (steps 3 and 4), with very small concentrations of exchangeable zinc and zinc bound to carbonates (steps 1 and 2 respectively). Residual zinc comprises a small fraction throughout, up to 5% in E2B; whereas most zinc is recovered during step 3: all in excess of 50%, other than C3B where 49% was extracted. Data for the 'blank' sample showed a similar pattern: almost half (46%) zinc was attributed to the Fe/Mn oxide fraction, with significant amounts of zinc extracted during step 2 and 4, and a lesser amount (5%) associated with step 1. Residual zinc in the blank was 8%, which in percentage terms was greater than all residual fractions in the samples from the treatment tank, but was less in absolute terms than all other compost samples. Several samples (A2A, C2A, E2A) had in excess of ten times the absolute amount of residual zinc, compared to the blank. Percentage residual zinc for these samples was 4%; 4% and 3%, respectively for A2A; C2A and E2A.

Neculita, Zagury and Bussière (2008) presented data from extractions using a modified Tessier method on compost from laboratory scale column based bioreactors. Mine water chemistry, treatment configuration and scale all differ from the work conducted here, however some general comments can be made on how both sequential extraction data compare. Samples were taken from both the top and the base of the column – analogous in some ways to the sampling of top and bottom layers of the Nenthead tank. Neculita, Zagury and Bussière (2008) found that, with duplicate columns treating mine water for a 7.3 day residence time, the greatest zinc fraction (37 – 50%) was associated with step 3, comparable with Nenthead data. In contrast, substantial zinc concentrations were associated with steps 4 and 5: specifically 4 in the top layers (36 – 46%) and 5 in the lower (28 – 36%) (Neculita, Zagury and Bussière, 2008). What is of significance is that substantial amounts of zinc appear more tightly bound in the 2008 study compared to Nenthead data, specifically at depth. Furthermore, while data from the Nenthead tank showed typically very low exchangeable zinc (step 1) in the surface layer, Neculita, Zagury and Bussière (2008) found that

this was where most exchangeable zinc occurred (8 – 12%). A second duplicate set of columns were investigated, with an increased hydraulic residence time of 10 days. These columns yielded similar results, though there was a slight increase in residual zinc in the bottom layers of the columns: 33 - 41%. The other trend of interest in relation to data from the study of Neculita, Zagury and Bussière (2008) is the higher proportion of exchangeable zinc being identified in the upper part of the column, rather than the bottom in the case of the Nenthead data. It is not clear what this could be attributed to, and the comparison is limited due to modifications of the Tessier method made by Neculita, Zagury and Bussière (2008).

Acid leaching of VFP substrate

Zinc recovery from the substrate is presented in Figure 6, which shows both zinc concentration in the leachate and zinc concentration in substrate residues, determined by aqua-regia digestion. Extraction was shown to be effective with moderately weak strength acids, with extraction efficiencies of over 80% in all acid-leach tests after 100 hours. Zinc recovery of 93.9% and 95.1% was achieved with 100mol/m^3 sulfuric acid, whereas the most concentrated acid (500mol/m^3) achieved extraction efficiencies of 95.1% and 96.0%. There appears to be only a marginal gain in efficiency for a fivefold increase in acid concentration. It is considered that under the conditions of these batch tests, the 100mol/m^3 acid represents the optimum balance between concentration and extraction efficiency.

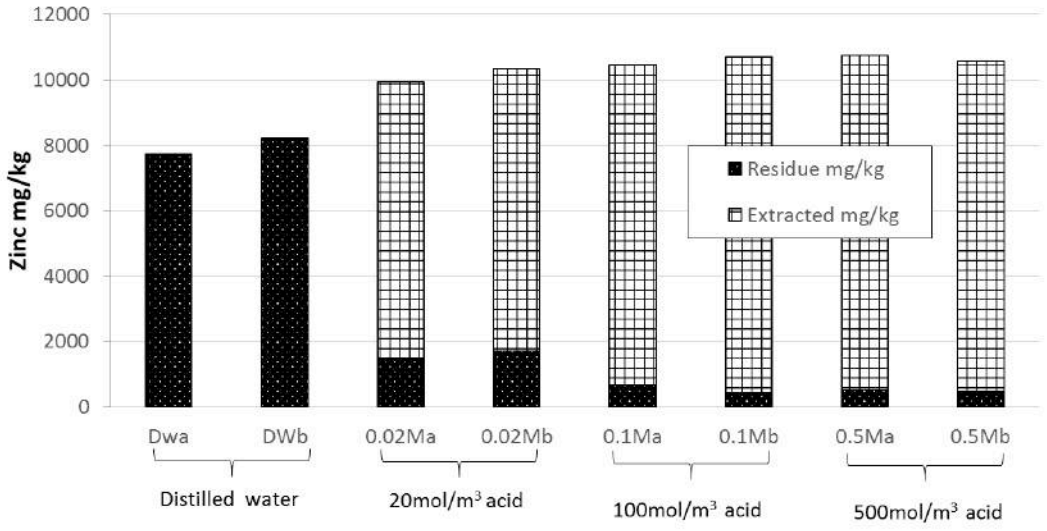

Figure 6 Zinc concentrations from leachate and residue after batch leaching

Batch leach data for zinc show good replication between duplicate columns; less than ±5% variation for all four experimental pairs, and less than ±2.5% variation between the sulphuric acid duplicates. Aqua regia digest duplicates were within 5% for distilled water blank samples and 500mol/m^3 acid, but duplicates for 20mol/m^3 and 100mol/m^3 had 7% and 20% discrepancies, respectively. This is perhaps attributable to heterogeneity of sample residues exposed to aqua regia.

CONCLUSIONS

Geochemical analysis was undertaken on substrate taken from a pilot-scale mine water treatment system following sieving by both wet and dry methods. Samples were also collected and analysed from 11 different positions within the treatment system. In addition, batch-leach tests were conducted on a composite substrate sample, to determine extraction efficiencies for a range of sulphuric acid concentrations.

Wet sieving suggested that substantially more zinc was associated with the fine grained fraction of substrate (≤212μm fraction). This trend was not seen in the dry sieved sample analyses, and these results may have been affected by cementing of substrate fragments during drying. Significantly more zinc was found in the upper layer of the substrate than at depth within the treatment tank. Moreover, zinc in the surface layer was more tightly bound, whereas some zinc at depth was recoverable by ion exchange. Sequential extractions to the Tessier method suggest that in both substrate layers, most zinc is bound with moderate strength and associated with Fe/Mn oxides; however, it should be noted that sample preparation and exposure to oxygen may have influenced speciation (Rapin *et al.*, 1986). Leach tests demonstrated that dilute sulfuric acid was effective at removing zinc from the compost substrate, with 100mol/m^3 providing the optimum balance between concentration and extraction performance. Further experimentation to test the absolute capacity of the acid for metal recovery is planned, in order to assess the feasibility of large-scale metal recovery operations (i.e. how much metal could be solubilised for a given acid volume).

Data presented in this paper indicate that zinc-laden mine water treatment substrates may be de-contaminated by: a. separation on the basis of particle size, and b. leaching with dilute acids. Additionally, spatial sampling identified that metals accumulated more rapidly within the surface layers of the treatment system, which may facilitate selective recovery: it may be that periodic removal and replenishment of surface substrate layers may offer a means of effectively extending the life of a given system, as suggested in a review by Gray, Gandy and Jarvis (2012). These processes may offer mechanisms of decreasing whole-life costs by extending system lifetimes, reducing waste and recovering metals. Further research is required to consider the practicalities and costs of substrate decontamination at a large scale, and options for concentrating metals within lower-volume materials to levels at which they might have a commercial value.

ABSTRACT

In March 2014, the UK's first full-scale passive treatment system for metal mine drainage was commissioned. The treatment system harnesses bacterial sulfate reduction (BSR) to immobilise the main contaminant metal, zinc, within the compost substrate of two parallel 'Vertical Flow Ponds' (VFPs), each of which has a treatment area of approximately 800 m^2. The final discharge from the treatment system enters a nutrient-sensitive upland river. Appropriate infrastructure was designed and installed to enable close control and monitoring of flow-rate and water quality. Such features include open channel flow with sharp-crested weirs for flow measurement, and an innovative penstock arrangement for fine adjustment of flow into the VFPs.

Effluent quality from the treatment system has evolved during early operation. Over the first 3 months of operation mean influent zinc concentration was 3.74 mg/L compared to 0.12 mg/L in the effluent (mean zinc removal of 97%; n = 15). Strongly reducing conditions are evident, with sharp decreases in sulfate concentration between influent (mean of 31.7 mg/L) and effluent (< 10 mg/L within approximately 2 months of commissioning) suggesting that BSR is an important metal attenuation mechanism. However, water first emerging from the VFPs had up to 82 mg/L ammonium, Biochemical Oxygen Demand (BOD) of up to 100 mg/L, and Chemical Oxygen Demand (COD) of up to 3084 mg/L, resulting in secondary contamination of the receiving watercourse. The issue was short-lived, with organics concentrations decreasing sharply. Within 4 months of commissioning the system the river was back to acceptable standards with respect to ammonium, BOD and COD concentrations. In this instance there were no downstream water users impacted by the secondary contamination. In other settings, mitigation measures may be required to address such issues during early operation of passive mine drainage treatment units of this type.

Keywords: passive treatment, secondary contamination, zinc, compost

INTRODUCTION

In March 2014 the UK's first full-scale passive treatment system for metal mine drainage treatment was commissioned, and at the time of writing has been operational for 6 months. The treatment system is located at the abandoned Force Crag mine in the Lake District National Park, north west England. The mine site lies at an elevation of 275 m.a.s.l. (above sea level), though the abandoned mine workings extend west by a horizontal distance of approximately 1 km, to an elevation of 600 m a.s.l. The mine operated intermittently for 157 years, but was finally abandoned in 1992 following a collapse in the lower workings. The mine is hosted in Ordovician-aged mudstone and lithic-wacke sediments (Kirk Stile Formation) (Barnes *et al.*, 2006). The vein-hosted mineralization present at Force Crag is dominated by galena (lead-ore) and sphalerite (zinc-ore) with barite and quartz gangue (Tyler, 2005). A series of nine individual levels form the workings at Force Crag, with Level 0 being the lowest level. Two adits currently drain the workings at Force Crag, namely Level 1 (the primary discharge) and Level 0.

Despite the occurrence of diffuse mining pollution, originating from the processing and mining waste located at the site, long-term monitoring demonstrated that the Level 1 discharge was the main point source of metal contamination to the receiving waters at Force Crag. Pollution from the mine site enters the Coledale Beck. Whilst the Coledale Beck is contaminated with metals due to both point and diffuse source pollution from the mine site, it is also a nutrient sensitive stream, with very low concentrations of both nutrients and organic compounds.

Table 1 illustrates that the main source of metals pollution to the Coledale Beck, the Level 1 discharge, is circum-neutral drainage (pH 5.6 – 7.7). The discharge is poorly mineralized, with low concentrations of all major ions, including sulfate, which has a concentration in the range 16.0 – 39.5 mg/L. The main metal of concern is zinc, which is present at concentrations in the range 1 730 – 4 660 μg/L. This concentration of zinc, and also the pH of the discharge, is typical of many discharges around England and Wales. The Level 1 discharge has a variable flow-rate (8.5 – 24.4 L/s) which is influenced by rainfall events (there is a clear inverse correlation between flow-rate and zinc concentration, indicating a dilution effect).

The installation of a treatment system for the Level 1 discharge was an initiative of the UK Coal Authority, the Environment Agency for England and Wales, the National Trust (the site owner) and Newcastle University. The treatment system was funded by the UK Department for Environment Food and Rural Affairs (Defra).

In this paper we discuss the design and early performance of the treatment system. However, whilst the main concern in relation to treatment performance is typically metal removal, an important consideration at the Force Crag site was the possibility of secondary contamination due to organic substances leached from the treatment media (see below). Therefore this paper focuses also on the evolution of treatment system effluent quality with respect to some of the more important organic constituents.

TREATMENT SYSTEM DESIGN AND LAYOUT

The passive treatment system at Force Crag is a downwards flow compost bioreactor, or Vertical Flow Pond (VFP). The treatment principle is to harness bacterial sulfate reduction (BSR) to attenuate divalent metals (Zn in particular) within the compost as their sulfides, as shown in Reactions (1) and (2).

$$2CH_2O + SO_4^{2-} \rightarrow H_2S + 2HCO_3^- \quad (1)$$

$$H_2S + Zn^{2+} + 2HCO_3^- \rightarrow ZnS(s) + 2H_2O + 2CO_2 \quad (2)$$

This is a widely reported approach to passive mine water treatment (e.g. Mayes et al., 2011; Neculita et al., 2007; Sheoran and Sheoran, 2010). However, a key issue in the UK is to keep

absolute system size to a minimum due to land constraints at many of the upland sites at which metal mine water discharges occur. On the basis of lab-scale (Mayes et al., 2011) and pilot-scale experiments (Gandy and Jarvis, 2012) the VFP units at Force Crag were therefore designed to have a hydraulic residence time of 15 – 20 hours, which is substantially shorter than typical designs.

As shown in Figure 1, the treatment system comprises two VFPs operating in parallel. Each VFP is lined with HDPE to prevent leakage. At the base of each VFP is a perforated pipe network. There are 4 separate perforated pipe networks in each VFP, each covering an equal area of the base of each VFP. There are also therefore 4 effluents from each VFP. Each pipe passes through the HDPE liner to a manhole chamber, where the pipes are raised to ensure that there is a 350 mm water cover over the compost substrate i.e. water level in the VFPs is controlled by the invert level of the effluent pipes in the manhole chambers. The pipe networks are overlain by a 200 mm layer of carboniferous limestone. Over the limestone is a 500 mm layer of compost substrate, which comprises 45% v/v PAS100 compost (see below), 45% v/v woodchips, and 10% v/v dried activated sewage sludge from a local municipal wastewater treatment plant. For this treatment system the limestone was used purely for the purposes of maintaining good permeability around the perforated pipe network, rather than being a requirement for generating alkalinity and elevating pH. BSI PAS100 compost meets certain agreed standards with respect to safety (British Standards Institute, 2011), and was therefore selected given that water draining through it would be entering a watercourse. The composition of the treatment media was based on successful pilot-scale trials reported by Gandy and Jarvis (2012).

Each VFP has a treatment substrate area of 760 m^2, and the volume of substrate in each VFP is 400 m^3 (each VFP is a trapezoidal basin, with internal slopes of 1:2.5). This volume of substrate was based on a design flow-rate of 6 L/s (3 L/s to each VFP, to give hydraulic residence time of 15 – 20 hours in each VFP). It will be apparent from the range of flow-rate for the Level 1 discharge (Table 1) that not all of the Level 1 discharge is treated by the system. This was due primarily to land constraints. As shown in Figure 1, excess water therefore discharges to the Coledale Beck untreated. However, during low flow conditions in the Coledale Beck, when the impact of the Level 1 discharge was historically greatest, the Level 1 flow-rate is typically at the lower end of the range reported in Table 1, and therefore the majority of the water is treated under such conditions.

Effluent from both VFPs drains to a small aerobic wetland, from where it is discharged back to the Coledale Beck (Figure 1).

Table 1 Summary water quality data for the Level 1 mine water discharge from the Force Crag mine, 2011 to 2014 (unpublished data of Environment Agency and Newcastle University)

Variable	Range	Mean	n[A]
Flow (L/s)	8.5 – 24.4	14.8	21
pH	5.6 – 7.7	6.8	25
HCO_3^- (mg/L)	8.5 – 26.8	16.7	28
Cl (mg/L)	4.7 – 7.6	5.7	28
SO_4 (mg/L)	16.0 – 39.5	26.6	28
Ca (mg/L)	5.1 – 14.5	9.5	28
Mg (mg/L)	1.95 – 5.00	3.30	28
Na (mg/L)	2.40 – 3.60	2.95	28
K (mg/L)	0.32 – 0.62	0.46	28[C]
Fe (mg/L)	0.26 – 1.08	0.52	28
Mn (mg/L)	0.29 – 0.76	0.51	28
Al (mg/L)	0.05 – 0.20	0.08	28
Zn (total) (μg/L)	1 730 – 4 660	2 997	28
Zn (filt.) (μg/L)[B]	1 710 – 4 550	2 950	28
Pb (μg/L)	25.0 – 87.9	43.6	28[D]
Cu (μg/L)	1.80 – 8.57	5.11	28[E]
Cd (μg/L)	5.00 – 20.00	14.24	28[F]
Ni (μg/L)	10.00 – 20.00	16.09	28

[E] 13 samples measured by ICP-OES below detection of 10 μg/L; value of 5 μg/L used for calculation of summary statistics
[F] 2 samples measured by ICP-OES below detection of 10 μg/L; value of 5 μg/L used for calculation of summary statistics

METHODS

Since commissioning of the treatment system flow and water quality monitoring has typically been undertaken on a weekly basis (fortnightly occasionally). The primary objective of monitoring has been to evaluate (a) the performance of the VFP system for Zn removal and (b) the improvement and / or impact of the treatment system effluent on the Coledale Beck downstream.

Flow-rate is measured via sharp-crested 20° V-notch weirs located at the influent of the system and the final effluent from the treatment system (at the effluent from the effluent from the aerobic wetland; see Figure 1). Flow-rate from the effluent pipes from the VFPs is measured by bucket-and-stopwatch (mean value of 3 measurements for each effluent pipe). Flow-rate in the Coledale Beck is measured with a flat V weir installed and operated by the England and Wales Environment Agency.

Because a primary objective of the Force Crag treatment system is to gain an improved understanding of the rate of removal of metals in the system, having the facility to accurately control flow-rate to the treatment units was a key consideration. For this system, a novel downwards-opening penstock arrangement was designed i.e. water is allowed to escape over the top of the penstock. Adjustment of the penstocks (one for each VFP) upwards or downwards controls water level in an open channel that is hydraulically connected to the penstock chamber. At the end of each channel is a sharp-crested 20° V-notch weir. Adjustment of the penstocks therefore controls depth of water over the V-notch weirs, and hence the flow-rate to the VFPs. This open channel arrangement is preferable to a system of pipes and valves, as the latter are prone to clogging where iron concentrations are even slightly elevated (Table 1).

Water quality samples are routinely collected and analysed by Newcastle University. Sampling and analysis is undertaken in strict accordance with methods documented in APHA (2005). Blanks and standards are run routinely, and triplicate samples are collected for analysis periodically.

There are 4 individual effluents from each of the VFPs. To evaluate overall performance of each VFP a composite sample is taken, as well as individual samples from each effluent pipe. The composite sample is made up of a volume of water from each individual pipe that is proportional to its contribution to the overall effluent flow-rate. For brevity, only composite analysis results are reported here.

RESULTS AND DISCUSSION

Zinc removal

Figure 2 shows Zn removal by the treatment system for the first 6 months of its operation. Mean Zn removal efficiencies for VFP 1 and VFP 2 were 98.7% and 94.1% respectively for the period from 1 April 2014 to 23 September 2014. Overall treatment efficiency (Final effluent in Figure 2) was 96.8%. Sorption reactions, and precipitation of zinc as phases other than its sulfide, have been noted as possible sinks for zinc in previous investigations (e.g. Gibert et al., 2005; Neculita et al., 2008). At the Force Crag system it is too early to undertake detailed analyses of solid phases in the compost substrate. However, after elevated sulfate concentrations in the effluent waters for the first week of operation, sulfate concentrations decreased substantially between influent and effluent. Mean influent sulfate concentration to VFP 1 and VFP 2 was 30.4 mg/L (range: 19.3 – 38.2 mg/L) for the first 6 months of operation, whilst mean effluent concentrations were 10.1 mg/L for VFP1 (range: 0.4 – 27.8 mg/L) and 8.1 mg/L for VFP 2 (range 0.8 – 23.2 mg/L). Strong odours of hydrogen sulfide are also evident in the vicinity of the effluent manhole chambers.

Both total and filtered samples (0.45 μm) are collected for zinc analysis, and since June 2014 aliquots of both influent and VFP effluent waters have also been filtered through a 0.10 μm filter. For both VFPs, effluent filtered zinc concentrations were lower than effluent total zinc concentrations. For VFP 2 (which performed slightly less well than VFP 1), these data are illustrated in Figure 3. 0.45 μm filtered Zn concentration was, on average, 35.8% lower than total effluent concentration. 0.10 μm filtered Zn concentration was consistently below the 0.010 mg/L detection limit of the ICP-OES used for analysis (and are therefore shown as half this value – 0.005 mg/L – on Figure 3). The pattern was the same for VFP 1. This suggests that the zinc present in the VFP effluent waters is in colloidal phase. Future analyses will be undertaken to establish whether the colloidal zinc is sulfide or some other solid phase, with a view to investigating possible improvements to final water quality via additional treatment.

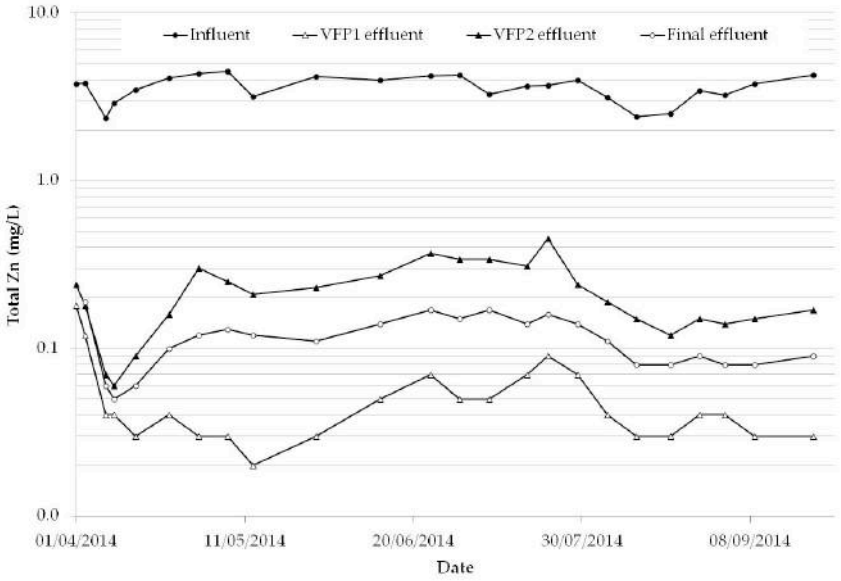

Figure 2 Zn removal at the Force Crag treatment system for the first 6 months of operation

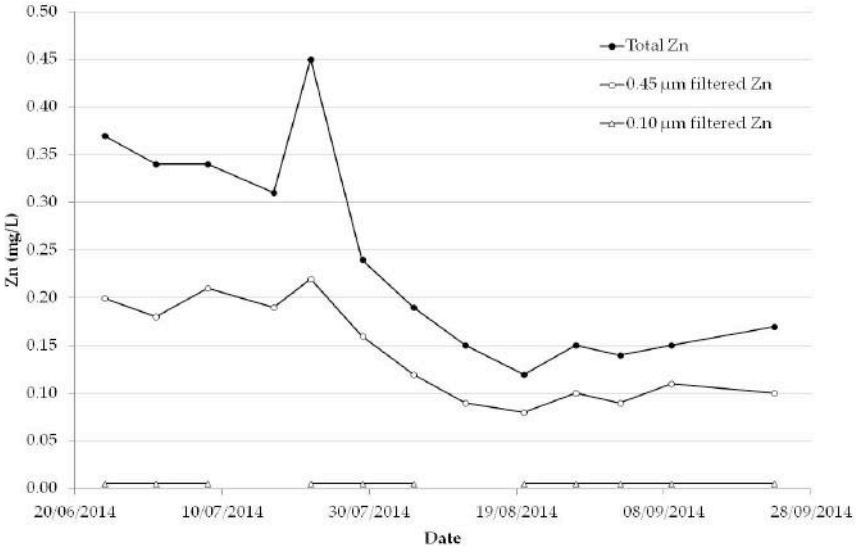

Figure 3 Differences in VFP 2 effluent total zinc concentration and effluent 0.45 μm and 0.10 μm filtered concentrations

Secondary contamination

The potential for secondary contamination from passive mine water treatment systems is rarely considered. As noted previously, the Coledale Beck is a nutrient-poor watercourse, with very limited organic enrichment. Concentrations of Biochemical Oxygen Demand (BOD), Chemical Oxygen Demand (COD), ammonium, nitrate and phosphate were therefore determined as part of the monitoring program for the Force Crag treatment system. A specific requirement of the

environmental regulator, the Environment Agency, was that ammonium concentrations in the Coledale Beck should not exceed 0.2 mg/L on a long-term basis.

Concentrations of BOD, COD, ammonium and nutrients, for both the Level 1 discharge itself, and the Coledale Beck upstream of the treatment system, are shown in Table 2, and illustrate the low concentrations in both. Effluent water from the treatment system was initially monitored twice weekly following commissioning. Final effluent nutrient concentrations, BOD, COD and ammonium are shown in Figure 4. Concentrations for the same variables for the Coledale Beck downstream of the treatment system are shown in Figure 5 (nitrate concentration is not shown in Figures 4 and 5 as it was consistently < 0.2 mg/L in the treatment system effluent).

Table 2 Nutrient and organic concentrations in the Level 1 discharge and Coledale Beck upstream of the treatment system (all concentrations in mg/L; range shown where relevant; n = 9)

Variable	Level 1 discharge	Coledale Beck upstream of treatment system
COD	< 1.0	< 1.0
BOD	< 1.0	< 1.0
NH_4	< 0.01	< 0.01
NO_3	< 0.2 – 0.3	< 0.2 – 0.8
PO_4	< 0.2 – 5.9	< 0.2 – 3.4

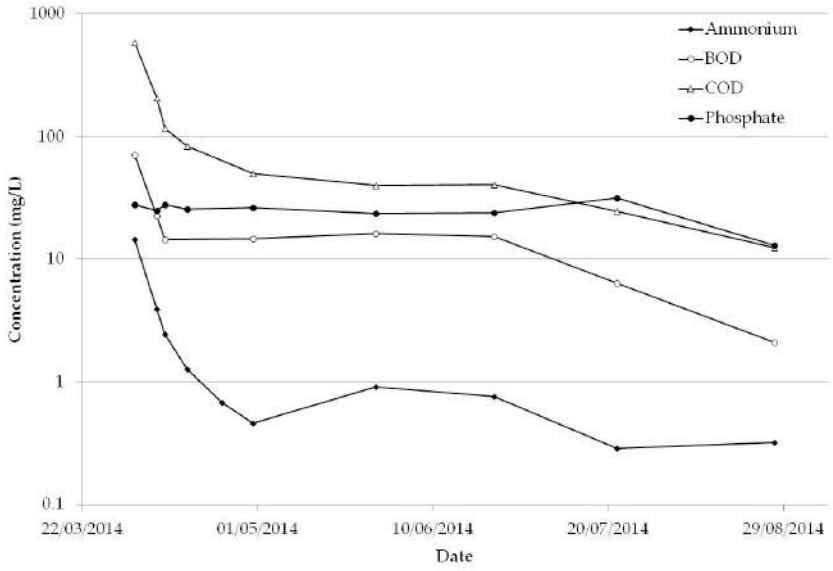

Figure 4 Concentrations of BOD, COD, NH4 and PO4 in the final effluent from the treatment system following commissioning in March 2014

There was a clear pattern of elevated concentrations of BOD, COD, PO_4 and NH_4 in the effluent water (Figure 4) compared to the Coledale Beck and Level 1 discharge (Table 2). In the final effluent water to the Coledale Beck initial concentrations of BOD, COD, PO_4 and NH_4 were 71 mg/L, 587 mg/L, 28 mg/L and 14.6 mg/L respectively. In the effluent directly from the VFPs concentrations were much higher: 82 mg/L NH_4, BOD of up to 100 mg/L, and COD of up to 3084 mg/L. However, these concentrations have dropped rapidly since water first emerged from the treatment system. These elevated concentrations were also reflected in the Coledale Beck downstream from the treatment system effluent (Figure 5), albeit absolute concentrations were lower due to dilution effects. Figure 4 illustrates that BOD, COD and NH_4 dropped rapidly within 5 – 10 days of commissioning, suggesting a 'flushing' effect through the compost substrate. NH_4

concentration in the Coledale Beck was also below the 0.2 mg/L value requested by the Environment Agency within 5 – 10 days.

The exception to this trend of rapidly decreasing concentrations was PO_4, which remained elevated in the effluent from the treatment system (Figure 4). Over the 6 month monitoring period, the mean PO_4 concentration was 4.3 mg/L in the Coledale Beck downstream of the treatment system effluent, compared to a mean of 1.8 mg/L upstream of the treatment system. The treatment system substrate therefore continues to act as a source of phosphate to the Coledale Beck. The downstream monitoring location on the Coledale Beck is only 70 m downstream from the final treatment system effluent point (this is below the mixing zone of treatment system effluent with the Coledale Beck). Additional dilution further downstream likely results in a decrease in PO_4 concentrations, and therefore in this instance the impact of elevated PO_4 is probably spatially limited. Nevertheless, the potential for elevated concentrations of nutrients, BOD, COD and NH_4 is an important consideration in the planning of passive, compost-based, treatment systems, especially where final discharge is to sensitive watercourses.

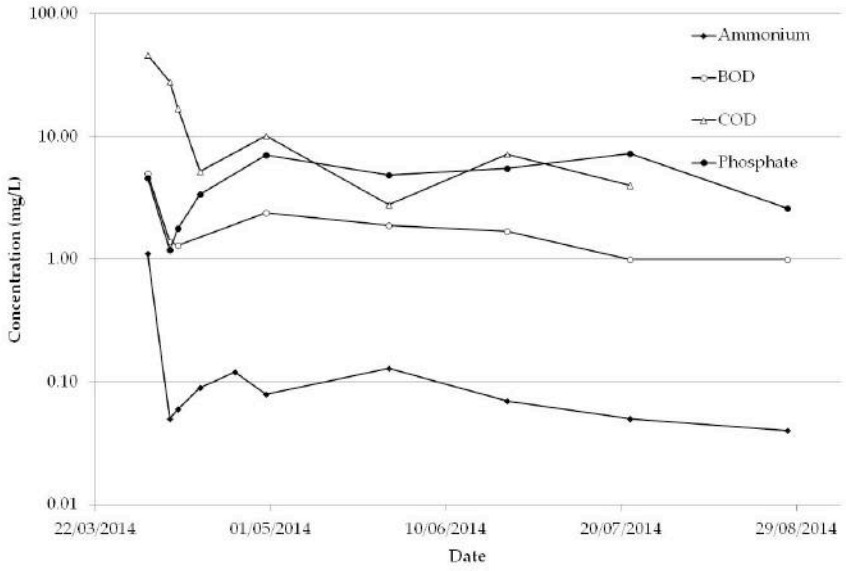

Figure 5 Concentrations of BOD, COD, NH4 and PO4 in the Coledale Beck downstream of the treatment system following commissioning in March 2014

CONCLUSIONS

The Force Crag mine water treatment system is the first full-scale passive treatment scheme for metal mine drainage in the UK. The system comprises two parallel Vertical Flow Ponds, which contain a compost substrate to encourage attenuation of zinc via bacterial sulfate reduction. The VFPs have a short hydraulic residence time for units of this type: 15 – 20 hours. For the first 6 months of operation the two VFPs consistently removed in excess of 90% of the zinc from the Level 1 discharge water at Force Crag, and overall treatment efficiency of the system for zinc removal was greater than 95%. Sulfate concentrations have consistently decreased across the treatment system, suggesting that bacterial sulfate reduction was an important attenuation mechanism. However, solid phase analyses of the compost substrate need to be undertaken to confirm this.

Over the first 6 months of operation secondary contamination was a concern. Concentrations of BOD, COD, NH_4, and PO_4 were initially elevated in the effluent water from the system, but rapidly decreased in all cases with the exception of PO_4. In the case of Force Crag, there are no downstream water users that could have been affected by these elevated concentrations, but in other situations measures may need to be put in place to deal with elevated organics / nutrients concentrations

from passive mine water treatment systems, especially if there are abstractions in close proximity to the effluent point from the treatment system.

ACKNOWLEDGEMENTS

The Force Crag treatment system was funded by the UK Department for Environment Food and Rural Affairs (Defra), and was an initiative of a partnership comprising the UK Coal Authority, Environment Agency, National Trust and Newcastle University. Construction of the system was managed by the Coal Authority. The consulting firm Atkins undertook the civil engineering design of the scheme, and the construction contractor was Bentleys. The views expressed in this paper are those of the authors only, and not necessarily any of the organizations mentioned herein.

2. *Phu Bia Mining Company, Lao Peoples Democratic Republic*

ABSTRACT

PanAust Limited (PanAust), through its Laos-registered subsidiary Phu Bia Mining (PBM), owns and operates the Phu Kham Copper-Gold Operation in the Lao Peoples Democratic Republic (Laos). The operation includes a flooded tailings storage facility that discharges through two toe drains installed in the facility's earthen dam. The toe drain discharges are alkaline with pH 6-7 and contain 2-10 mg/L iron and manganese. In May 2013, a passive system was installed to treat the toe drain discharges. The system consists of an oxidation pond followed by an oxic aggregate bed that is constructed with granite aggregate manufactured on-site. The system has treated, on average, 187 m^3/hr of flow to an effluent containing pH 7.2, 6.5 mg/L dissolved oxygen, 176 mg/L alkalinity ($CaCO_3$), 0.01 mg/L dissolved iron, and 0.14 mg/L dissolved manganese. The project demonstrates the feasibility of treating large toe drain discharges passively and the suitability of non-calcareous aggregate as a reactive media where the mine water is alkaline and contaminated with moderate concentrations of iron and manganese.

Keywords: copper mining, tailing storage facility, acid rock drainage, passive treatment

INTRODUCTION

The management of mine tailings in wet climates often includes their permanent subaqueous disposal in constructed storage reservoirs. The earthen dams that create the storage reservoirs are typically constructed with one or multiple internal seepage collection systems that collect infiltration into the dam and discharge through toe drains. During the years or decades over which the dam is raised and tailings are disposed of in the tailings disposal facility (TSF), the primary discharge is through the toe drains. As the toe drain effluent is often a final discharge point from the TSF, its quality is subject to discharge criteria defined in the mine permit. Mine operators typically attempt to maintain good quality water in the tailings reservoir (alkaline with low metals) so that the toe drain discharges are also good quality. Not uncommonly, however, the toe drain discharges contain elevated concentrations of iron (Fe) and manganese (Mn) that exceed the permit limits, requiring treatment during and after the mine's operation.

The Phu Kham Copper-Gold Operation in Laos includes a TSF created by a large earthen dam that contains two toe drains. The toe drains discharge alkaline water with concentrations of Fe and Mn ranging between 2 and 10 mg/L. In 2013, a passive treatment system was installed that receives the full flow from the toe drains. The system's construction is innovative in its use of granite aggregate instead of limestone aggregate for removal of Mn. This paper describes the construction of the treatment system in 2013, an investigation of the condition of the aggregate in 2014, and its treatment performance over its first 1.5 years of operation.

METHODOLOGY

Water samples were collected by PBM staff. Flow rates were measured at V-notch weirs located 10-20 metres below each of the two toe drain discharges. Water samples were collected at the weirs, within the treatment system, and at the final effluent channel. Analyses were made in the field for pH, DO, temperature, specific conductivity, and oxidation-reduction potential. Water samples were collected daily and transferred within 4 hours to the on-site laboratory where alkalinity was measured by titration, and concentrations of dissolved (<0.45 micron) Ag, As, Cu, Fe, Pb, Ca, Mg, Mn, Mo, Ni, Na and Zn were measured by atomic emission spectroscopy. A separate set of samples were collected approximately monthly from the toe drains and submitted to ALS Environmental laboratory in Bangkok for analysis of total concentrations of a much wider suite of elements.

Project site

The Phu Kham Copper-Gold Operation in Xaysomboun Province in Laos is located in a challenging mountainous environment subject to high monsoonal rainfall. The main rock types in the project area are red bed (korat group), limestone, andesite ash flow tuff (metamorphosed to schist), cataclastite and granite. The host sequence forms the upper plate of a thrust fault with red bed siltstone making up the foot wall. The Phu Kham deposit is sericitic-altered porphyritic igneous and magmatite - chalcopycite skarn clasts. The mineralisation shows a trend along north-north-west which is mainly hosted in highly foliated schist between red bed as the foot wall and cataclastite, limestone and granite as the top of the hanging wall. The sulphide mineral assemblage is predominantly pyrite, chalcopyrite, chalcocite, bornite, and covellite.

Before the Phu Kham operation commenced, acid rock drainage (ARD) was identified as the single most significant environmental risk. Potentially acid-forming waste rock and tailings were identified as by-products of the mining and processing of ore as part of the Environmental and Social Impact Assessment process. As a result, a detailed acid rock management plan was formed prior to mining and processing commencing.

PanAust has developed an integrated life-of-mine approach accounting for the entire 182 million tonnes of potentially acid forming (PAF) waste (Miller et al., 2012). The overall objective has been to prevent any ARD legacy from waste rock and tailings during the mine's construction, operation and after closure. To implement the plan, detailed operational guidelines incorporate ARD management practices into daily operating activities.

The ARD management plan is based on the fundamental strategy of isolating sulphidic mine waste from atmospheric oxygen. This essentially places the material within a pH and oxidation regime similar to the original ore body where pyrite is thermodynamically stable. This is the most geochemically secure option for ARD control.

Engineering options for achieving isolation from atmospheric oxygen include placing sulphidic material under a permanent water cover or construction of an engineered seal that essentially reduces oxygen transfer to geological rates. At Phu Kham, both strategies have been adopted with the higher sulphidic acid-generating waste rock and tailings reporting to the tailings impoundment (which maintains a minimum two metres of water cover) and the lower sulphidic acid-generating waste isolated in cells and zones (PAF cells) within the downstream portion of the tailings storage facility embankment.

RESULTS AND DISCUSSION

Toe drain characterisation

The primary toe drain (#1) has discharged since 2008. The effluent has always been alkaline. Table 1 shows the average total metal concentrations between 2008 and 2012. Concentrations of all hazardous metals are very low and well below effluent targets. The only metals that exceed effluent targets are Fe and Mn.

Table 1 Average pH and total metal concentrations for Toe Drain #1, Feb 2008 – May 2012. Analyses by ALS Environmental (Bangkok).

	pH	Al	As	Cd	Cu	Fe	Pb	Mn	Ni	Zn

Limit	6-9	-	0.1	0.03	0.3	1.0	0.2	0.5	0.2	0.5

Passive system construction

The design of the treatment system is shown in Figure 1. The system includes a settling pond followed by a bed of aggregate. The design follows US Bureau of Mines guidance provided in 1994 (Hedin, Nairn & Kleinmann, 1994) and more recent advances in the use of limestone aggregate in mine water treatment (Hedin et al., 2013). The intention of the design is to oxidize and settle Fe solids in the pond and to oxidize and trap Mn solids in the aggregate bed. The two toe drains are combined into a single piped flow that discharges into the pond through a horizontal fountain. The Fe pond has a surface area of 1,800 m^2 and a depth of 2 m. The pond contains three geotextile curtains that spread flow across the pond and promote solids settling. Water flows from the pond through a wide shallow channel in to the aggregate bed. The bed has a surface area of 4,200 m^2, is 2 m deep, and contains 10,100 tonne of material.

The bed was constructed with granite aggregate produced on-site. Limestone, which is commonly used in Mn systems such as this, was not available. Figure 2 shows the particle size distribution of the aggregate used in the treatment system.

The elevation of water in the system is controlled by the final effluent. The design intended that the water elevation in the aggregate bed should be 10-15 cm below the aggregate surface. This feature was expected to minimise short circuiting of flow on top of the aggregate and also limit plant growth in the system.

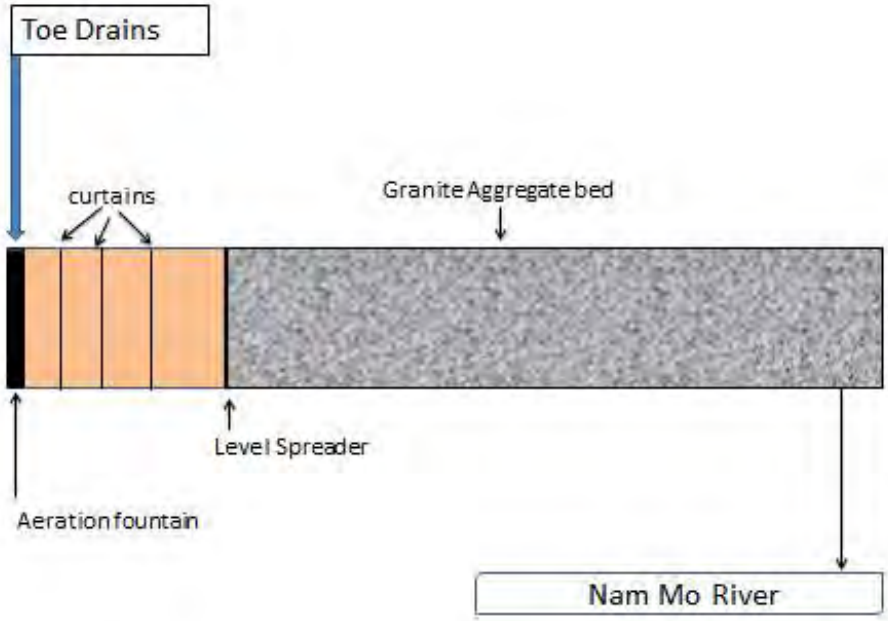

Figure 1 Design of the passive treatment systems

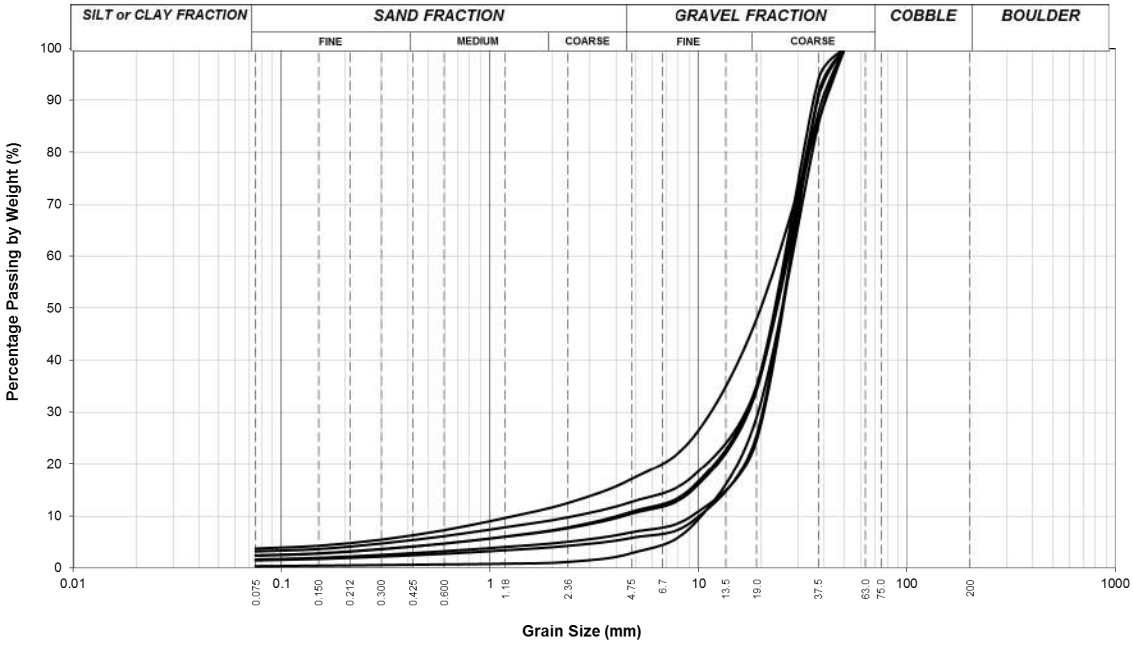

Figure 2 Particle size distribution for aggregate used in the passive system. The lines represent multiple samples collected from the bed after its construction.

Passive system treatment effectiveness

Table 2 shows the average chemistry of the treatment system influents, the calculated influent to the pond, the influent to the aggregate bed, and the final system discharge. All elemental concentrations shown are dissolved. Flow through the oxidation pond decreased Fe^D to from 2.1 mg/L to less than 0.1 mg/L and Mn^D from 4.0 mg/L to 2.6 mg/L. Flow through the aggregate bed decreased Fe^D below 0.01 mg/L and Mn to 0.07 mg/L.

Figure 3 shows concentrations of Mn^D between June 2013 and October 2014. Final effluent concentrations of Mn^D did not consistently meet the 0.5 mg/L target until July 9, 2013; 27 days after the system was first put into operation. Since that date, the discharge has contained less than 0.5 mg/L on every sampling occasion.

Table 2 Average flow and chemistry for the passive treatment system, Jun 2013 – Oct 2014. Flow rates are measured at weirs at Toe Drains #1 and #2. Other stations by addition.

	Flow	pH	DO	Alk	Ca^D	Mg^D	Na^D	Fe^D	Mn^D
	m^3/hr	s.u.	mg/L	mg/L	mg/L	mg/L	mg/L	mg/L	mg/L
Toe Drain #1	34.4	6.4	2.7	142	109	21	7.0	3.0	4.9

Into pond*	52.2	6.4	2,7	177	119	25	7.4	2.1	4.0
Into granite bed	52.2	6.9	6.4	183	122	25	6.5	<0.1	2.6
Final	52.2	7.2	6.5	176	116	25	6.4	<0.1	0.1

** calculated mixture of Toe Drain #1 and #2*

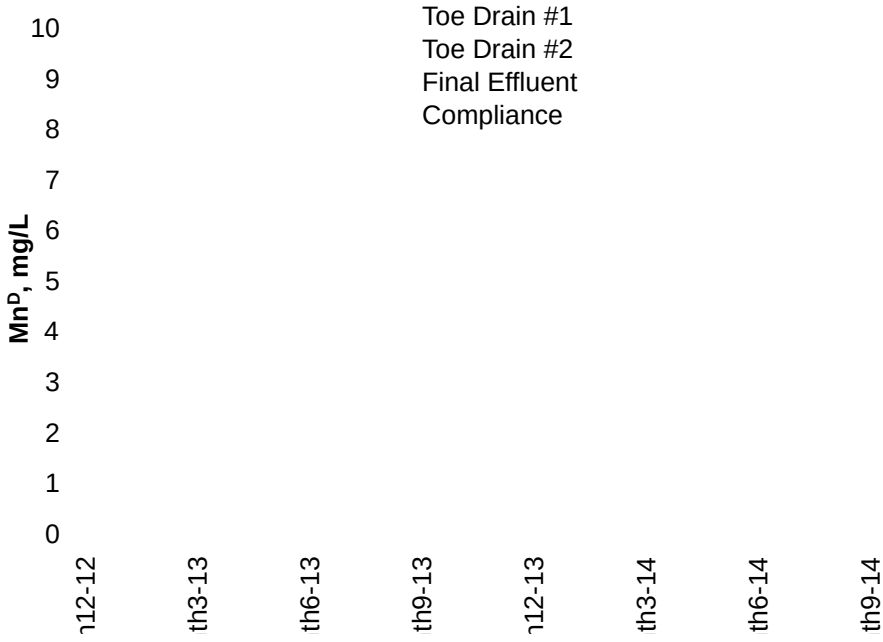

Figure 3 Concentrations of dissolved Mn at the toe drains (system influents) and the aggregate bed final effluent.

Table 3 Average loads (kg/d) of major water constituents at the treatment system stations, Jun 2013 – Oct 2014. % removal is the loss between the sum of the two influents and the final.

	Alk	Ca^D	Mg^D	Fe^D	Mn^D	Na^D
	kg/d	kg/d	kg/d	kg/d	kg/d	kg/d
Toe Drain #1	422	324	62	8.9	14.6	21
Toe Drain #2	375	211	52	0.5	3.7	12
Into granite bed	825	550	113	0.2	11.6	29
Final	794	523	113	0.0	0.6	29
% removal	0%	2%	2%	99%	96%	13%

Table 3 shows calculated loads of major constituents through the passive system. The system has negligible effect on alkalinity, calcium (Ca) and magnesium (Mg). A modest removal of sodium (Na) is indicated. The major effect of the system is removal of 96-99% of the Fe and Mn loading.

In mid-2014 water was observed flowing on top of a portion of the aggregate bed. In October 2014 an excavator was mobilised to investigate the change in hydraulics and also to investigate the condition of the aggregate. Flow on the top of the aggregate was limited to the first 25% of the bed. The investigation found algal growth on top of the stone that had created a dense biofilm that promoted flow of water on top of it. When the algal growth was disrupted by mixing the stone, water flowed into the aggregate and no longer flowed on the surface. The cause of the algal growth was suspected to be due to settling of the stone in the first portion of the bed, which allowed water on the surface during high flow conditions. During these conditions, algae growth was enabled. As a result of this observation, the effluent of the bed was lowered by 50 cm so that water would never flow on the surface and growth of algae would be inhibited.

The aggregate in the bed was inspected for signs of Mn removal. The raw granite is grey. Mn oxides form a black coating on the rocks. The aggregate in the final 25% of the bed did not have any black coloring, indicating that little Mn removal is occurring in this section (Figure 4a). As the investigation moved forward into the bed, stones stained black became visible (Figure 4b). In the first quarter of the bed, most of the stone in the top 30 cm was black (Figure 4c). The Mn staining was limited to the top 50 cm of the bed. Beneath 50 cm the aggregate retained its original grey color. These observations indicate that little Mn removal is occurring in the bottom 1.5 m of aggregate. When combined with the observations from the end of the bed, it was apparent that only 15% of the aggregate was involved in Mn removal. This condition likely has two explanations. First, removal of Mn is so effective in the first half of the bed that there is little Mn left for removal in the second half of the bed. This explanation suggests there is a large excess capacity for Mn removal in the second half of the bed which will be useful should Mn loadings increase. The observation that there is little visible Mn removal occurring below 50 cm suggests that flow is not well distributed through the bed. As the influent and effluent structures are both at the surface, there is an apparent preference of flow in the top 50 cm of the bed. This condition could be partially corrected by reconstructing the effluent as a perforated pipe placed on the bottom of the bed. There are no plans to make this change at this time.

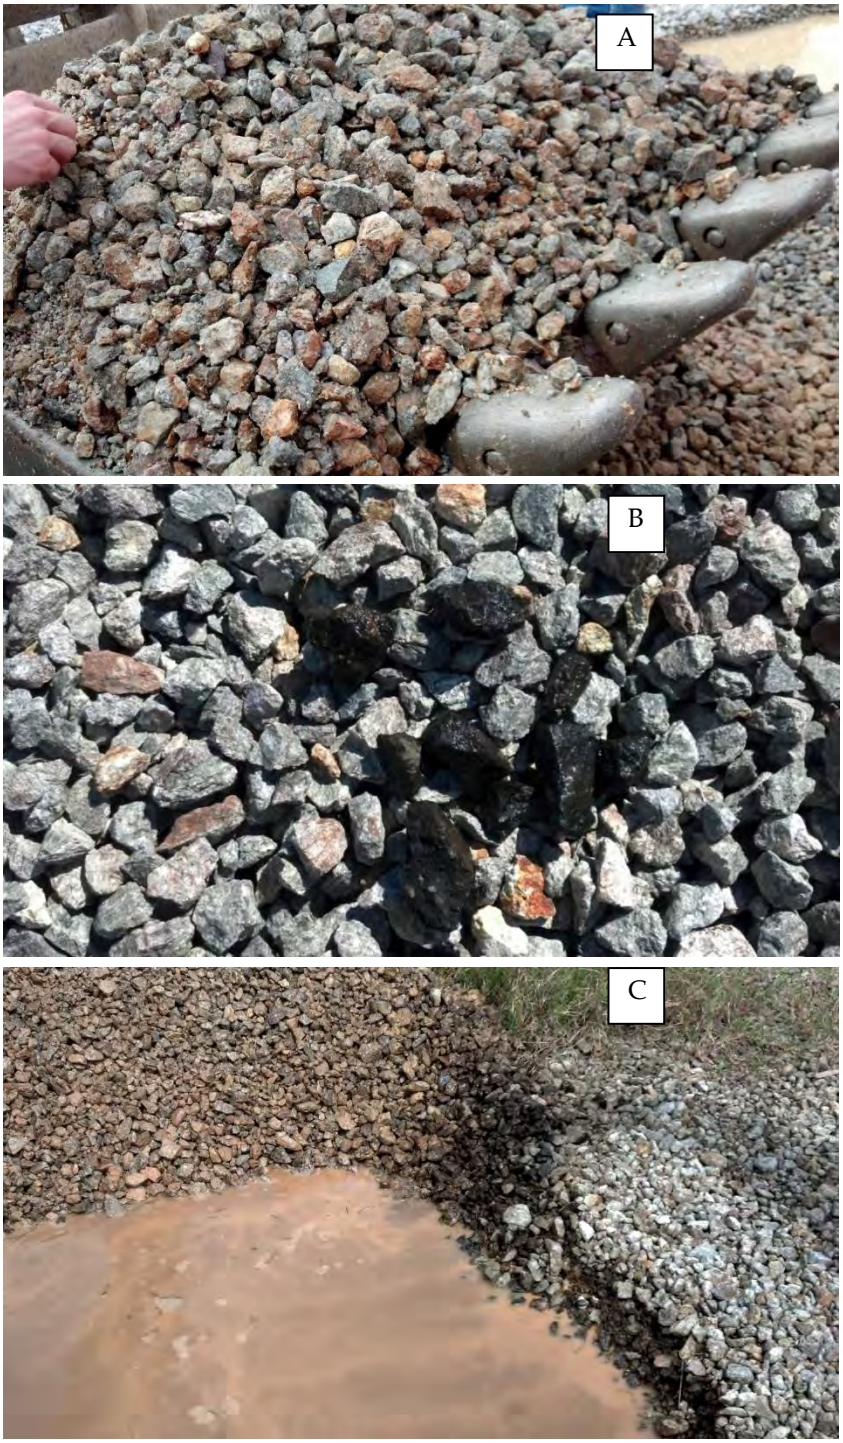

Figure 4 Aggregate encountered during system investigation. A) clean granite aggregate at the end of the system. B) black Mn-coated granite placed on clean stone to show contrast; C) layer of Mn-coated stone found in the first half of the bed.

This project demonstrates the feasibility for passive treatment of toe drain discharges when their chemistry is alkaline and the contamination is limited to moderate concentrations of Fe and Mn. These conditions are not uncommon as the primary author has observed similar chemistry at

tailings facility toes drains in Brazil and Tasmania. Mine planners should recognise that toe drains may need long-term treatment and reserve adequate land for placement of passive treatment systems below the toe drain discharges.

This project demonstrates that the passive removal of Mn from alkaline mine water does not require a limestone substrate. In the coalfield of eastern USA, where passive treatment technologies have been developed, limestone aggregate is preferred because it is readily available and its acid-neutralising capacity is considered a benefit. The very effective Mn removal in this system suggests that that the removal of Mn is dependent on physical aspects of the substrate, not chemical aspects. This finding should be of benefit in areas where mine waters are naturally alkaline and limestone aggregate is not available.

ABSTRACT

This paper presents data from a field trial for the passive removal of Fe from circa pH 3 metal mine water. In a 1 m^3 intermediate bulk container (IBC) converted into a vertical flow reactor (named here the VFR), mine water was passed through in a downward direction through an unreactive reactive gravel bed under aerobic saturated conditions. The VFR was deployed for a period of 414 days at the Cwm Rheidol mine, an abandoned historic Pb/Zn mine in Wales, UK that discharges circa pH 3 AMD with average Fe concentrations of 95 mg/L. Removal of iron, as high as (85%) was shown with an average of 65% achieved over the trial period from an average flow of 0.38 L/min. Results were encouraging, a very simple system providing an option to treat acidic coal mine drainage where iron is the principal contaminant or pre-treat 'metal mine' water by removing the bulk of the Fe as an iron-rich sludge to help prevent clogging of subsequent treatment stages for more environmentally toxic elements. The Fe removal mechanism is thought to be predominantly by the crystal growth and/or aggregation and filtration of nanoparticulate Fe(III) in the VFR. Centrifugation of influent water samples from site indicated that 80 – 90 % of the Fe in the inflow water is present as $Fe(III)_{(s)}$ particles < 35 nm. Microbial Fe(II) oxidation is suspected to be important along the flow path before water enters the VFR and to a small extent within the VFR. Analysis of the sludge indicates that schwertmannite is the dominant mineral phase.

Keywords: mine water, passive treatment, vertical flow reactor, Wales/UK

INTRODUCTION

Historically, north and south Wales, Cornwall and the midlands were extensively mined for base metal sulphides and coal. It is estimated that there are tens to thousands of abandoned mining facilities including onshore mining and quarrying sites (Palumbo-Roe and Colman, 2010). The clean-up of water from abandoned coal mines is the responsibility of the UK Coal Authority, but since the introduction of the Water Framework Directive in 2006, the Coal Authority and Natural Resources Wales have been working closely together to find long-term, low cost treatments options for the clean-up of the metal mines.

National Resources Wales (formerly known as the Environment Agency Wales) published the Metal Mines Strategy for Wales (Johnston, 2004) which lists the top fifty most polluting sites in Wales that were identified, following the monitoring of 5042 km of river stretches, 108 km of which failed ecosystem objectives as a direct consequence of pollution from abandoned mines (Jarvis et al., 2007). 38 of those top 50 sites are located in the Mid-Wales district of Ceredigion.

Metal mine water is commonly treated by active means, where chemicals are added to raise the solution pH and precipitate metals and metalloids. This tends to form a high volume of sludge, which, if containing metals other than Fe, for example, Zn, Pb, Cd may be classified and disposed of as hazardous waste, further adding capital and operational costs. Consequently, active treatment might be impractical, bearing in mind that the Coal Authority is a governmental organisation and mine water can continue to pollute for tens to hundreds of years. As such, active treatment is not currently considered for application to the majority of discharges in former UK mining regions. Furthermore, the metal mining areas tend to be concentrated in remote steep sided valleys, where access is difficult and a lack of basic infrastructure, such as power, exists. For this reason, the adoption of passive treatment is favoured. However, passive treatment options for metal mine drainage are not well developed in the UK.

Looking outside of the UK many countries have developed and deployed a host of these passive technologies (*e.g.* anoxic limestone drains) for treating metal-rich AMD (Brodie et al., 1991, Hedin et al., 1991, Skousen, 1991). Passive mine water treatment is commonly achieved via harnessing of naturally occurring physiochemical and biological processes, for example the manipulation of solubility via changes in pH by reaction with limestone (Blowes et al., 2003), altering the redox conditions through the use of organic matter (Lottermoser, 2007, Wildeman et al., 1993), the addition of high surface area materials used to provide sorption sites (Jarvis and Younger, 2001, Younger, 2000) or the use of low cost reactive materials (Warrender et al., 2011). The longevity of these treatments can be compromised by clogging due to the Fe (or Al) precipitates formed during the neutralisation of AMD with limestone or other alkalinity producing systems (Younger et al., 2002). This study considers these treatment methods with a modular approach, whereby a system such as a VFR could be used to remove Fe (as the bulk contaminant) from AMD. Such a technology could be deployed where Fe alone is the contaminant of concern (*e.g.* acidic coal mine drainage) or as a pre filter for Fe removal where Fe and other solubilized metals such as Zn occur together, thus allowing prolonged longevity for the second metal removal stage. The benefits of this would be the reduction of the volume of the 'hazardous' waste and the production of a clean (in terms of free of organics) iron-rich sludge that could have reuse value. The focus of this study is therefore to test the VFR as an Fe removal pre-treatment system for AMD.

On its course through the system, mine water passes down through the gravel bed support media. The vertical flow design reduces the footprint compared to more traditional systems that require large areas of land. Sapsford et al. (2007) detailed the testing of a VFR achieving 50% Fe removal from circum-neutral (pH 6–7) coal mine drainage with Fe concentrations of 8–10 mg/L. Iron removal occurred via filtration of iron hydroxide particles (formed in the water column) and surface-catalysed oxidation of Fe(II) (and precipitation) of Fe(III) hydroxide surfaces. This paper reports the results and possible Fe removal mechanisms of a VFR trialled for removal of Fe from pH 3 mine water.

METHODOLOGY

The system was adapted from the original design used in the initial field trial at the Taff Merthyr site in South Wales (Dey et al., 2003), using a modified 1 m³ intermediate bulk container (IBC, see fig. 1 in Sapsford, Florence, Pope and Trumm, these proceedings). A length of coiled, slotted drainage pipe was placed in the bottom of the tank. 30 mm angular coarse grained siliceous chips were added to the container to secure the pipe and provide a stable base on top of which a 200 mm depth layer of 5–10 mm grain size siliceous gravel was added (Fig. 2). A down flow of mine water was then maintained through the water column and through the ochre bed. Driving head was set via a swan neck mechanism through which the treated water was discharged. The VFR was set up alongside the River Rheidol to take a proportion of the flow from the lower number 9 adit discharge pipe of the Cwm Rheidol mine located at the base of the mine. Water was piped to the VFR under gravity from the adit discharge pipe (Fig. 1).

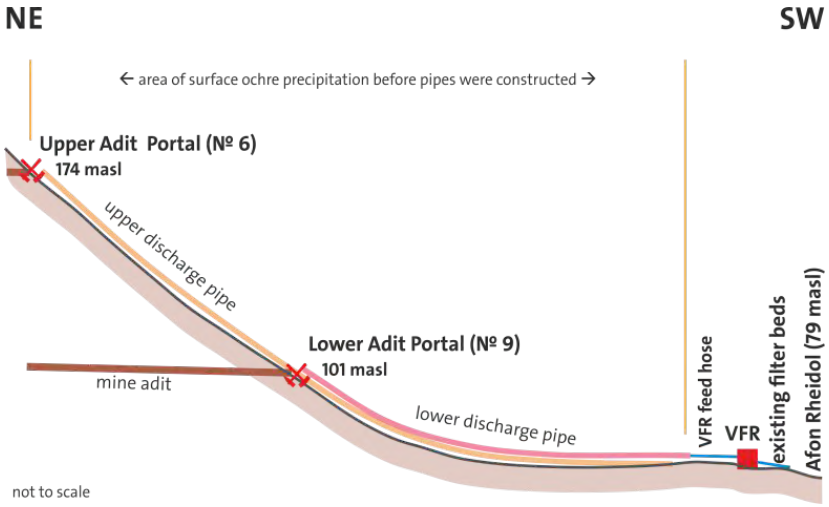

Figure 1 Schematic cross section of the upper number 6 adit and the lower number 9 adit and the location of the VFR at Cwm Rheidol. masl: meters above sea level.

Field data and water sampling

All field measurements of pH, EC, ORP and temperature were taken using Hanna combination meters HI-9828. The dissolved oxygen (DO), electrical conductivity and pH probes were calibrated at each site visit using the manufacturer's calibration procedure set out in the operator's manual. Flow rates were measured using the bucket-and-stop-watch-method.

At each of the 34 site visits between 2011-05-17 to 2012-07-04, filtered and unfiltered water samples were collected from the inflow and outflow. For the filtered samples, 0.2 μm Acrodisc PF syringe filters fitted to Plastipak syringes were used. In this study, the term filtered is used to describe samples that pass a 0.2 μm filter and is not a definition used to describe 'dissolved' species. All water samples were collected in 30 mL containers and rinsed with the sample and acidified with HNO_3 to stabilize the water chemistry. Samples collected on site were placed immediately into a dark cool box and stored at 4 °C until analysis was possible. Samples were analysed using a Perkin Elmer Optima 2100DV ICP-OES. Filtered unacidified inflow and outflow samples were also collected for sulphate analysis using a Dionex® ICS-2000 Ion Chromatography System Whilst samples for Fe total and Fe filtered were collected and analysed from each sample visit, Fe(II) was only measured on 11 of the sampling intervals. On the occasions that Fe(II) was measured in the field, filtered samples were analysed using a potable Merck NOVA60 spectrophotometer with appropriate Merck Fe test cells. Samples collected for Fe(II) analysis in the laboratory using a Hitachi U1900 spectrophotometer, were filtered and acidified with 20% (v/v) HCl. Samples for Fe(II) that could not be analysed on the same day were frozen until analysis was possible.

Centrifugation

A centrifugation method adapted from Hüttig and Zänker (2004) was used to determine the Fe particle size distribution in the unfiltered inflow water. In this context, truly dissolved relates to a particle size of less than 50 nm, which is close to the 20 nm cut off between "truly dissolved" and colloids suggested by Shiller (2003). 20 tubes of fresh mine water were collected in the field (10 × 2 to duplicate the experiment). Parallel centrifugation of each 2 × 50 mL of raw water was carried out at rotor speeds calculated as per Table 1 at rotor speeds of 300, 500, 700, 1000, 3000 and 5000 over a period of 1 h and 3500 rpm (rounds per minute) over a period of 2 h due to the limitation of the centrifuge instrument speed. Equivalent RCF values (relative centrifugal force, which is equivalent to the *g*-force used in table 1) at a given point in the centrifuge tube were calculated according to the equation 1:

$$RCF = 11.18 \times r \times U1000 \quad [1]$$

Where *r*: distance between the rotation axis and the particle in the centrifuge tube in cm and *U*: rpm rounds per min. After centrifuging, the supernatant was syringed from the centrifuge tube using a pipette. The sample was transferred to a new sample container, acidified with 20% nitric acid and the total unfiltered Fe concentration analysed by ICP-OES.

Table 1 Centrifuge parameters and calculated values

RPM	*t*, h	*g'*, -	*d*, nm
raw	-		
0	1		
300	1	283	683
500	1	474	417
700	1	659	293
1000	1	945	207
2000	1	1889	101
4000	1	4181	50
5000	1	5254	39
3500	2	3913	35

The maximum size of the particles still present in the supernatant was calculated with an assumed density of the colloids and under the assumption of a spherical form of the particles in accordance with equation 2:

$$d = 18\eta \ln r1 r0 (\rho 2 - \rho 1) \omega 2 t \quad [2]$$

with d diameter of particle in cm, ρ_2 density in g cm^{-3} (3.96 g cm^{-3} for ferrihydrite), r_0 distance of water level in vial to rotation axis before taking sample in cm, r_1 distance of water level in vial to rotation axis after taking sample in cm, t duration of centrifuging in s, η viscosity of water at 25 °C (0.008941 g cm^{-1} s), ρ_1 density of water at 25 °C (0.997 g cm^{-3}) and ω angular velocity in s^{-1} = U × $2\pi 60$.

PHREEQC Modelling

A full water analysis was used for chemical thermodynamic modelling with PHREEQC interactive Version 3.1.1.8288 (2013-12-05) and the WATEQ4F database (6895 2012-08-21 18:10:05Z) extended with kinetic data of schwertmannite.

Sludge analysis

Samples for XRD analysis were dried overnight at 60 °C, finely ground and placed in a slide window covered by glass plate, amorphous samples were scanned for 12 h. Settling velocities of the Cwm Rheidol sludge from within the VFR were calculated by measuring the distance at which the particles settled over time.

RESULTS AND DISCUSSION

Fe inflow and outflow concentrations

The data for iron show that average removal for Fe(total) is 65% on the sampling occasion across the 13 months period (Table 2). Fe removal rates remained consistent throughout the trial period and the flow rates stabilised between days 33 and 387 averaging 0.39 L/min (Fig. 3), which shows that after the initial drop, the permeability of the bed did not decrease significantly over time. On average, about 85% of the Fe in the influent is Fe-filtered (*i.e.* passing a 0.2 μm filter) and on average 99% of the effluent iron passes a 0.2 μm filter. The removal of Fe-Filtered is on average 53 mg/L (Table 1). This demonstrates that the VFR removes Fe(III) of < 0.2 μm, where the Fe could either be particulate (smaller than 0.2 μm, *i.e.* colloidal or nanoparticulate) or truly dissolved. Likely candidates for the removal of Fe-Filtered are (i) Microbial Fe(II) oxidation and precipitation of a Fe(III) solid phases (ii) Filtration of particulate-$Fe(III)_{(s)}$ which is < 0.2 μm and/or (iv) adsorption of dissolved Fe(III) to HFO followed by precipitation (self-seeding crystal growth). These are discussed in more detail below.

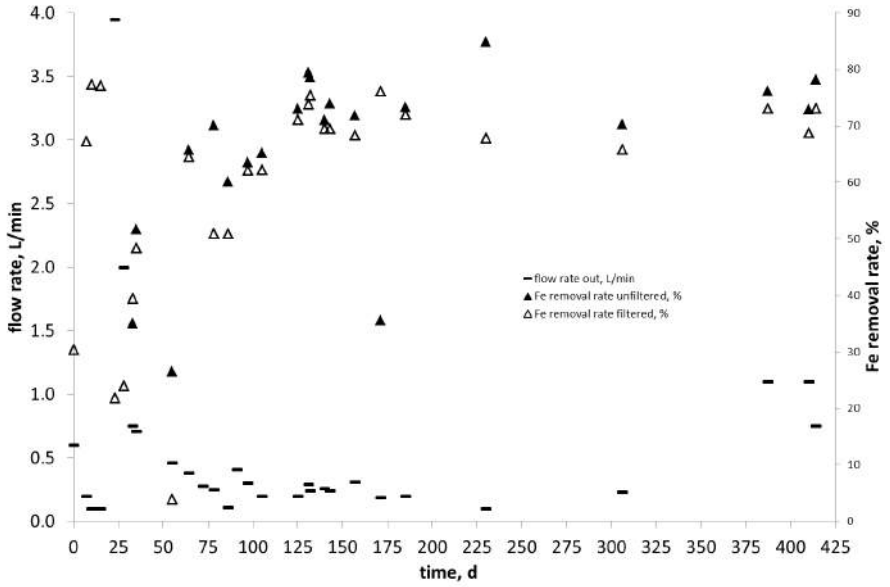

Figure 3 Filtered and unfiltered Fe(total) removal rate and flow rate of the VFR over time

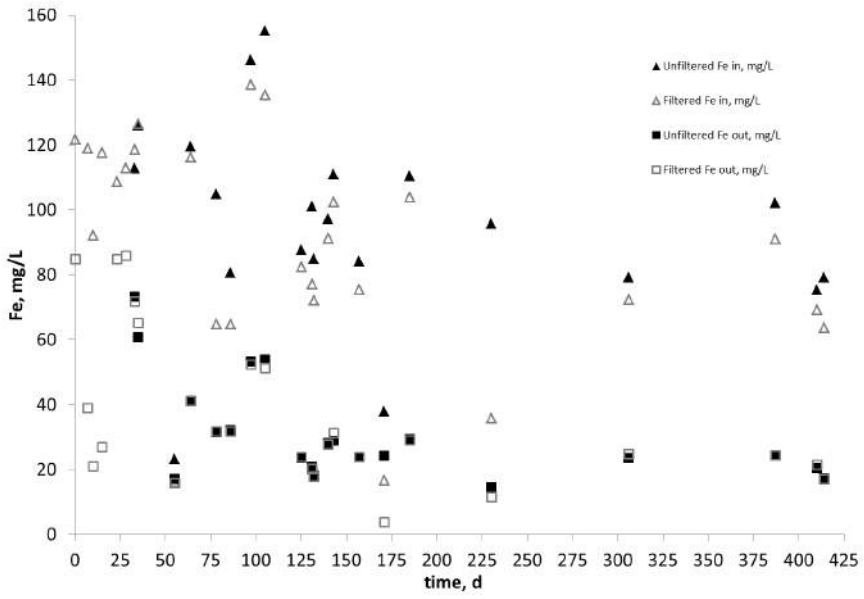

Figure 4 Filtered and unfiltered VFR inflow and outflow Fe(total) concentrations over time

Oxidation of Fe(II) and precipitation of Fe(III)(s)

Where Fe(II) analyses were performed in the field, it was apparent that Fe(II) only made up a small proportion of the influent Fe (highest observed was 42 % of the influent Fe-Filtered on 18-11-11). Fe(II) was removed in the VFR, with 7 of the 11 sampling occasions falling below the detection limit of the spectrophotometric method used (0.2 mg/L). The minimum removal of Fe(II) was 83 % on 30-06-12 (note: with only a short residence time of 10 h). Thus it is clear that despite Fe(II) being variable, it was typically a small component of the Fe-Filtered and that it was removed effectively in the VFR. Based on the microbial analyses (Florence, 2014) and the published rates for abiotic and biotic Fe(II) oxidation at low pH, the proposed mechanism for the observed results is microbial Fe(II) oxidation.

However, the change in filtered Fe between the influent and effluent cannot be simply explained by the oxidation of Fe(II), and in all of the cases observed during sampling the removal of filterable influent iron that initially passes a 0.2 μm filter cannot be explained by oxidation of iron (II) to an insoluble Fe(III) product. Thus the dominant removal for filterable iron must involve changes in dissolved Fe(III) or colloidal to nanoparticulate Fe(III) that passes the 0.2 μm filter.

Iron removal mechanism: Precipitation versus filtration of nanoparticulate-Fe(III)(s

70% of the Fe in the inflow passing a 0.2 μm filter is retained in the VFR (Fig. 4). On average, the remaining 30% of the inflow Fe is still present in the outflow. Water at Cwm Rheidol is typically well oxidised. The remaining 30% of the Fe that is not being removed was Fe(III) in either truly dissolved form (single solvated Fe(III) ions) or particulate $Fe(III)_{(s)}$ of < 200 nm. A centrifuge study was used to examine the size distribution for possible particulate Fe(III). The Fe data showed that Fe does decrease as centrifugation speed increases, however 87% of the iron measured in the raw mine water was still present after centrifugation for 2 h at 3500 rpm which corresponds to a stokes diameter of 35 nm. This means that on the sampling occasion, the Fe present in the mine water sample was less than 35 nm in size. This suggests that the Fe removal mechanism in the VFR involves either (i) precipitation and filtration of dissolved Fe(III) as it grows from molecular clusters to larger sizes range precipitates or aggregation and filtration of nanoparticulate Fe(III) < 35 nm in size that was present in the VFR influent.

At this scale, given the very small size of the particles involved, it becomes somewhat arbitrary what the operational definition of dissolved and particulate iron is. There is no general consensus in

the literature, under which threshold size particles can be considered "truly dissolved", and the distinction between the two is analytically challenging (Mudashiru, 2008). Commonly, 1–1000 nm are called colloids, 1–100 nm are nanoparticles and several authors call particle sizes under 30–50 nm "truly dissolved" (Daughney et al., 2004). Yet, 1 nm is still larger than the size of a molecule which is in the range of several Ångstroms but in the range of hydrated ions (Ranville and Schmiermund, 1999). As such, it could be viewed as the removal mechanism working in the system is providing retention time for the growth of ferric iron from truly dissolved state to particles large enough to be filtered out in this the VFR. Based on the results of the centrifuging and this definition of colloid ranges, it can therefore be suggested that the removal mechanism occurring in the VFR is one or a combination of nanoparticle filtration or precipitation and aggregation of truly dissolved (*i.e.* originally molecular-scale) Fe. The role of heterogeneous 'seeding' by the precipitated solids in the system is also potentially very important but it is not possible to distinguish this mechanism from the field data collected.

Sludge Composition and settling behaviour

The consistency of the sludge that accumulated within the tank was unusual and noteworthy: The sludge looked like it had been polymer dosed. Settling velocity experiments showed that the VFR precipitates had comparable settling rates to polymer dosed HDS sludge yet remained permeable throughout the field trial (Fig. 5, left). Bacterial presence is thought to be responsible for the unusual consistency of the flocs in the VFR (Fig. 2, right), which was supported by a supporting microbiological study (Florence, 2014). Sulphur analysis of the VFR sludge showed the sample to contain 4.4% sulphur which is an indication of that schwertmannite was formed. This is also consistent with XRD analysis (Fig. 5, right) that showed peaks of an amorphous Fe(III) (hydroxy) oxide that is characteristic of aged schwertmannite (Peretyazhko et al., 2009).

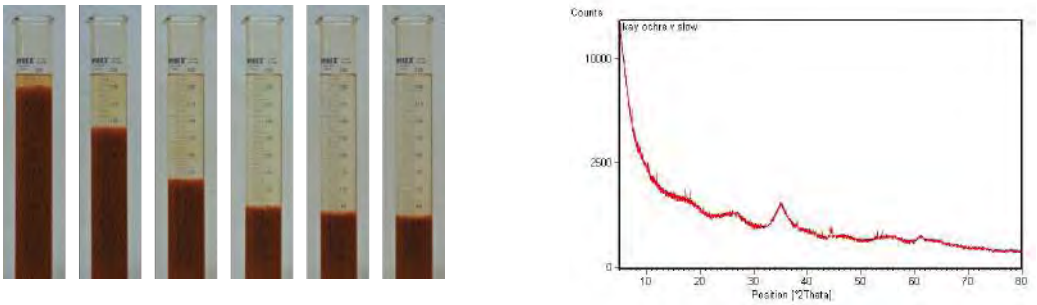

Figure 5 Left, settling properties of the precipitates that formed in the VFR at 15, 60, 120, 194, 240 and 284 s settling time. Right, XRD analysis of VFR ochre. The peaks at around 15, 35 and 45°2θ are characteristic for schwertmannite.

PHREEQC modelling

In support of the field and laboratory analyses of Fe speciation, PHREEQC modelling, suggests that Fe predominantly exists as Fe(III) (91%) and to a lesser degree of Fe(II) (9%) in the influent. The dominating Fe(III) an Fe(II) species are $FeSO_4^+$ (81%) and $FeSO_4^0$ (9%) respectively. Likely important phases that were predicted oversaturated for the mine water were K- jarosite and schwertmannite.

Iron removal in the context of the study site

Studying the layout of the mine is important as this helps to depict the chemical reactions responsible for the site being a producer of AMD (Fig. 1) and how the VFR is removing Fe from the mine water. Hydrolysis and oxidation of Fe(II) to Fe(III) occurs in the extended adits and mine workings prior to reaching the VFR. The adit length (600 m), flow rate (3 L/min) and a convex channel (0.5–1 m wide and 0.05 deep) results in a flow of approx. 0.10 m/min; data which is used to calculate the distance at which particles > 0.2 μm will settle based on Stoke's law. This was found to be 300–500 m. The first reaction occurring is the partial ochre precipitation in the adits (reaction 3):

$$Fe^{3+} + H_2O \rightarrow FeOOH\downarrow + H^+ + 2e^- \quad [3]$$

Mine water is further aerated and agitated during the pipe transport and more ochre forms in the pipe. The mine water that is now collected from the adit dicharge pipe and drained to the VFR contains the following aqueous components (based on PHREEQC results):

$$[Fe^{2+}] << [FeOH^{2+}] < [Fe^{3+}]$$

Solubility calculations and the chemical analysis at the discharge pipe shows, that part of the iron remains truly dissolved (and passes through the VFR), but that the water is still oversaturated with iron phases and able to precipitate iron, potentially as (nano-)particles < 0.2 μm in the acid mine water according to equation 3. In the VFR, due to the slow flow, prolonged residence time and intimate contact with precipitates compared to the adit and pipe flow, the (nano-)particles and/or dissolved Fe are removed. Yet, some of the dissolved Fe(III) remains in solution according to the solubility of the controlling Fe-phase at this pH (schwertmannite) and passes through the VFR without being removed.

CONCLUSION

The VRF trial at the abandoned Cwm Rheidol mine was effective at removing a large proportion of the Fe from low pH AMD. Whilst further work is required to understand the precise mechanisms of Fe removal in the VFR, where chemical, environmental and biological conditions are conducive, the VFR system has excellent potential as a Fe removal system for 'pre-treatment' (to remove a bulk of the iron) at metal mines such as Cwm Rheidol or to remove Fe from acidic coal mine drainage. Based on the results of the 13 month trial, a 50 m × 35 m VFR could remove approximately 70% of the Fe from the number 9 adit at Cwm Rheidol for at least a year without maintenance.

Passive Limestone Treatment of Mining Influenced Water with Low PH and High Concentrations of Ferric Iron

Linda Figueroa
Civil and Environmental Engineering, Colorado School of Mines, USA

ABSTRACT

Mining influenced water (MIW) with low pH and high ferric iron concentrations is typically treated in active systems by hydroxide addition. Limestone is an attractive reagent for neutralization and iron precipitation because it equilibrates at a neutral pH and thus is more amenable to lower operation and maintenance treatment systems. Existing design guidance is limited to passive limestone treatment of MIW with low ferric iron concentration or active limestone treatment of MIW with high ferric iron concentration. Extrapolation of current passive limestone bed design guidance has led to design failure for high ferric iron concentrations. Experimental and modelling analysis suggests that passive limestone reactors can be used for treatment of low pH and high ferric iron MIW.

Characteristics of passive limestone systems that will accommodate low pH and high ferric iron concentrations differ from conventional passive design guidance. Significantly smaller limestone aggregate sizes are needed to promote faster rates of limestone dissolution to minimize the reactor footprint. The limestone aggregate must be dispersed within a support matrix to provide pore space to collect iron hydroxide precipitates and maintain limestone reactivity. A multiple reactor approach is required to facilitate replacement of spent reactor media while maintaining treatment capacity.

Passive limestone treatment systems are underutilized for MIW with high ferric iron concentrations but they can be successfully designed using a modified strategy. This paper will present experimental and theoretical analysis to support a design strategy for passive limestone reactors for low pH and high ferric iron MIW.

Development of a Linear Channel Reactor for Simultaneous Sulfate Reduction and Sulfide Oxidation

Robert van Hille, Tynan Marais and Susan Harrison
Centre for Bioprocess Engineering Research, University of Cape Town, South Africa

ABSTRACT

Acid rock drainage from diffuse sources, such as waste rock dumps and coal spoils, poses a significant environmental threat to water resources in South Africa. Passive or semi-passive treatment systems are appropriate for these types of discharge. This research describes the development of a novel reactor unit that achieves simultaneous sulfate reduction and partial oxidation of the sulfide to elemental sulfur that can be recovered as a valuable resource.

The hydrodynamics within the linear channel reactor ensure the majority of the reactor remains anaerobic. Carbon microfibers are provided as a substrate for attachment of the sulfate reducing community and are rapidly colonized. The efficient biomass retention allows for operation at low hydraulic residence time, without cell washout. Sulfide is delivered to the air-water interface, where a floating biofilm containing sulfide oxidizing species develops. The biofilm restricts oxygen penetration, creating the necessary pH and redox environment for partial Sulfide oxidation.

The reactor was fed a synthetic solution containing 1 g/l sulfate, with lactate as the electron donor and carbon source at a COD to sulfate ratio of 0.7. Sulfate reduction efficiencies of over 90% were achieved at hydraulic residence times as low as 1 day. Complete conversion of the Sulfide occurred in the biofilm layer. The biofilm was harvested by collapsing onto a mesh screen 5 mm below the surface. A complete biofilm reformed within 24 hours. After 3-5 cycles the screen was removed and the sulfur recovered. A sulfur mass balance confirmed sulfur recoveries of over 70% of the reduced sulfate, or over 13.5 g/m^2.day. The reactor unit shows good potential as part of an integrated semi-passive process for ARD treatment.

ABSTRACT

Acid mine drainage (AMD) has long been considered to be an environmental hazard worldwide. South Africa faces a significant threat due from AMD, owing to its mining industry. Conventional methods of treating AMD are not always applicable. Constructed wetlands minimize some of these problems. These CWs rely mainly on microbial dissimilatory sulfate reduction (DSR) to treat AMD and a good carbon source is essential for the efficacy of this process. In South Africa, charcoal is known to be cheap, readily available and affords many chemical properties, which could be used to construct low-cost, low maintenance, efficient treatment CWs.

Although charcoal-based CWs can remediate AMD, the mechanisms are still not completely known and in this study we begin to quantify them. For this laboratory-scale study, three batch experiments in anaerobic bottles were conducted. All bottles were filled with a mineral medium containing 400 mg L^{-1} sulfate, the first bottle contained charcoal and glucose, the second contained glucose only and the third contained charcoal only. All three bottles were inoculated with an enrichment culture of sulfate reducing bacteria and the long-term incubation was realized under strict anaerobic conditions.

During the one year monitoring the sulfate concentrations decreased in all three experiments. In experiment I (bottle with charcoal and glucose) and experiment II (bottle with only glucose) sulfate concentrations decreased by an almost identical amount. Both, experiment I and II showed a much greater decline of sulfate concentration than experiment III (bottle without glucose). Thus it was concluded that the sulfate reducing bacteria were quite tolerant to the formed hydrogen sulfide (about 100 mg L^{-1} by calculation) and that the charcoal did not contain any bioavailable carbon source for DSR. Further experiments will test the appropriateness of charcoal to buffer/equalize high toxic heavy metal concentrations in continuous flow-through systems with highly varying concentrations.

ABSTRACT

One of the world's richest manganese (Mn) deposits and largest Mn mining areas lies in the foothills of the Caucasus Mountains, near the city of Chiatura in the Republic of Georgia. This study was an initial evaluation of the effects of Mn mining on water quality in the Chiatura region. Seven river and stream locations (three on the Kvirila River and four on tributaries), five untreated drinking water supplies (four springs and one groundwater well), and one untreated industrial wastewater discharge (Mn processing) were sampled and analyzed for field indicator parameters, anions, cations, and metals. Five river bed sediment sites (co-located with river water sites) were also sampled and analyzed for metals. Three of the public water supplies were contaminated by coliform bacteria, and concentrations of dissolved Mn, Fe, and Ni exceeded Georgian drinking water criteria in the groundwater supply well. The Kvirila River had very high concentrations of total Mn and Fe relative to an upstream location, especially downstream of the industrial discharges. Several tributaries also had elevated concentrations due to nonpoint source pollution from mine waste near the streams. Mn and Fe loads in the Kvirila River and tributaries were primarily in the particulate form. The river bed sediments at all five sampled river sites contained elevated metal concentrations. Mn and Ni, in particular, were very high in the Kvirila River near the discharges compared to background soil levels. Although Mn and Fe oxide solids in sediment can increase adsorption and attenuation of other metals from the water column, the contaminated sediments can also serve as a long-term residual source of metal contamination of river water, with potentially significant adverse ecological and human health effects.

Keywords: Georgia, manganese, metals, mining, water quality

INTRODUCTION

Numerous former Soviet Union (FSU) nations have diverse mining industries that account for a relatively large percentage of their economic output. The Republic of Georgia's output of ferrous and nonferrous metals, ferroalloys, industrial minerals, and fuels is second only to agriculture in terms of gross national product (Levine and Wallace 2004). The country has more than 300 explored mineral deposits, only about half of which (copper, iron ore, barite, lead, zinc, arsenic, clay, sand, gravel, and a range of secondary metals, including gold and silver) have been brought into production. Georgia has been a major producer of high-grade manganese (Mn) for about a century. It has one of the world's richest Mn deposits and largest Mn mining areas in the foothills of the Caucasus Mountains, centered around the city of Chiatura, in the Imereti region of western Georgia.

The Mn ore deposits near Chiatura, first discovered in 1849, have been exploited since 1879. The ores include pyrolusite and psilomelane (oxide ores) and rhodochroisite (carbonate ore). The country's largest producer, Chiaturmarganets, mines Mn ores from open cast and underground operations in Chiatura, which are supplied to the nearby Zestafoni ferroalloys plant. The Chiatura deposit was estimated to be 215 metric tons of Mn ore, of which about half has been depleted since mining began. Following the dissolution of the Soviet Union, mineral production in Georgia declined sharply. However, Mn has become a critical component in metallurgy, where it has a twofold application: it scavenges impurities such as oxygen, sulfur, and other elements during the steel-making process, and imparts toughness, hardness and abrasion resistance as an additive to steel. Approximately 90% of the Mn consumed in the world is used in Mn ferroalloys. The rest is used to produce nonferrous products, such as aluminum alloys, fertilizers, bricks, and paint, and for water purification.

Although the mining and processing industries in FSU nations have provided many economic and societal benefits, they also have caused significant environmental impacts, including acid mine drainage (AMD) in some areas and contamination of groundwater, surface water, and soils. The degree and significance of AMD and metal contamination of water and soils are affected by complex biochemical reactions in the disturbed ore bodies and associated mine waste materials (tailings and waste rock; Caruso and Bishop 2009; Church et al. 2007; Nimick et al. 2004). Microbes in soils and water help to oxidize the sulfide minerals and catalyze acid- and dissolved metal-generating reactions. However, in Mn deposits, AMD generation is often not the major problem.

Mn is a redox sensitive metal that can exist in water as the manganous ion (Mn^{2+}), or in the oxidized state (Mn^{4+}). Most Mn salts are very soluble in water, but Mn oxides arenot and can easily form solid oxy-hydroxide precipitates that can coat streambeds where concentrations are high. Mn speciation is governed by pH and redox conditions, with Mn^{2+} dominating at lower pH and redox potential, and an increasing proportion of colloidal Mn oxy-hydroxides above pH 5.5 (Scott et al. 2002). Dissolved concentrations undergo diel variations in streams (Brick and Moore 1996; Filipek et al. 1987). Toxic metals and nutrients can co-precipitate with or sorb to Mn oxides (MnOx) on the streambed. Surface catalyzed oxidation and photoreduction can be important processes with regard to fate and transport, particularly in mountain streams (Scott et al. 2002). Light promotes oxidation, precipitation of MnOx, and removal from streams through photosynthetically enhanced oxidation processes (Scott et al. 2002).

Mn in water can be significantly bioconcentrated by aquatic biota at lower trophic levels. Uptake by aquatic invertebrates and fish greatly increases with temperature and decreases with pH, but is not significantly affected by dissolved oxygen (DO). Dissolved Mn concentrations of about 1 mg/L can cause toxic effects in aquatic organisms, and many countries have adopted 0.2 mg/L for protection of 95% of species with 50% confidence (Howe et al. 2004). Mn can be toxic to humans through exposure routes that include ingestion, dermal exposure, and inhalation of particulate forms in air. Inhalation of particulates, especially by workers at Mn mines and processing plants as well as nearby residents, is one of the primary exposure mechanisms and human health risks in the Chiatura mining region. Ingestion of contaminated water or soils/waste material and dermal exposure of residents are also major risks. These risks can be particularly high given the lack of regulations and pollution control, and the high density of poor communities interspersed with the mines, processing facilities, and waste piles, as well as downstream. Mn compounds are well known neurotoxic substances that may cause manganism in humans, a severe neurological disorder characterized by disturbances of movement, as well as Parkinson's disease (Howe et al. 2004; Olanow 2004).

The primary objective of this study was to evaluate the extent and significance of metal contamination, in particular Mn, in waters in the Chiatura region and potential risks to human health from operational and abandoned mines and mine facilities. The study was conducted in collaboration with the Science and Technology Center of the Ukraine, Georgia National Center for Disease Control and Public Health, and the Technical University of Ukraine through the US State Department and US Environmental Protection Agency's Biochemical Weapons Redirect Program. The goal of this program is to aid FSU states in redirecting their biochemical research institutes and scientists to peaceful objectives.

METHODOLOGY

Study Area

Chiatura is located in the Imereti region of western Georgia in a canyon of the Racha Mountains, in the southern foothills of the Greater Caucasus Mountains, 180 km west of Tbilisi, the capital and largest city (Fig. 1). The mines, main factory, and other industrial facilities are situated over an area of 50 km^2. The city lies in a mountain valley along the Kvirila River (named because of its yellow color); the main Chiatura Mine is also located in the valley adjacent to the city (Fig. 2). The city and its ore-enriching plants cluster in the narrow valley, with mines in the surrounding hills linked by cable railways and aerial carriers. The smelter receiving Mn concentrate from mines in Chiatura is located in the city of Zestafoni, 30 km to the southwest. The primary Mn factory (owned and operated by the Chiatura Manganese Company) is located adjacent to the left bank of the river in the village of Perofi in the Darkveti area. There is a railway connection between Chiatura and Zestafoni.

The Chiatura Mn deposits are situated in the north periphery of the Dzirula crystalline massif, in the middle reach of the Kvirila River. The area represents an almost horizontal plateau, divided by the Kvirila River and its tributaries. The ancient rocks are Palaeogene formations overlain by Jurassic rocks. These are overlain by Cretaceous sediments. Oligocene rocks are in upper layers with Mn beds, topped with middle-upper Miocene and ancient– modern Quaternary alluvial formations. The deposits are confined by major faults to the southwest. Within the boundaries of the deposit, Quaternary, Tertiary, Upper Cretaceous, Jurassic, and Palaeozoic hydrogeological

complexes can be delineated. Alluvial water-bearing horizons generally have high concentrations of Mn. Waters of the Sarmatian water-bearing horizons are used for water supply by the settlements on the left bank of the Kvirila River. The average hydraulic conductivity of these formations is

approximately 0.8–0.9 m/day; the depth to water is 6–8 m and the water is dominantly calcium bicarbonate, with 0.6–0.8 g/L of total dissolved solids and 9.8 mg-eq of hardness.

The climate in Chiatura is humid; the winters are moderately cold and the summers are hot and dry. Due to its location in the foothills of the Greater Caucasus Mountains, the Chiatura region receives a significant amount of precipitation, including a high snowpack with peak seasonal snowmelt in spring. The average annual precipitation is 1,100–1,200 mm, with greater depths at higher elevations and a maximum in autumn and winter. This water can drive the mobilization and transport of pollutants, including metals, from source areas such as tailings and waste rock piles to ground and surface waters in the form of nonpoint source pollution. Drinking water in the area is supplied primarily by four springs with headworks and one communal groundwater well; no water treatment or chlorination occurs.

There are approximately 20 Mn mines in the Imereti District and Chiatura region. Eleven mines are open pit and nine are underground mines. Sixteen of the 20 mines are located in tributary watersheds north of the Kvirila River and four are located south of the river. It is not known how many of these mines are currently operating because this type of information is not readily available from Georgian authorities or from the mining company. The Kvirila River flows through the center of themain ChiaturaMn deposit and is a tributary of the Rioni River, which flows west to the Black Sea. Numerous small mountain rivers and streams discharge to the Kvirila River, and several villages are located in the canyons of these tributaries. Mn mines are also located near some of these villages. Tailings and slag waste is present in large quantities above ground throughout the area. The waste contains primarily Zn, Pb, Ni, Co, Mn, and other potentially toxic substances based on preliminary information from the mining company. Industrial wastewater is also directly discharged untreated from the Chiatura Mn factories (including the peroxide enrichment factory (PEROF) and the ‘‘central keeping facility’’ (CKF), which is the main ore processing facility) to the Kvirila River. The environmental conditions, the proximity of the mines, tailings, and discharges to the river and human settlements, and the lack of adequate management or regulation of operations cause significant environmental and human health risks not only to the Chiatura region, but to all territories that the river flows through on its way to the Black Sea.

Figure 1 Location map of the Republic of Georgia, Caucasus Mountains, and Chiatura

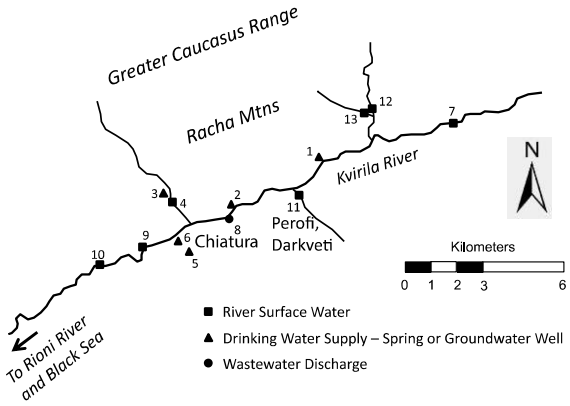

Figure 2

Figure 2 Sampling location map for Chiatura. Sites numbers refer to locations in Table 2

Sampling and Analysis

Water quality samples were collected at seven river and stream locations and five drinking water supply locations (four springs and one groundwater well) throughout the Chiatura study area (Fig. 2; Table 1). One sample was also collected directly from the industrial wastewater discharge from the main Mn factory (Perophi peroxide enrichment factory). Samples were collected as part of three synoptic sampling events during spring (April high flow) and late summer/autumn (September low flow) 2009, and early summer (June high flow) 2010.

Field indicator parameters included temperature, pH, DO, and specific conductivity (SC). Laboratory analytes included alkalinity, chloride (Cl), sulfate (SO_4), nitrate (NO_3), 5-day biochemical oxygen demand (BOD_5), chemical oxygen demand (COD), E. coli, metals (Na, K, Ca, Mg, Al, Cd, Co, Cu, Fe, Mn, Ni, Pb, and Zn), and As. All water quality-sampling tasks followed USEPA Region 8 standard operating procedures (SOP) for field sampling protocols (USEPA 2002). Field meters were calibrated according to the USEPA Region 8 SOP for the HydroLab multiprobe (USEPA 2003). Precision and accuracy for field indicator parameters were based on the USEPA field sampling protocols (USEPA 2002), or the manufacturer's specifications. Total carbonate hardness was estimated from Inductively Coupled Plasma Mass Spectrometry measurements of dissolved calcium and magnesium as $CaCO_3$. Samples for hardness, alkalinity, SO_4, NO_3, and Cl were collected in 250 mL HDPE containers and chilled to 4°C for preservation. A minimum of 125 mL of sample was collected for both dissolved and total metals analysis. Dissolved metals samples were filtered within 15 min of collection using a 0.45 μm filter (USEPA 2002). Total and dissolved metals were only sampled and analyzed during the first sampling round in April 2009. Only dissolved metals were sampled and analyzed during the other two sampling events. All metals samples were collected into HDPE or LDPE containers and preserved with 0.5 mL nitric acid in the field. Samples were analyzed by either a privately contracted laboratory (GAMMA), the Georgia Ministry of Environment Protection and Natural Resources, or the Technical University of Ukraine. Chain-of-custody procedures followed the USEPA field sampling protocols (USEPA 2002).

Table 1 Summary of Chiatura area water quality sampling locations

Table 1. Summary of Chiatura area water quality sampling locations

Site	Location	Description	Type
1	Grudo water supply	Near village of Grudo	Drinking water supply/Spring
2	Monasteri water supply	Water collecting reservoir near Fasknara	Drinking water supply/Spring
3	LeJubani water supply	Near village of LeJubani	Drinking water supply/Spring
4	Rgani stream	Right bank tributary	Tributary
5	Gagarin groundwater well water supply	On Gagarin Street	Drinking water supply/Well
6	Sakurdglia water supply	Near village of Sakurdglia	Drinking water supply/Spring
7	Kvirila River upstream	Near village of Sareki upstream of most mines	Main stem river
8	PEROF	Peroxide enrichment factory	Industrial wastewater discharge
9	Kvirila River upstream of CKF	Near administation building and village of Tiri	Main stem river
10	Kvirila River downstream of CKF	Downstream of most mines	Main stem river
11	Shuqruti Stream	Left bank tributary	Tributary
12	Jruchula River	Right bank tributary	Tributary
13	Darkveti Stream	Right bank tributary	Tributary

Dissolved As, Pb, and Zn were not sampled or analyzed after the first sample round in April 2009 because neither the total or dissolved forms of these metals were detected at any locations during that round. This was also partly the result of our limited budget for analysis, a typical issue in FSU countries. It is believed that these metals are only present at very low concentrations in the ore and the Chiatura environment, but the reason for their low levels is not known. Ca and Mg, alkalinity, sulfate, Cl, NO_3, BOD_5, and COD were also not sampled or analyzed during the last sampling round (June 2010) due to funding limitations. E. coli was only sampled and analyzed once during the first sampling round at the drinking water supply locations.

River bed sediment samples were collected at five locations during the three water quality sampling events. These were co-located with five of the surface water sampling sites: the Kvirila River upstream of Chiatura, the Kvirila River upstream and downstream of the CKF, Shuqruti stream, and the Jruchula River.

Field and analytical results were evaluated over time/between high and low flow sampling events and across locations and water types (river surface waters, spring or groundwater drinking water supply, and wastewater discharge). Results were also compared to applicable water quality standards and criteria. Georgian Ministry of Labour, Health and Social Affairs (2007a) maximum allowable concentrations (MACs) for drinking water were used for most analytes. Georgian regulations do not include MACs for toxic substances (including metals) in river bed sediments. Therefore, representative reference or 'background' values for Georgian soils (Ministry of Justice of Georgia 2003a, b) were used for comparison.

RESULTS AND DISCUSSION

The focus of the results here is on dissolved and total metals. With regard to indicator and other analytes, however, pH ranged from 6.5 to 8.8 across the 13 locations and three sampling events, reflecting circumneutral or slightly alkaline conditions. SC values were greatest in the Darkveti Stream samples (up to 1,869 µS/cm). Alkalinity was low and within the guidelines, with a range of 1.9–5.4 mg/L. Sulfate was above 100 mg/L in several stream samples, although all values were below the criterion of 250 mg/L, and concentrations at other sites were low. Alkalinity and sulfate values indicate that AMD is not a problem in this area. In April 2009, E. coli values exceeded the criterion (1 cfu/100 mL) at three locations (up to at 12 cfu/100 mL at the Grudo water supply).

With the exception of Mn and Fe, few samples had dissolved or total metal/semi-metal concentrations that exceeded drinking water MACs, and even the frequency of detection was rather low. In surface waters, the only dissolved or total metals that exceeded drinking water MACs were Mn and Fe at numerous locations and Ni in Darkveti Stream. Darkveti Stream generally had the highest concentrations of most metals, but values in the Kvirila River upstream and downstream from the CKF, and in Jruchula, Shuqruti, and Rgani streams, also sometimes exceeded criteria. As expected, the PEROF industrial (peroxide enrichment factory) discharge from the enrichment factory, which is untreated, had the highest levels of total Mn and Fe, but relatively low levels of dissolved Mn and Fe. Concentrations of dissolved and total Al, As, Cd, Pb, and Zn were all below detection limits.

For total metals sampled and analyzed in April 2009, Mn and Fe concentrations exceeded the MACs in most surface water samples. Total Mn concentrations were also very high upstream of the CKF, and in the Darkveti and Shuqruti stream samples. In the PEROF discharge, total Mn concentrations ranged from 0.85 to 7.62 mg/L. Total Fe concentrations increased to 18.4 and 22 mg/L in September 2009 and June 2010. These increases were likely due to increased mining and processing operations during this time period.

With regard to dissolved metals, Mn concentrations were very high in the Darkveti September 2009 (2.4 mg/L) and June 2010 (6.65 mg/L) stream samples relative to the MAC (Fig. 3). Only two other locations exceeded the MAC: the Shuqruti April 2009 stream sample and the Gagarin water supply well in both April and September 2009. Dissolved Mn concentrations in the PEROF discharge ranged from <0.2 to 0.34 mg/L. Mn loads in most surface waters are dominated by suspended Mn.

Dissolved Fe was only detected above the MAC in the PEROF discharge during the second sampling round in September 2009, and in the Rgani stream and Gagarin water supply samples in June 2010 (Fig. 4b). Similar to Mn, dissolved and total Fe data also indicate that Fe loads in the Kvirila River are dominated by particulate Fe.

All drinking water supply samples met the criteria for metals, except for the Gagarin groundwater supply well, where dissolved Mn, Fe, and Ni exceeded the MACs on at least one occasion. The June 2010 Mn and Fe concentrations were higher than in the previous sampling events in the Gagarin groundwater supply. Dissolved Co and Cu were only occasionally detected below the MACs. Total and dissolved metal concentrations were very similar between the other four public drinking water supplies.

Evaluation of temporal changes showed that concentrations of dissolved Mn increased in Darkveti Stream from April 2009 to June 2010. Increases of Na, K, Ni, and Co were also observed in 2010. These increases are generally attributed to greater inputs from metal sources and concentrations over time, rather than correlation with season or river flows. Both Mn and Fe concentrations were greater in the PEROF discharge in 2010 compared to previous years. Total Mn increased to 34 mg/L in the PEROF discharge in 2010, which was much higher than previous values.

Mn oxides do not readily dissolve and can easily form solid oxy-hydroxide precipitates that can coat streambeds where high concentrations occur, or can be transported as suspended particles under adequate hydraulic conditions (Scott et al. 2002). Other metals and nutrients can co-precipitate with or sorb to Mn oxides (MnOx) on the streambed (Butler and Caruso 2009; Gadde and Laitinen 1974). This adsorption can increase significantly with an increase in pH (Gadde and Laitinen 1974). Therefore, hydrous Mn oxides can play an important role in the fate and transport of other metals in rivers, such as Cd, Cu, and Zn, and should be considered in modeling and remediation (Butler and Caruso 2009). Adsorption of metals to bed sediment is also a function of

the percent of fine particles and clay, as well as organic matter/carbon (Caruso and Bishop 2009). The physical and chemical characteristics of the bed sediment and form of solid Mn and Fe on the river bed in the study area should be analyzed further.

The oxides and hydrous oxides of both Mn and Fe dissolve under reducing conditions that can occur with burial or mixing below surface layers of sediments beneath oxygenated waters (Van Cappellen and Wang 1996). Fe^{2+} and Mn^{2+} in pore water generated in the anaerobic zone can adsorb onto sediment, co-precipitate as a number of mineral phases, or move (by pore water diffusion and dispersion) back to the sediment-water interface. Redox of Fe and Mn is complex and can occur through a number of pathways, including benthic microbial and macroinvertebrate activity (Van Cappellen and Wang 1996). Biotic oxidation is an important process for removal of Mn^{2+} onto Mn oxides in the hyporheic zone and is directly proportional to Mn^{2+} concentration and pH (Fuller and Harvey 2000; Harvey and Fuller 1998; Marble 1998). Surface catalyzed oxidation and photoreduction can also be important with regard to fate and transport, especially in mountain streams (Scott et al. 2002).

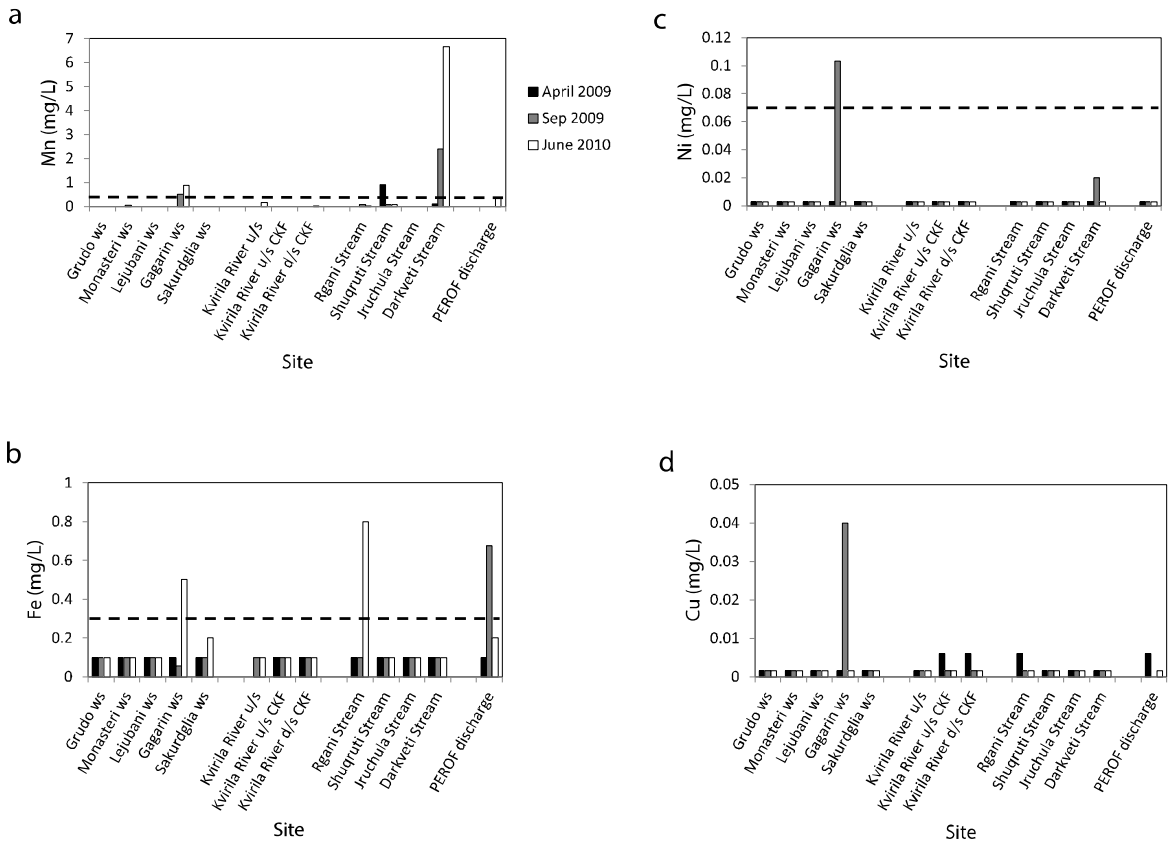

Figure 3 Chiatura dissolved metals results in water for a Mn, b Fe, c Ni, and d Cu. Dashed line is Georgian maximum allowable concentration (MAC). All MACs are for drinking water; MAC for Cu is 2.0 mg/L (not shown); ws water supply; u/s upstream; d/s downstream

River bed sediment metals concentrations were elevated at all five surface water sites. Background concentrations from Georgian estimates for soils were not available for Al and Fe, but Al values

ranged from 3.9% in the Kvirila River upstream of the CKF to 6.7% in the Jruchula Stream. Cd concentrations exceeded the background value of 0.5 mg/kg at all five locations, and were highest in the Kvirila River upstream and downstream of the CKF (3.2–4.5 mg/kg). Cu values followed a similar pattern, exceeding the background concentration of 3 mg/kg and having the greatest values at those two locations (44–70 mg/kg). Mn concentrations in the Kvirila River upstream and downstream of the CKF were very high and exceeded the background value for soils of 1,500 mg/kg (in the range of 80,000–95,000 mg/kg or 8–9.5%). Mn values also exceeded the background value at the other sites. Fe concentrations ranged from 1.5% in the Kvirila River upstream of the CKF to 3.9% for the furthest upstream Kvirila River sample). Fe concentrations were also elevated in the Kvirila River upstream and downstream of the CKF during some sampling rounds (2.4–3.6%).

The Kvirila River bed sediment metal concentrations generally were higher in 2010 than in 2009 with the exception of two locations (upstream and downstream of the CKF) where Mn concentrations in 2010 decreased (5.35 and 4.8%) compared to 2009 (9.5–8.0 and 8.5–8.0%, respectively). Cu values also decreased somewhat at these two locations. The reason for these decreases is not known, but transport and flushing of sediment from high flows could be a factor, as could dissolution of metal oxides or adsorbed metals to the water column. No other temporal trends were apparent in sediment concentrations at other locations. Although MACs for metals in river bed sediments have not been established by the Georgian government, comparison of Mn and Fe concentrations in sediment samples from the Kvirila River upstream and downstream of the CKF with Georgian background values for soils indicates that the sediments meet the criteria for ''highly-polluted soils''; sediment samples from the Jruchula and Shuqruti streams meet the criteria for ''low-polluted soils'' (Georgia Ministry of Labour, Health and Social Affairs 2007b).

CONCLUSION

Drinking water samples taken from three of the public water supplies (Grudo, Monasteri, and LeJubani) in the Chiatura mining area were contaminated by coliform bacteria. E. coli concentrations exceeded the criterion of 4 cfu/100 mL in samples from the Grudo and Monasteri supplies. Concentrations of dissolved Mn, Fe, and Ni exceeded the drinking water MAC in the Gagarin groundwater supply well.

Simple water treatment systems should be installed for the Grudo, Monasteri and LeJubani water supplies. The water should not be used for drinking without disinfection due to the risk of water-borne infectious and viral diseases. Drinking water in the catchment reservoirs of the Grudo, Monasteri, and LeJubani water supply systems should also be routinely disinfected. Drinking water quality in Chiatura's central water supply lines should be monitored based on Georgian government requirements and standard international practice to protect public health.

The communal Gagarin Street groundwater supply well should be cleaned and disinfected in accordance with Georgian government regulations and standard practices. Long-term consumption of this water may damage the digestive tract. The well should be re-sampled and analyzed for Mn, Fe, and Ni on a routine basis. If these metals continue to occur at levels above the MACs, the use of well water for drinking should be discontinued.

The Kvirila River is contaminated with Mn and Fe relative to the upstream location. Total Mn levels were almost 15 times the MAC downstream of the discharge from the CKF. Concentrations of total Mn were 2–12 times the MAC in Darkveti, Shuqruti, and Rgani streams, and total Fe values were 8–

55 times the MAC in these tributaries. Mn and Fe loads in the Kvirila River and most tributaries are primarily in the particulate form. Concentrations of dissolved metals in samples from the seven surface water locations were below the MAC except for dissolved Mn in Darkveti Stream and the Kvirila River upstream and downstream of the CKF. The primary sources of Mn and Fe in the Kvirila River are the untreated industrial wastewater discharged from the CKF, tailings and waste rock associated with the Mn ore disposed of on the Kvirila River floodplain, and the main tributaries (primarily Darkveti and Shuqruti streams).

Concentrations of all metals, including Mn and Fe, in river bed sediments were elevated at all seven river sites. Mn and Ni, in particular, were very high compared to background soil levels in the Kvirila River upstream and downstream of the CKF. Although Mn and Fe oxide solids in sediment can increase adsorption and attenuation of other metals from the water column, contaminated sediments can also serve as a long-term residual source of metal contamination of river water with significant adverse ecological and potential human health effects.

Use of the Kvirila River before and after the CKF, as well as Darkveti Stream, for drinking, economic, cultural, and household purposes should be prohibited. Based on Mn concentrations, these areas are extremely highly polluted water, according to Georgian regulations. Use of these rivers may result in increased exposure to Mn and associated diseases and symptoms. Water in Shuqruti and Rgani streams meets the criterion for moderately polluted water. Water from these rivers may be used as a drinking and economic water supply source only if the pollution level is reduced through end-of-the-pipe treatment.

Solid mine waste (tailings and waste rock) have been disposed of on the floodplain surface along the Kvirila River and some tributaries. This waste material is a significant source of metals that will continue to impact the water quality and ecological health of the Kvirila River and some tributaries. Industrial mine waste from the enrichment and processing plants should be managed in a way that isolates the material from the rivers and groundwater. The specific pollution sources in the Kvirila River should be identified and evaluated, and routine sampling of the river should be conducted at key locations. Discharge of untreated wastewater from the peroxide enrichment factoryinto surface waters should be discontinued as soon as possible and treatment facilities should be installed at the plant.

ACKNOWLEDGEMENTS

We thank Iryna Tomashevska and Victor Korsin of the Science and Technology Center in Ukraine, and Bill Freeman (Office of International Affairs) and Doug Steele (Office of Research and Development) of the US Environmental Protection Agency for administrative and logistical support, and overall direction of the project. We also thank several anonymous reviewers for very helpful comments on the original paper.

Best Available Technologies Economically Achievable (BATEA) to Manage Effluent from Mines in Canada

Kristin Pouw, Kathryn Campbell and Lisa Babel
Hatch, Canada

ABSTRACT

Hatch was commissioned by the Canadian Mine Environment Neutral Drainage (MEND) Program to complete a study to identify best available technologies economically achievable (BATEA) for the augmentation of existing effluent treatment systems, to improve effluent quality from mines in Canada. The study was commissioned in order to provide reference information to policy makers, industry, and civil society organizations for use in evaluating potential forthcoming changes within the Canadian *Metal Mining Effluent Regulations* (*MMER*) to the types of regulated mining facilities (addition of diamond and coal mines), the list of regulated parameters, and the authorized limits of regulated parameter concentrations in effluent discharged to the environment. This paper presents the overall objectives and methodology of the study and the participatory process used to gather and validate information, an overview of the various Canadian mining subsectors examined (metal mining: base metal, precious metal, iron ore, and uranium; diamond mining, and coal mining), a summary of technologies considered to be best available technologies (BAT) for Canadian mine effluent treatment, and incremental costs of implementing and operating BAT. BAT are defined as those technologies which have been demonstrated through full scale operation to achieve the present *MMER* regulated parameter limits via treatment of mine effluent under representative Canadian climate conditions. Finally, the paper presents Hatch's findings on best available technologies economically achievable (BATEA) for augmentation of effluent treatment systems, interpreted as technologies that can improve effluent quality through upgrades to existing treatment systems for a given subsector, within reasonable incremental capital and operating costs, as compared with previous capital expenditures and current operating cost expenditures. The study largely focuses on the improvement of effluent quality at existing operations; however, some BATEA suggestions for greenfield operations are also made. Parallels between the Canadian mining jurisdiction and other major international mining jurisdictions are drawn.

INTRODUCTION

Environmental regulations for the mining industry are becoming more stringent in many jurisdictions, amplifying the need for effective and efficient effluent treatment systems that are also economically viable. In Canada, the quantity and quality of mining effluent discharged to the environment are regulated at the federal and provincial/territorial levels. Potential forthcoming changes to the federal *Metal Mining Effluent Regulations* (*MMER*) generated a need to examine conventional approaches to effluent treatment at mining and mineral processing operations, with a focus on concentrations demonstrated by conventional technologies and which technologies are economically and operationally viable at Canadian operations, considering site conditions such as remote location and seasonal climatic variability.

The proposed changes to the *MMER* are outlined in the Environment Canada 2012 discussion paper, "10-Year Review of Metal Mining Effluent Regulations," and include:

- The addition of total ammonia, aluminum, iron, and selenium to list of regulated parameters for metal mines (base metal, precious metal, uranium, iron ore).
- The reduction in authorized limits of regulated parameter concentrations in effluent for metal mines.
- The addition of diamond and coal mines to the types of regulated mining facilities[1], and,
  - the introduction of authorized limits for pH, chloride, phosphorus, total suspended solids (TSS), and total ammonia as regulated parameters for diamond mines,
  - the introduction of authorized limits for pH, aluminum, arsenic, iron, manganese, selenium, TSS, and total ammonia as regulated parameters for coal mines (Environment Canada, 2012).

Environment Canada is undertaking the review of the *MMER* within a context of multi-stakeholder consultation, whereby stakeholders including industry, industry associations, regulators, non-governmental organizations, and First Nations organizations are engaged in working groups in order to provide feedback on the proposed changes through a series of meetings and workshops. As part of this multi-stakeholder consultation process, Hatch was commissioned by the Mine Environment Neutral Drainage (MEND) Program, on behalf of regulatory and industry stakeholders, to complete a study of water management and treatment practices at mining operations in Canada and to identify best available technologies economically achievable (BATEA) for the augmentation mining effluent treatment.

Hatch's study identifies and describes best available technologies (BAT) employed at metal, diamond, and coal mine operations in Canada and proposes BATEA for each sector. BAT were identified and characterized via extensive questionnaires issued to mining operations and technology vendors, as well as independent research. BATEA were selected based on a comparative assessment of the benefits in terms of effluent quality improvement against the incremental implementation and operating costs for each applicable BAT. BATEA selections are generic, in that they are based on the augmentation of a sector model effluent treatment system and do not consider site-specific factors not captured by the model. BATEA selections are also neutral, in that

[1] The diamond mining and coal mining sectors are presently not regulated by the *MMER*.

Hatch is not a water treatment technology supplier and has no vested interest in technology selection.

METHODOLOGY

Establishing Sector Models

A base case model for each sector representing the most commonly utilized water management practices and treatment process was established based on information collected from mine and mill operations. This model was utilized to identify and evaluate potentially augmentative technologies to improve effluent quality. To identify the most common practices, Hatch prepared a list of Canadian metal (i.e., base metal, precious metal, iron ore, and uranium), coal, and diamond mines. This list included the company, operation name, subsector classification by primary commodity, the location, and the operational status of the mine. After extensive revision and refinement of this list with the assistance of provincial, territorial, and federal industry associations, an operations contact list was generated. A comprehensive operations questionnaire was distributed to the contact list in order to solicit information on factors that impact treated effluent quality (i.e., mining, processing, and waste disposal practices, water management and effluent treatment systems, and untreated and treated effluent quality), as illustrated in Figure 1.

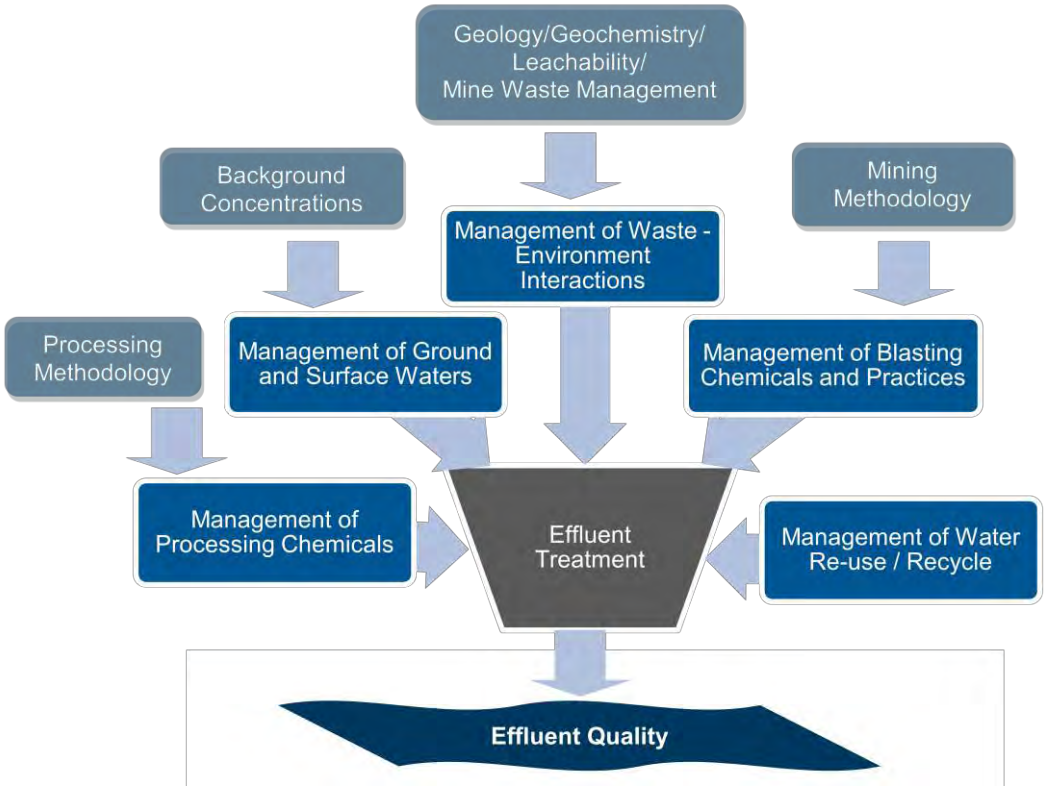

Figure 1 Factors of mine effluent quality

The questionnaire had an overall completion rate of 45% on an operations basis (i.e., 45% of individual operations identified as relevant to the study submitted completed questionnaires). This corresponds to 75 of the 164 operations contacted. By sector, the questionnaire completion rate varied between 32% and 75%. A more detailed summary of the questionnaire completion status by sector is provided in Table 1.

Table 1 Operations questionnaire completion by sector

Sector/Subsector	Number of Companies	Number of Operations Contacted	Number of Questionnaires Submitted
Metal			
Base Metal	31	57	31 (54%)
Precious Metal	33	56	18 (32%)
Iron Ore	4	6	2 (33%)
Uranium	4	16	7 (44%)
Diamond	4	4	3 (75%)
Coal	12	30	13 (43%)

Questionnaire responses were processed into a database format so the data could be easily compared and analyzed. Where necessary, follow-up inquiries were made with questionnaire respondents to clarify information provided prior to inclusion in the database and study report, in order to limit interpretation bias.

The database was compared with regulatory reporting information provided by Environment Canada, which included effluent discharge volume and quality data for all of the operations subject to *MMER*, as well as effluent discharge volume and quality data for the diamond sector, and a summary of effluent treatment technologies employed by operations in Ontario. Similar data for the coal sector was provided by the Coal Association of Canada, however discharge volumes were not provided. Additionally, because the coal sector data was anonymous, effluent quality data could not be related to operational practices and other effluent-influencing factors.

Later, a short follow-up survey was distributed to collect additional information from operations about effluent treatment system flow rates, final discharge point names used in *MMER* reporting, treatment system process unit operations, mechanism of removal of targeted contaminants, and influent and effluent quality data.

In combination with the questionnaires and resources described above, Hatch also undertook independent research to collect supplemental information about mining operations. This independent research drew from in-house knowledge and publicly available information concerning mining operations and effluent treatment processes (e.g., environmental compliance approvals, certificates of authorization, permits, etc.).

Based on the information collected, Hatch established a generic effluent management and treatment base case model for each mining sector. Each base case consists of a model water management block flow diagram, a model water treatment block flow diagram, nominal and design treatment flow rates, and treated effluent quality produced by model or model-like effluent treatment systems. The effluent treatment model developed for the base metal subsector of the metal mining sector is provided as an example in Figure 2. The models represent the most common practices and treatment systems for the sector described to Hatch by industry via the information provided in the

questionnaires, as illustrated in Figure 3. While more technologically advanced systems may be employed at Canadian mines, the model serves to exemplify the most common system as reported by industry.

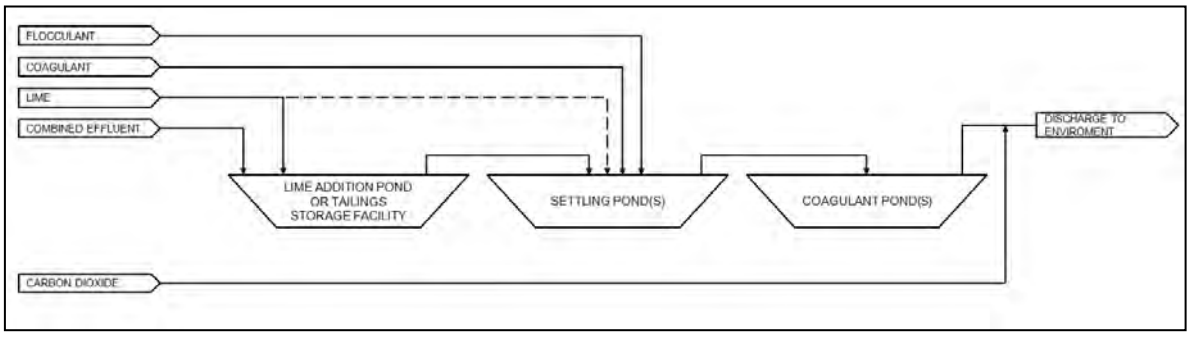

Figure 2 Base metal subsector effluent treatment model

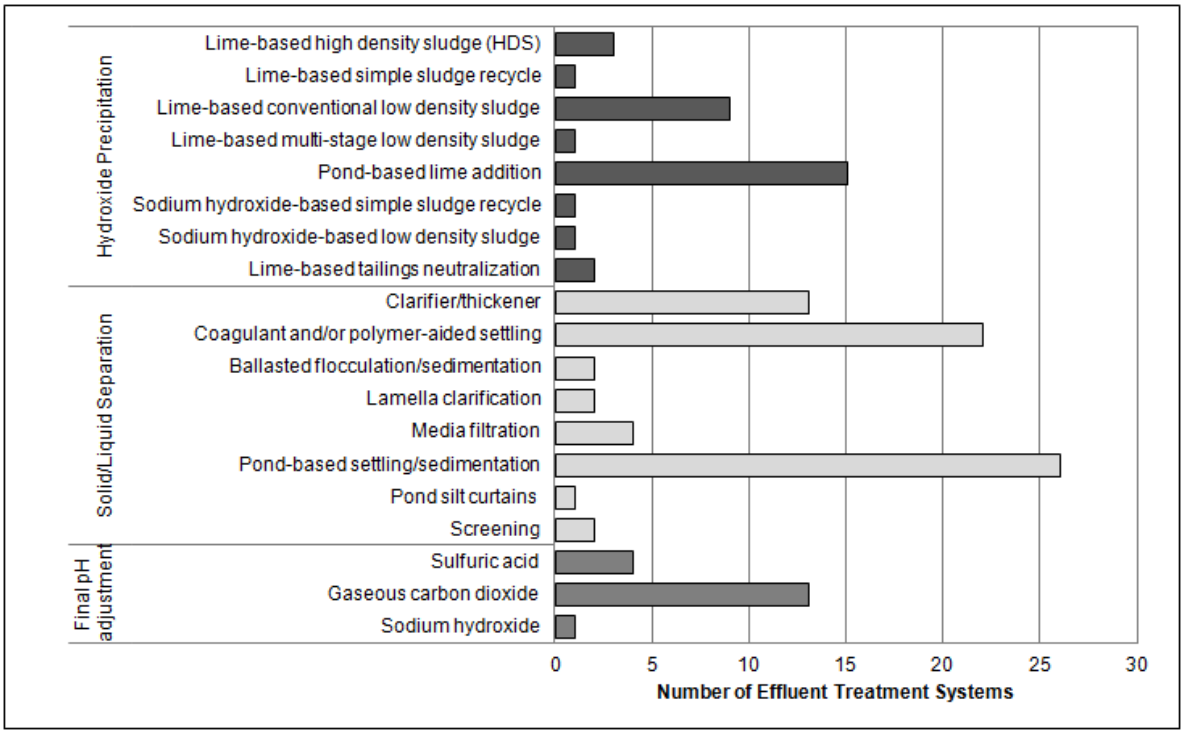

Figure 3 Distribution of hydroxide precipitation, solid/liquid separation, and final pH adjustment technologies for the base metal subsector

Model nominal and design treatment flow rates were generated from effluent discharge volume data and operations questionnaires, using a number of analytical approaches to generate statistical information and then applying judgment to select mid-range values. Model treated effluent concentrations for each current and proposed *MMER* parameter were determined by generating statistical treated effluent quality values for operations that employ model and model equivalent

treatment systems and also self-identify as targeting the parameter for removal with treatment. This was done to minimize the statistical influence of operations that do not employ model or model-equivalent treatment systems and that do not target the specific parameter being analyzed for treatment (i.e., treatment is not required for parameter compliance with discharge limits).

Identifying BAT Technologies

To identify best available technologies, Hatch first compiled a list of treatment technologies currently available on the market, both active and passive, that are applicable to the control of effluent quality for those contaminants that are currently or potentially regulated by the MMER. A questionnaire was distributed to vendors to solicit input concerning proprietary technologies, including existing case studies of their use, and capital and operating cost information.

The technologies included in the preliminary technologies list were then screened against the following criteria questions:

1. Can this technique achieve current MMER discharge limits?
2. Has this technique been demonstrated at full scale on mining effluent?
3. Has this technique been demonstrated under representative Canadian climate conditions?

Technologies that met all three criteria were carried forward in the study as best available technologies (BAT) for the treatment of Canadian mining effluent. BAT technologies are summarized in Table 2.

Table 2 Best available technologies and targeted (X) and synergistically removed (+) contaminants

Best Available Technologies	pH	Al	As	Cl	Cu	CN	Fe	Pb	Mn	Ni	P	Se	Zn	Ra-226	TSS	NH_3/ NH_4^+

For each best available technology, the following aspects of implementation and operation were elaborated: incremental capital and operating costs, removal efficiencies and/or achievable concentration levels, applicability to Canadian mining effluent treatment, and the synergies and challenges resulting from the application of the technology for the control of effluent quality.

For each sector, the list of BAT was assessed to identify which technologies could augment the model effluent treatment system and improve treated effluent quality. Order of magnitude capital equipment and installed cost and operating cost estimates were then prepared for each augmentative BAT technology for each sector. Cost estimates were generated through the use of in-house capital and operating cost information, vendor and operations questionnaires, and cost data reported in literature. It is acknowledged that actual costs could vary significantly from the presented figures, depending on numerous site-specific factors. Augmentative BAT that could improve treated effluent quality from existing treatment systems at a reasonable incremental cost were designated best available technology economically achievable (BATEA). For some subsectors, the model flowsheet was designated to be BATEA since BAT would either not improve treated effluent quality or could not be implemented at a reasonable cost.

RESULTS AND DISCCUSION

Review of the **base metal subsector** included a total of 43 operations. The model effluent treatment system for the subsector, as determined by the prevalence of questionnaire responses, consists of hydroxide precipitation for metals removal and pond-based settling for bulk TSS removal. Coagulant and flocculant are dosed to facilitate metal precipitate and TSS sedimentation. The pond-based system also enables passive natural degradation of ammonia which does not readily occur in reactor based lime addition/clarification systems. The pH of the settling pond decant is adjusted, most commonly with carbon dioxide to meet *MMER* pH limits and/or meet un-ionized ammonia/toxicity requirements prior to discharge to the environment. The design and nominal flow rates selected to estimate capital and operating costs for system augmentation for the model treatment system were 2 000 m^3/h and 870 m^3/h, respectively. Based on an evaluation of improvement in effluent quality relative to incremental capital and operating cost, BATEA was selected as sulfide precipitation with polymeric organosulfide chemicals for dissolved metals polishing and the model effluent management and treatment system for total ammonia, bulk metals, and TSS removal. The incremental capital cost and operating cost for augmenting the model flowsheet with the BATEA were estimated to be C$550/$m^3/h$ and C$0.33/$m^3$, respectively. The incremental cost to implement this augmentative technology considers infrastructure not included in the model treatment system. Further details on the basis of the cost estimates are available in the full report.

Review of the **precious metal subsector** included a total of 40 precious metal operations. The model effluent treatment system for the subsector, as determined by the prevalence of questionnaire responses, consists of SO_2/air cyanide destruction on tailings and low density sludge lime hydroxide precipitation for bulk metal removal from effluent from tailings, mine, and waste rock areas. The design and nominal flow rates selected to estimate capital and operating costs for system augmentation for the model treatment system were 600 m^3/h and 180 m^3/h, respectively. Using the methodology outlined previously for the base metal subsector, BATEA was selected as sulfide precipitation with proprietary polymeric organosulfide chemicals for dissolved metals polishing, active aerobic biological oxidation for total ammonia removal, and the model effluent management

and treatment system for cyanide, bulk metals, and TSS removal. The incremental capital cost and operating cost for augmenting the model flowsheet with the BATEA were estimated to be C$50/m^3/h and C$0.20/m^3, respectively, for the polymeric organosulfide chemicals, and C$32,670/m^3/h and C$0.60/m^3, respectively, for active aerobic biological oxidation. The incremental cost for implementation of this augmentative technology is less than for the base metal model system, as the precious metal model treatment system infrastructure is better suited for the use of this technology and thus less additional equipment is required. Further details on the basis of the cost estimates are available in the full report.

Review of the **iron ore subsector** included all 6 operating iron ore operations. The model effluent treatment system for the subsector, as determined by the prevalence of questionnaire responses, consists of pond-based settling for bulk TSS removal with flocculant dosing to aid settling. The design and nominal flow rates selected to estimate capital and operating costs for system augmentation for the model treatment system were 7 000 m^3/h and 3 900 m^3/h, respectively. Using the methodology outlined previously for the base metal subsector, BATEA was selected as the model effluent management and treatment system for TSS, metals, and total ammonia removal. Hatch expects that with proper design and operation of water management infrastructure, a TSS concentration of 15 mg/L or lower can be achieved by the sector.

Review of the **uranium subsector** included a total of 12 operations. The model effluent treatment system for the subsector, as determined by the prevalence of questionnaire responses, consists of 2 stages: a high pH stage for precipitation of metals that precipitate in basic conditions and a low pH stage for metals and other parameters that precipitate or co-precipitate in acidic conditions. Between and after these pH stages, clarification and filtration are employed to separate precipitates from treated water. The design and nominal flow rates selected to estimate capital and operating costs for system augmentation for the model treatment system were 500 m^3/h and 350 m^3/h, respectively. Using the methodology outlined previously for the base metal subsector, BATEA was selected as active aerobic biological oxidation for total ammonia removal and the model effluent management and treatment system for metals and TSS removal. The incremental capital cost and operating cost for augmenting the model flowsheet with the BATEA were estimated to be C$31,800/m^3/h and C$0.45/m^3, respectively. Further details on the basis of the cost estimates are available in the full report.

Review of the **diamond sector** included a total of 4 operations. The model effluent treatment system for the sector, as determined by the prevalence of questionnaire responses, consists of settling pond(s), clarification, and media filtration for TSS removal. Coagulant is dosed into the clarifier. Prior to discharge to the environment, pH is adjusted using sulfuric acid to meet un-ionized ammonia/toxicity limits. The settling and polishing ponds enable passive natural degradation of ammonia and phosphorus. The design and nominal flow rates selected for the model treatment system were 3 000 m^3/h and 2 000 m^3/h, respectively. These flow rates were used to estimate capital and operating costs for system augmentation. Using the methodology outlined previously for the base metal subsector, BATEA was selected as the model effluent management and treatment system for chloride, bulk metals, ammonia, and TSS removal.

Review of the **coal sector** included a total of 16 operations. In the model effluent treatment system for the sector, as determined by the prevalence of questionnaire responses, bulk TSS is removed via pond-based settling and polishing which may be aided by the addition of flocculant. The settling and polishing pond(s) enable passive natural degradation of ammonia. The design and nominal flow rates selected for the model treatment system were 3 000 m^3/h and 1 000 m^3/h, respectively.

Using the methodology outlined previously for the base metal subsector, BATEA was selected as the model effluent management and treatment system for metals, total ammonia, and TSS removal.

It is important to note that BATEA cannot be applied universally to every mine in each subsector due to site-specific considerations. Factors such as feed water quality, flowrate, location, site conditions, legacy conditions, regulatory constraints, etc. will impact the cost of implementation and operation and may make these BATEA selections economically unattractive or their effluent concentrations technologically unachievable.

Hatch cautions that the use of polymeric organosulfide reagents should only be considered BATEA for operations that are capable of and dedicated to careful control of operating regimes to prevent effluent toxicity, as well as, careful control of residuals storage conditions to prevent long term instability and the potential generation of acid through sulfide oxidation and metals remobilization.

Table 3 provides a summary description of the model effluent treatment flowsheet, proposed BATEA, and achievable treated effluent quality with the proposed BATEA for each subsector. In the "Treated Effluent Quality" column, for those parameters not removed by the model treatment processes, the values presented are based on the 95th percentile of the final effluent concentrations for the entire subsector. The BATEA treated effluent concentrations are based on case study data and actual operating site data provided by vendors and industry as part of this study. Further details on the basis of treated effluent concentrations are available in the full report. These concentrations may not be achievable at every site due to local site conditions or operational factors which could affect the efficiency of the process. A pragmatic approach should be taken when assessing the probability of achieving these effluent target values under site-specific conditions.

CONCLUSION

For each subsector, utilizing the methodology presented herein to assess information compiled on the subsector and on effluent treatment technologies, Hatch selected BATEA for the removal of current and proposed contaminants under the Canadian federal *Metal Mining Effluent Regulations.* The study also provided valuable reference information to regulatory and industry stakeholders regarding subsector water management and treatment practices, the treated effluent quality achieved by model water management and treatment practices for each subsector, and effluent treatment technologies.

The study was published by MEND as Report 3.50.1 on their website at: ***mend****-nedem.org/wp-content/uploads/****MEND_3.50.1****_BATEA.pdf*

ACKNOWLEDGEMENTS

The authors of this study would like to extend their sincere thanks to MEND for sponsoring the study and to the industry associations, operations, technology vendors, and reviewers who provided invaluable inputs to this study.

Table 3: Summary of proposed BATEA

(sub)Sector	Model Effluent Treatment Flowsheet	Proposed BATEA	Effluent Quality
Base Metal	• hydroxide precipitation for metals • coagulant and flocculant dosing and pond-based settling for TSS • natural degradation of ammonia • pH adjustment with CO_2	model +: polymeric organosulfide reagents for metals polishing	Al < 0.79 mg/L As <0.01 mg/L Cu <0.03 mg/L Fe <0.30 mg/L Pb <0.02 mg/L Ni <0.05 mg/L Se <0.04 mg/L Zn <0.02 mg/L TSS <10 mg/L NH_3/NH_4^+ <4 mg/L
Precious Metal	• SO2/air cyanide destruction on tailings effluent • reactor-based hydroxide precipitation for metals from tailings, mine, and waste rock • natural degradation of ammonia	model +: polymeric organosulfide reagents for metals polishing and active aerobic biological oxidation for ammonia	Al < 0.05 mg/L As <0.05 mg/L Cu <0.03 mg/L CN <0.1 mg/L Fe <0.30 mg/L Pb <0.01 mg/L Ni <0.05 mg/L Se <0.05 mg/L Zn <0.02 mg/L TSS <12 mg/L NH_3/NH_4^+ <2 mg/L
Iron Ore	• flocculant dosing and pond-based settling for bulk TSS • natural degradation of ammonia	model – no economically achievable augmentative technology	Al < 0.80 mg/L As <0.001 mg/L Cu <0.005 mg/L Fe <5.50 mg/L Pb <0.003 mg/L Ni <0.003 mg/L Se <0.005 mg/L Zn <0.04 mg/L TSS <62 mg/L[2] NH_3/NH_4^+ <8 mg/L
Uranium	• high pH hydroxide precipitation for metals • low pH hydroxide precipitation and co-precipitation for metals and metalloids • inter-stage clarification and filtration for TSS	model +: active aerobic biological oxidation for ammonia	Al < 0.70 mg/L As <0.06 mg/L Cu <0.04 mg/L Fe <0.50 mg/L Pb <0.002 mg/L Ni <0.20 mg/L Se <0.02 mg/L Zn <0.04 mg/L Ra-226 <0.11 Bq/L TSS <2 mg/L NH_3/NH_4^+ <2 mg/L
Diamond	• pond-based settling, clarification (with coagulant), and media filtration for TSS • pH adjustment with sulfuric acid	model – no economically achievable augmentative technology	Cl^- <1 240 mg/L P <0.1 mg/L TSS <7 mg/L NH_3/NH_4^+ <2.35 mg/L
Coal	• flocculant dosing and pond-based settling for bulk TSS • natural degradation of ammonia	model – no economically achievable augmentative technology	Al < 0.90 mg/L As <0.001 mg/L Fe <0.82 mg/L Mn <0.13 mg/L Se <0.38 mg/L TSS <77 mg/L NH_3/NH_4^+ <0.37 mg/L

[2] Proper design and operation of water management infrastructure can achieve TSS ≤ 15 mg/L.

Minimizing Life Cycle Costs at High Flowrates

Joseph Tamburini and H.C. Liang
Tetra Tech, USA

ABSTRACT

Open pit mining can require large dewatering operations at high flowrates. When this dewatering water is required to be treated prior to discharge back to the environment or reinjection, the resulting life cycle costs can be significant and can impact mine operations. A confidential mine in Nevada, USA was faced with such a problem, requiring it to treat greater than 8,500 m3/hr (37,500 gpm) of water from dewatering wells to remove arsenic. Typical arsenic treatment technologies such as adsorption, ion exchange and coagulation/microfiltration have been shown to be effective removing arsenic; however, the associated capital costs would be prohibitive at such high flowrates. Therefore a conventional ferric hydroxide precipitation followed by clarification process was selected as a capital cost-effective alternative; at approximately 50% the cost of other arsenic removal technologies.

Several process configurations were investigated, but the two main configurations considered involved either settling ponds or clarifiers for solid/liquid separation. Additionally, two different site locations were considered, and due to the high flowrates, small differences in elevation resulted in vastly different pumping conditions. In order to determine the "best" configuration, the design team performed a Life Cycle Value Analysis that included monetary factors such as capital and operating costs; but also included non-monetary factors such as Reliability, Complexity, Flexibility, Land Requirements, Risk, Maintenance, among others. This approach allowed all factors that were important to the mining company to be considered appropriately.

Interestingly, this approach yielded a result that the clarifier alternative was preferred over settling ponds, despite it having a higher capital cost. Operational costs over the life of the facility tilted the analysis toward the site location at a higher elevation despite the need to build a 2,150 m^3/hr (9,500 gpm) pump station in order to get some of the water to that elevation.

Keywords: Life Cycle, Water Treatment, Arsenic

INTRODUCTION

A large combination open-pit and underground mine in Nevada, USA has a sophisticated dewatering well system surrounding the mine works to allow extraction of ore from both the pit and the underground mine. Currently, this equates to 6,400 m^3/hr (28,200 gpm) of water in the dewatering system. After a thorough analysis of current dewatering water the current arsenic levels in the mine complex were determined to be approximately 0.020 mg/L. Future wells will increase the total dewatering flowrate to 8,500 m3/hr (37,500 gpm) and likely will have higher arsenic concentrations. These concentrations exceed the Nevada Division of Environmental Protection (NDEP) Profile I arsenic reference value of 0.010 mg/L. Since the arsenic concentration is similar from well to well, the mine will be required to treat arsenic from all of the water prior to infiltration and irrigation. A new Water Treatment Plant (WTP) must be constructed and be able to achieve high reliability of treatment.

To determine the WTP design requirements, the dewatering flowrate was modelled based on the water production from different well production zones as shown in Figure 1.

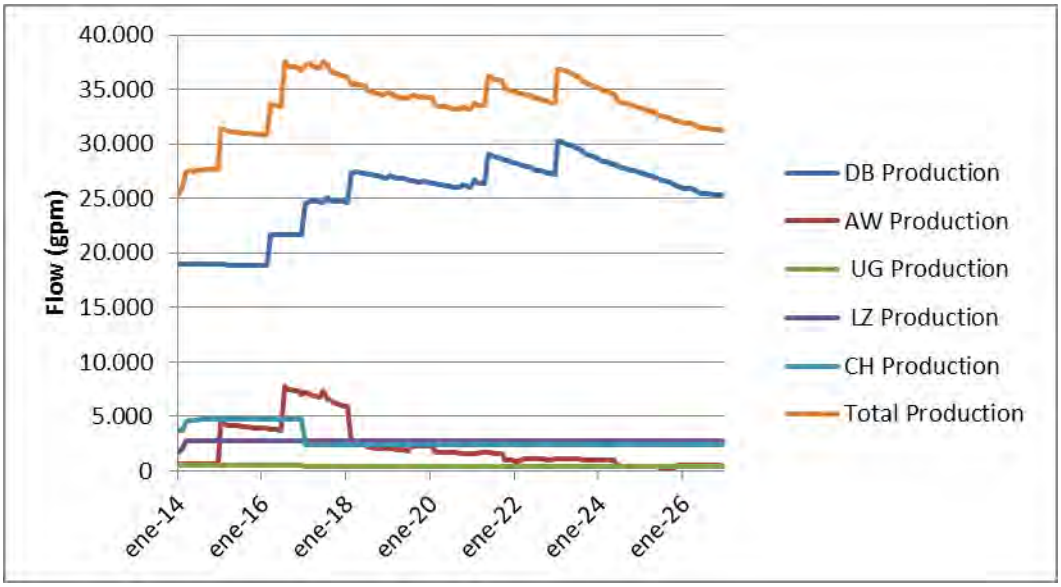

Figure 1 Dewatering Flowrate Projection by Production Zone

Finally, arsenic concentrations from each dewatering well were flow weighted to create a total projected arsenic concentration (mg/L), as presented in Figure 2. Average arsenic loading is important to understand for long-term chemical consumption when determining the operating costs; but peak arsenic values are also important for sizing chemical feed equipment and determining sludge handling alternatives. Therefore, three different sets of arsenic loading values were determined, the average, 85th percentile and the 95th percentile.

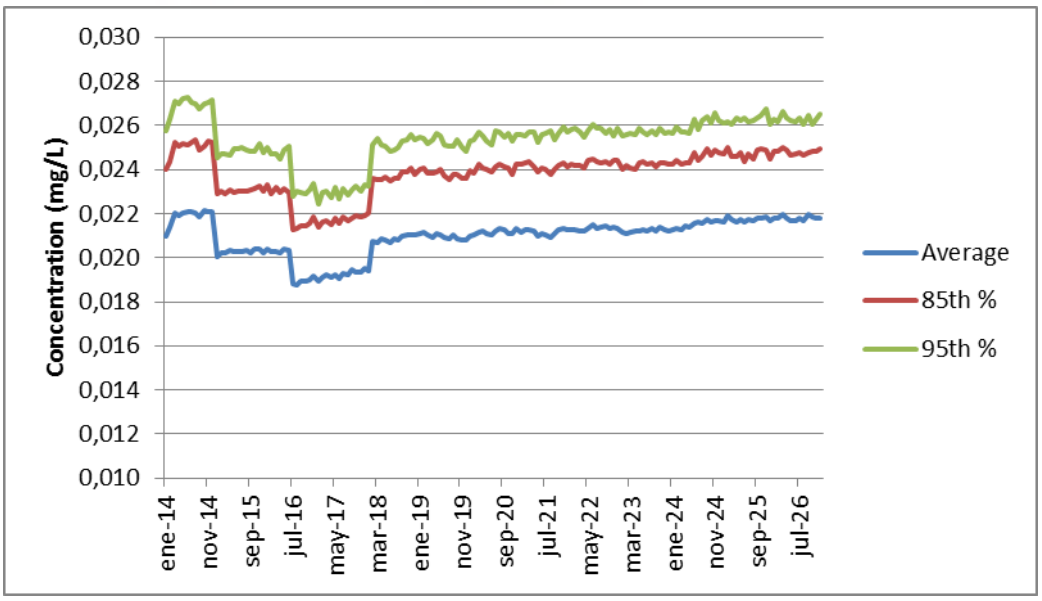

Figure 2 Projected Arsenic Concentration into the new WTP

Due to the high flowrates at the new WTP, mine staff's familiarity, and the cost effective nature of treatment, it was determined to utilize ferric hydroxide precipitation as the preferred method for arsenic removal. This process works by adding a ferric iron source (typically, ferric sulphate or ferric chloride) which forms a ferric hydroxide floc particle, as shown in Equation 1, which has an overall positive charge.

$$Fe_2(SO_4)_3 + H_2O \leftrightarrow Fe(OH)_2^+ \qquad (\text{at } pH < 7.3) \qquad (1)$$

Dissolved arsenic (V), or arsenate, has a net negative charge under most all pH conditions and adsorbs to the ferric hydroxide to form a precipitant that can be removed from the water solution.

$$H_2AsO_4^- + Fe(OH)_2^+ \rightarrow \text{Precipitant} \qquad (2)$$

During bench-scale testing, it was found that a portion of the arsenic present in the dewatering source was in the arsenic (III), or arsenite, form. Dissolved arsenic (III) has no net charge associated with it, and hence, cannot be removed via ferric hydroxide precipitation. Approximately 1.8 mg/L of hypochlorite bleach was added to oxidize all the arsenic to the arsenic (V) state so that it could be removed in the ferric precipitation step.

The project team desired to compare the life cycle costs of constructing a WTP utilizing settling ponds versus using clarifiers to settle this precipitant.

Additionally, there were two different site locations to evaluate. The "boneyard" site was at the bottom of a valley and allowed all the water from the dewatering wells to flow to that site without any modifications to any wells or without any additional booster pump stations. The second site, the "waste rock" site, was at a higher elevation on an old waste rock pile. Most of the dewatering zones could be pumped to the waste rock site without any additional modifications; however, one production zone required a booster pump for 2,150 m^3/hr (9,500 gpm) to get all the water to the WTP.

In order to evaluate which of the two different WTP processes and which of the two different site locations was best for this project, the team performed a Life Cycle Value Analysis (LCVA) on the alternatives. This paper will discuss how the LCVA process was used to quantify both monetary and non-monetary factors to make the best decision for this particular application.

METHODOLOGY

The LCVA approach combined monetary factors such as Capital Cost and Operation Cost (both Level 4 cost estimates at this stage of the project) as well as non-monetary criteria. The "non-monetary" criteria are summarized in Table 1. Monetary factors are easy to quantify; however, non-monetary factors are much more difficult to quantify. In order to accomplish this, each factor was given a weighting factor to determine how important each criterion was to that particular mine, which helped engage mine staff in the decision process. The "non-monetary" criteria developed by the mine were weighted as shown in Table 1.

Table 1 Non-Monetary Criteria Weighting Factors

Non-Monetary Criteria	Weighting Factor (1-4)
Reliability	4
Operational Complexity	2
Flexibility / Adaptability	3
Maintenance Requirements	1.5
Labour Requirements	2
Land Requirements	1
Risk / Liability	3
Truck Traffic	1
Redundancy	2

These criteria and weighting factors were input into the LCVA tool and each of the alternatives were scored on these particular "non-monetary" criteria on a scale of 1 to 5 with a score of one meaning that the particular alternative was not well suited for that particular criterion. The alternative score was then multiplied by the weighting factor to determine an overall score for each alternative for each non-monetary criterion. The scores for all non-monetary criteria were then added together to determine an overall "non-monetary" score for each alternative. These scores were used to quantify how well each alternative performed on criteria that were important to the mine other than just costs.

Finally, the monetary costs were normalized by dividing each cost by the lowest cost alternative, and the "non-monetary" scores were normalized by dividing each score by the lowest score. A simple monte-carlo analysis was conducted to compare the alternatives based on the scenarios in Table 2.

Table 2 LCVA Scenarios

Scenario	Monetary Weighting	Non-Monetary Weighting
1	30%	70%
2	50%	50%
3	70%	30%
4	100%	0%

RESULTS AND DISCUSSION

Solid / Liquid Separation Process

The two solid/liquid separation processes that were evaluated were double-lined earthen settling basins and standard circular clarifiers. The results of the non-monetary criteria for the solid/liquid separation process are summarized in Figure 3.

		Basins	Clarifiers
Weighting Factor		IS / WS	IS / WS
Reliability	4	2.0 / 8.0	4.0 / 16.0
Operational Complexity	2	3.5 / 7.0	3.5 / 7.0
Flexibility/Adaptability	3	1.5 / 4.5	3.0 / 9.0
Maintenance Requirements	1.5	2.0 / 3.0	4.0 / 6.0
Labor Requirements	2	3.0 / 6.0	3.0 / 6.0
Land Requirements	1	1.0 / 1.0	3.0 / 3.0
Risk/Liability	3	2.0 / 6.0	4.0 / 12.0
Truck Traffic	1	3.0 / 3.0	3.0 / 3.0
Redundancy	2	3.0 / 6.0	3.0 / 6.0
Overall Score		44.5	68.0
Alternative Ranking		**2**	**1**
Relative Ranking		1.55	1.00

Figure 3 Non-Monetary Evaluation for the Solid / Liquid Separation

The biggest "non-monetary" differences between the two alternatives in this study were Reliability, Flexibility and Risk. Settling basins, as configured for this project, were designed for sludge to be continuously removed from the basins with a stationary sludge pump. Many people on the design team expressed concern that this may not effectively remove sludge from everywhere else; leading to excessive buildup of sludge elsewhere in the pond. Therefore, there was an inherent Risk associated with the settling basin alternative. There were also questions about how clear the effluent water from the settling ponds would be if/when sludge build-up in the pond began to increase, so the system's Reliability to treat water consistently throughout the year came into question.

The simple monte-carlo analysis for the solid/liquid separation is summarized in Table 3.

Table 3 Final LCVA Analysis for the Solid / Liquid Separation Process

Alternative	Cost Rank	Weighted Cost Rank	Process Rank	Weighted Non-monetary Rank	Total Weighted Rank	Final Rank
Weighting		**30%**		**70%**		
Settling Basins	1.05	0.31	1.55	1.08	1.40	2
Clarifiers	1.16	0.35	1.00	0.70	1.05	1
Weighting		**50%**		**50%**		
Settling Basins	1.05	0.52	1.55	0.77	1.30	2
Clarifiers	1.16	0.58	1.00	0.50	1.08	1
Weighting		**70%**		**30%**		
Settling Basins	1.05	0.73	1.55	0.46	1.20	2
Clarifiers	1.16	0.81	1.00	0.30	1.11	1
Weighting		**100%**		**0%**		
Settling Basins	1.05	1.05	1.55	0.00	1.05	1
Clarifiers	1.16	1.16	1.00	0.00	1.16	2

At the start of the project, the mine operations and the engineering team felt that settling basins would be significantly less expensive and that the clarifier option would be prohibitively costly. Much to the team's surprise, when the LCVA process was completed it turned out that the clarifier option was the preferred alternative when the non-monetary criteria were weighted at 30% of the decision or higher, as shown in Table 3. The more weight the "non-monetary" criteria were given, the greater the LCVA analysis favored clarifiers.

Site Location Selection

The two different site locations that were evaluated were the "boneyard" site and the "waste rock" site. The results of the non-monetary criteria for the site location selection are summarized in Figure 4.

Weighting Factor		Boneyard IS / WS	Waste Rock IS / WS
Reliability	4	3.0 / 12.0	3.0 / 12.0
Operational Complexity	2	4.0 / 8.0	4.0 / 8.0
Flexibility/Adaptability	3	3.0 / 9.0	3.0 / 9.0
Maintenance Requirements	1.5	4.0 / 6.0	4.0 / 6.0
Labor Requirements	2	3.0 / 6.0	3.0 / 6.0
Land Requirements	1	3.0 / 3.0	3.0 / 3.0
Risk/Liability	3	4.0 / 12.0	3.0 / 9.0
Truck Traffic	1	3.0 / 3.0	3.0 / 3.0
Redundancy	2	3.0 / 6.0	3.0 / 6.0
Overall Score		65.0	62.0
Alternative Ranking		**1**	**2**
Relative Ranking		1.00	1.05

Figure 4 Non-Monetary Evaluation for the Solid / Liquid Separation

There was little difference in the non-monetary criteria between the two different site locations. The only real difference was that the waste rock site sat on an old waste rock pile that had settled over time, and a geotechnical evaluation of the site indicated that certain engineering design measures had to take place to account for differential settling across the site. Therefore, there was some associated Risk with this site over the virgin ground at the bone yard site. The engineering measures necessary to account for differential settling were taken into account in cost of building at that site.

The simple monte-carlo analysis for the site location selection is summarized in Table 4.

Table 4 Final LCVA Analysis for the Site Location

Alternative	Cost Rank	Weighted Cost Rank	Process Rank	Non-monetary Rank	Total Weighted Rank	Final Rank
Weighting		**30%**		**70%**		
"Boneyard"	1.05	0.31	1.00	0.70	1.01	1
"Waste Rock"	1.00	0.30	1.05	0.74	1.04	2
Weighting		**50%**		**50%**		
"Boneyard"	1.05	0.52	1.00	0.50	1.02	1
"Waste Rock"	1.00	0.50	1.05	0.53	1.03	2
Weighting		**70%**		**30%**		
"Boneyard"	1.05	0.73	1.00	0.30	1.03	2
"Waste Rock"	1.00	0.70	1.05	0.32	1.02	1
Weighting		**100%**		**0%**		
"Boneyard"	1.05	1.05	1.00	0.00	1.05	2
"Waste Rock"	1.00	1.00	1.05	0.00	1.00	1

Overall, the LCVA analysis showed very little difference between the two site locations. It indicated that the waste rock site was preferred when non-monetary criteria were weighted 50% or less, but not by a wide margin; and conversely, the bone yard site was preferred marginally higher when non-monetary criteria were weighted over 50%.

CONCLUSION

The Life Cycle Value Analysis procedure was proved to be a helpful tool for the mine team to make a decision regarding the preferred solid / liquid separation processes and the preferred site location. This procedure quantified everything that the mine felt was important to them, including monetary and non-monetary factors. The selected alternative from this analysis was to design the clarifiers for the solid / liquid separation process because it was decided that the non-monetary factors accounted for at least 30% of the decision with all the uncertainly related to the settling pond implementation. The waste rock site was selected as the best location since the LCVA showed that there was little difference between the alternatives based on the non-monetary criteria, so this decision could be made based on which alternative offered the most cost-effective approach.

The LCVA process can be applied to many different types of decisions at a mine site, especially when non-monetary criteria weigh heavily, such as with environmental measures. Through this process, it was critical that the appropriate team members are engaged in the process from the beginning.

ACKNOWLEDGEMENTS

2. *Levay & Co Environmental Services, University of South Australia*

ABSTRACT

In principle, a sustainable approach to acid mine drainage (AMD) management and final closure should be to reduce the acid generation rate (AGR) sufficiently that the acid neutralization rate (ANR) can match the AGR from rock and tailings disposal. This approach has not yet been fully designed or achieved although some parts of the overall strategy, including surface passivation of sulfide minerals to reduce AGR, have been implemented. Most mine sites have non-value minerals capable of providing some neutralization of AMD. They are often not considered or surveyed in primary site ore assessment. Standard site assessment methods define total potential acidity (AP) or alkalinity (NP) of these materials, *e.g.* NP/AP ratio, but do not consider the **rates** at which acid generating and neutralising reactions may take place. It is these relative rates in disposal of rock and tailings wastes that determine whether acid and metalliferous drainage occurs. Methods are now available to assess the rates at which neutralization can be supplied from reactive silicate minerals (additional to carbonates) in on-site waste rock types. Knowledge of both the amount and the rates of acid generation and neutralization can be used to assess future acid rock drainage liabilities but, more importantly, to plan greenfield or operating disposal to make maximum use of these on-site materials. The complete definition of geochemistry and mineralogy of site materials can provide more effective and reduced-cost management of these mining wastes. The application of this approach is particularly pertinent for use with emerging waste emplacement construction techniques. Definition of ANR in non-acid forming wastes used for encapsulating acid generating wastes during controlled placement storage can potentially be used to define oxygen flux and moisture targets to achieve matching AGR. Examples where neutralising waste rocks have been identified and assessed at three sites in the AMIRA P933A project are discussed.

Keywords: acid neutralization; kinetics; silicates; site mineralogy

INTRODUCTION

A sustainable approach to acid mine drainage (AMD) management in pre-planning or in operation should be to use, where possible, geochemical resources available at the mine site to reduce the acid generation rate (AGR) sufficiently that the acid neutralization rate (ANR) can match the AGR from rock and tailings disposal before final rehabilitation. This matching of acid generation and neutralization rates in kinetically controlled processes is, in principle, the only sustainable option for long-term closure. This has not yet been fully designed or achieved, but this paper will describe this approach with case studies illustrating some parts of the overall strategy that have been implemented to date. There are real opportunities for improved practice using full geochemical and mineralogical assessment of site materials.

In principle, AMD management involves strategies, at any scale from molecular to site storage, to minimise the interaction of reactive sulfide surfaces with air and/or water. At the site engineering scale, minimisation and control strategies selected are influenced by a range of factors including climate, topography, hydrology, mine geology, geochemistry and mineralogy of waste rock, tailings and available neutralising materials. Our focus is on the geochemical and mineralogical part of this control. Implementation of this geochemical strategy requires, firstly, treatments to reduce the AGR sufficiently that the ANR can match the AGR (Gerson et al., 2014). Reduction of AGR (50-90%) by formation of silicate-stabilised iron hydroxide layers on pyrite has been addressed in other publications (*e.g.* Miller et al. 2009; Schumann et al. 2009; Zeng et al., 2013; Gerson et al., 2014). The addition of carbonates in covers and layers, where available as limestone or dolomite on site, is recognised as the primary geochemical method of AMD control in acid rock dumps (GARD Guide). Studies, both laboratory (Schumann et al. 2009; Huminicki and Rimstidt 2009; Nicholson et al. 1990) and field (Li et al., 2012; Li et al., 2011; Miller et al., 2009), have shown that under neutral pH conditions maintained by added carbonates, pyrite oxidation rates, *i.e.* AGR, can be reduced by more than one order of magnitude. The mechanism for the reduction in sulfide oxidation rate is found to be through formation of continuous, coherent iron oxyhydroxide coatings which develop on the surface of the reacting sulfide and reduce oxygen diffusion rates to the surface (Huminicki and Rimstidt 2009; Nicholson et al. 1990). The nature and stability of these surface passivating layers has been extensively investigated in our research (Smart et al. 2010; Schumann et al. 2009). Under conditions of pH>6, multi-layered coatings of amorphous iron oxyhydroxide develop notably as stable, thin, continuous and conformal coatings often overlaid with a thicker (1-2 μm) coating of (semi)-crystalline goethite-like material. In field samples, the amorphous oxyhydroxide pyrite-passivating layer normally contains significant (5-10 mol%) silicate content. Where clay minerals are present in the waste, strongly adhering particles with micaceous texture can form a further external armouring layer (Miller et al., 2009).

The roles of pH and dissolved silicate in stabilising these passivating layers are critical. Pyrite oxidation rates are reduced when the pH is maintained above 6 and when the surrounding solution contains dissolved silicate (10–20 mg/L as Si) (Zeng et al. 2013). In the presence of dissolved silicate, the iron oxyhydroxide layer formed during pyrite oxidation retains its amorphous, conformal structure, while in the absence of silicate, conversion of this layer to the more-crystalline and less-passivating, separate goethite-like crystals occurs. These differences are illustrated in Figure 1. If initial alkaline amendments are made so that these passivating layers are formed and maintained then, for wastes with low to moderate AGR containing some reactive silicates, AGR may be sufficiently reduced (more than 90%) to enable matching by silicate ANR in the long-term. This sulfide passivation, with the use of reactive silicates from site rocks, forms the first part of the geochemical strategy for sustainable AMD management.

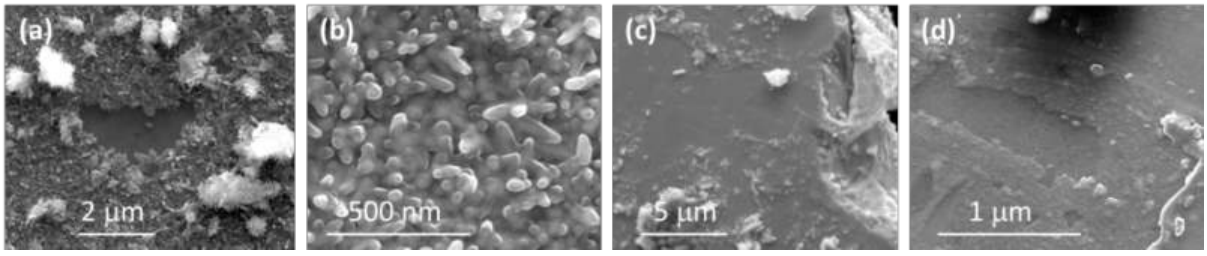

Figure 1 Evidence of the effect of the presence of silicate on pyritic surface layers at neutral pH. (a) and (b) pyrite surfaces immersed in calcite saturated water for 160 days showing clear crystalline overgrowths; (c) and (d) pyrite immersed under the same conditions with added silicate (20 mg/L Si) showing clear difference in surface layer morphology and significantly reduced pyrite oxidation (Zeng et al., 2013).

A specific example of the use of on-site alkaline materials for amelioration of AMD from previous rock dump fills has been provided by Cook et al. (2008). Re-mining of the Buffalo Creek coal seam site (Virginia, USA) to obtain coal from lower in the geologic column exposed new overburden, including an alkaline sandstone, that was used to add covers to the existing valley-fill AMD rock dumps. Drainage from the fills had resulted in high acidity/high metal (pH 3.5–4.5 with 100–200 mg/L $CaCO_3$ acidity) in the sub-watersheds. Addition of the sandstone covers improved water in the main stream of each drainage area from the fills. The water quality in the tributaries of Laurel Creek dramatically improved to pH 6.2 and acidities of <1 mg/L. Placement of alkaline material, recognised in the new mineralogy, into the extended valley fills eliminated the need for chemical treatment. With more than 10 years of data, it is apparent that there is high probability for the long-term success of the amendments.

A second example is the successful implementation and testing of on-site amendments to AMD from the historic B-Dump in the Savage River Rehabilitation Program (SRRP), a cooperative arrangement between the Tasmanian Government and current operators Grange Resources. Studies at this site have already been fully documented in previous ICARD meetings (Hughes et al., 2009, Hutchison et al. 2009, Li et al., 2011, Li et al., 2012). This used a water-shedding compacted top cover (from graded material) with over-dumped side covers and a base-dumped flow-through barrier comprised of chlorite-calcite schist waste material from the site. The covers have effectively reduced the overall AGR within the dump by about 43% over the past five years. Alkalinity from the covers has been migrating down into the acid-forming waste and forming passivating layers of silicate-stabilised iron oxy-hydroxide verified on pyrite grains (Li et al. 2011). Sulfate, Al and Cu flux in Main Creek have decreased by 50% after B-dump was capped. The discharge from Main Creek to the river has neutral pH, low sulfate (218 mg/L) and metal concentrations, *e.g.* Al 200 µg/L and Cu 30 µg/L, that are now below the SRRP fish target (Hughes et al. 2009).

In the context of requirements for implementation of the geochemical approach, a critical second requirement remains, however, to recognise, **measure** and control relative rates of acid neutralization from different waste mineralogies available on site. One of the significant inputs employed for the SRRP remediation is a comprehensive report (Thornett, 1999) on the rock types and mineralogy of the site prepared for the previous owners Australian Bulk Minerals. This identified a large variety of potentially neutralising mineralogy including the abundant chlorite-calcite schists with some dolomite, magnesite, talc-carbonate schist, dolerites and reactive silicates in mafic rocks, amphibole-chlorite-albite schists, serpentinites and possibly tonalite. This was recognised by site personnel and Rumble (2005) in planning of the amendments and provided the basis for the successful remediation.

Hence, there are two requirements that can potentially improve current practice in AMD control. The first is the need for detailed mineralogy, additional to standard AMD classification testing, of all site lithology, not just value lithology, preferably in greenfield assessment but also in operating and legacy sites. This enables a first-level estimate of both AGR and ANR for different lithologies based on the mineralogy alone (Ciccarelli et al., 2009, Miller et al. 2010). The AGR from the waste rock in passivated form at pH 6 can be estimated from well-established oxygen consumption and sulfate release methods (*e.g.* Hollings et al., 2001; Sracek et al., 2006). Associated with this should be

ANR carbonate and ANR non-carbonate (ANRnc; mainly reactive silicates) testing of potentially neutralising rock types using the dissolution cell and mineralogical methods to be described. These estimates can provide a reasonable basis to assess whether the ANR can match the reduced AGR at source. The second requirement is to plan to use these materials in layer dumping with AMD wastes and in cover design together with the engineering considerations. Short-term costs of this approach are likely to be greater than current practice but with the very high costs of closure and on-going management and liability in retained capital (*e.g.* several hundred million dollars at Newmont, Dowd, 2005), it may ultimately be more cost-effective. This comparison has not yet been fully evaluated but is clearly worthy of further development for sustainable AMD control.

METHODOLOGY

Current AMD test methods use static acid base accounting (ABA) assessment of potential acidity and neutralization together with long-term kinetic leach columns (KLC) usually requiring years to give reliable data (AMIRA/EGi ARD Test Handbook, 2002; MEND, 2009). The methodology required to use the our kinetic approach is a combination of AGR and ANR measurements (both in total mg H_2SO_4/kg/week or g H_2SO_4/tonne/week) on a time scale that allows snap-shot assessment of the ARD dump or tailings material prior to and during evolution of the AMD profile. The well-established oxygen consumption and sulfate release methods (*e.g.* Hollings et al., 2001; Sracek et al., 2006) on representative samples can provide reliable cross-checks and estimates of AGR at any point in this evolution. The requirement for short-term cross-checks and estimates of ANR can be met by a combination of dissolution rates from the sample mineralogy with dissolution cell measurement of released cations at the measured sample pH.

The mineralogical ANR estimates combine mineralogical assessment (Rietveld XRD, QEMSCAN or MLA) with dissolution rate data of individual minerals. The non-iron carbonate content of the mineralogy can be assumed to provide ANR for the equivalent AGR, *i.e.* at the same mg H_2SO_4/kg/week since their reaction rates exceed pyrite oxidation rates (Blodau, 2006). It is the additional neutralization from reactive silicate minerals that requires assessment. Eary and Williamson (2006) combined mineral dissolution rate data from Palandri and Kharaka (2004) with solution speciation modelling to examine dissolution of a number of theoretical rocks, with silicate mineralogy ranging from silicic through to mafic and containing 0–3 wt.% pyrite. Their results suggested that anorthite feldspar and some mafic minerals such as forsterite, augite and hornblende may dissolve quickly enough to neutralise acidity from pyrite oxidation. For instance, anorthite gives measurable short-term neutralization in the ABA Sobek test with estimated ANC of 10 kg H_2SO_4/t (AMIRA/EGi, 2002; MEND, 2009). Abundant chlorite minerals have also been shown to mediate acidity in both the Waite Amulet (Jambor et al., 1999) and Savage River (Li et al. 2012) examples. A similar mineralogical approach was used by Miller et al. (2010), wherein silicate ANR derived from mineral dissolution rates were compared with rates calculated from leachate analysis of solutions obtained from long-term kinetic leach column tests from which any carbonates had been previously exhausted. They found good agreement between the rates derived from mineralogy and those obtained from leach column tests when the pH was below 3. However at pH>4, ANR values calculated from mineralogy generally exceeded those derived from leach column testing (over 2-10 years) based on assays for metal cations (Na, K, Ca, Mg and Al) released in neutralization reactions as in the method of Paktunc (1999).

The amounts (mmol) of each cation in the 4-weekly leachate are determined from the assayed concentrations and the leachate volume. Thus (static) non-carbonate acid neutralising capacity ANCnc (mg H_2SO_4/kg) was determined from equation (1) with *Na, K, Mg, Ca* and Al in mmol; the factor 49 converts mmol H^+ ions to mg H_2SO_4; *m(kg)* is the mass of the sample in the column. *e.g.*

$$ANCnc = [(Na + K) + ((Mg + Ca) \times 2) + (Al \times 3)] \times 49 / m(kg) \quad (1)$$

For solution assays collected over specific time periods, usually 4 weeks, this can be represented as a rate, *i.e.* ANRnc in mg H_2SO_4/kg/week (or kg H_2SO_4/t/yr) for comparison with AGR measurement from sulfate release. The reason for the lower ANRnc measured by this method at pH>4 is likely to be due to the removal of some of these ions by secondary mineral formation particularly gypsum.

To improve the comparison with mineralogy, a short-term kinetic dissolution cell test to measure the ANRnc was developed using an initial pH-controlled flow-through method from which assays for metal cations (Na, K, Ca, Mg and Al) can be obtained after a steady-state dissolution rate is attained (usually 2 weeks) and ANRnc calculated as in Eq 1. This experimental procedure has been previously described in Ciccarelli et al. (2009). A summary is given here. The sample is first reacted with pH 2 HCl to remove all carbonates (verified with XRD and carbonate assay). The reaction cell is connected to an input reservoir at the pH of the original site sample and this solution is pumped through the reaction cell by a peristaltic pump with the sample in a holder with 0.45 μm filter papers placed above and below the sample to restrict sample loss. Leachate discharged from the exit port near the top of the reaction chamber is collected in output reservoirs for analysis of dissolved metals. Each of the collected effluent solutions is daily transferred into a sealed bottle pre-purged with Ar gas. The continuous flow-through tests are run under standard temperature (25°C) and atmospheric pressure conditions at an effective flow-rate of 40-50 mL per day, calibrated daily.

An example of this procedure applied to a fresh Savage River chlorite-calcite schist after carbonate removal is shown in Figure 2. This delivered an ANRnc of 480 mg H_2SO_4/kg/week at influent pH 4 and 90 mg H_2SO_4/kg/week at pH 5 both with effluent pH 7 at steady state. In the dump, the effective pH (as free proton concentration) close to the pyrite surfaces is likely to be below that in the bulk solution generating faster dissolution of reactive silicates adjacent to the pyrite. This can be compared with sulfate AGR from the B dump, to which this schist was added, of 10 mg H_2SO_4/kg/week in the seep at the toe of the dump (Li et al., 2012). The initial fast dissolution of Mg and later K may be due to ion exchange at high energy surface sites in silicate fines, *i.e.* chlorite and minor anorthite (Brantley and Chen, 1995) remaining after the pH 2 pre-treatment to remove carbonates. This initial greater reactivity can roughly double the effective initial ANRnc. More detail and other examples can be found in Ciccarelli (2012).

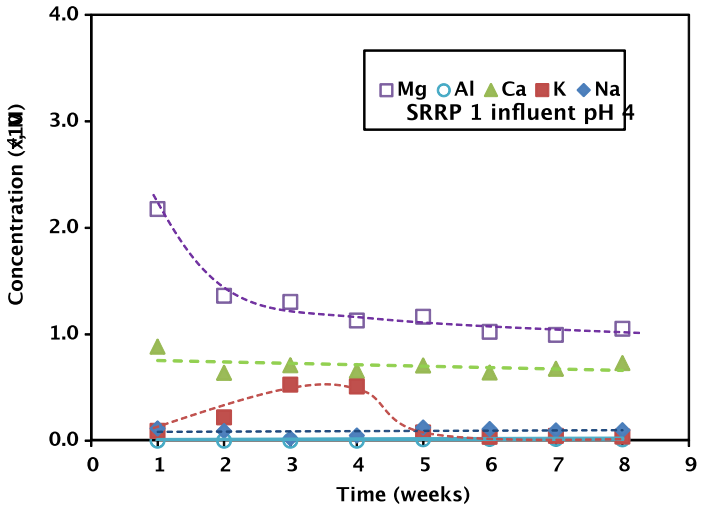

Figure 2 Major cation concentrations from the kinetic dissolution cell test of a Savage River chlorite schist waste sample at a flow rate of 4 L/kg/day and an influent solution pH of 4.

RESULTS AND DISCUSSION

Two other examples of the recognition and measurement of ANRnc in waste rocks potentially offering site treatment options not previously envisaged are discussed here.

BHP Billiton Iron Ore (BHPBIO)

A BHPBIO case study investigated the strategy of pyrite passivation and AMD reduction through the use of on-site ANR-generating wastes to minimise AGR in overburden storages at Mt.

Whaleback, Pilbara, Western Australia (Gerson et al., 2014). A Jeerinah shale and the highly reactive Mt. McRae shales were used as AGR-generating materials in kinetic leach columns (KLC). For ANR generation, a Jeerinah dolerite gave promising results. The mineralogy (determined from Rietveld XRD, QEMSCAN, bulk assay and carbon analysis) contains low carbonates (calcite 2-3 wt.%, ankerite 0.5-1 wt.%) with abundant reactive silicates including chlorite >30 wt.% (≈20 wt.% poorly crystalline not seen in QEMSCAN but not in XRD), anorthite 5 wt.%, tremolite 9 wt.% with a large amorphous fraction, 54 wt.%, in XRD probably consisting of chlorite-like material (from bulk assay reconciliation). The ANC of the carbonates from assay is around 30 kg $CaCO_3$/t but the measured ANC (modified Sobek test, AMIRA/EGi, 2002) of the dolerite is 47 (pH 2.4) to 84 (pH 1.2) kg $CaCO_3$/t depending on the final pH after the acid aliquot choice. Calcium concentrations were independent of initial pH suggesting that calcite and ankerite were quantitatively dissolved in each case with the remaining silicates (principally clinochlore chlorite) present in the dolerite contributing between 17 and 54 kg $CaCO_3$/t, depending on the *in situ* reaction pH. This initial characterisation is valuable for short-term neutralization but, given the abundance of silicates in most mine waste materials, it is the **rate of dissolution** rather than total concentration which determines the ability of silicates to buffer acidity resulting from sulfide oxidation. The ANRnc estimate from the mineralogy at pH 4 is 395 mg H_2SO_4/kg/week and at pH 5 is 81 mg H_2SO_4/kg/week suggesting significant neutralization as well as potential AGR reduction via pyrite passivation.

Blending 10 wt.% dolerite into the Jeerinah shale resulted in leachates characterized by neutral pH and a slight excess of alkalinity with low dissolved metal concentrations (not detectable in most cases). These results indicate that co-disposal of Jeerinah shale with Jeerinah dolerite, will substantially reduce the risk of drainage containing elevated levels of metals emanating from waste emplacements in which these materials are stored. Initially, dolerite was evaluated as a cover material for Mt. McRae shale. Results demonstrated that Jeerinah dolerite failed to supply sufficient alkalinity to keep the pH high enough to bring about pyrite passivation. However, leachates from the column tests in which Jeerinah dolerite was added to Mt. McRae shale as a base layer or as a vertical interlayer were characterized by: pH>7 effluent; no acidity (slight excess of alkalinity); low salinity (conductivity ≈100-200 μS/cm); low dissolved metal concentrations (non-detectable in most cases) and unexpectedly low sulfate, Ca and Mg concentrations. It appears that, under these test conditions, dolerite provides a preferential flow path for solution in the presence of Mt. McRae shale and could potentially be used in waste rock emplacements to channel acidic water flowing from ARD waste and to treat the seepage by removing both acidity and salinity.

Using the analyses for AGR and ANR, the evolution of W39 Terrace Dump at Mt. Whaleback has been characterized using water monitoring data collected at the AMD dam. The water samples had an average pH of 4.2 with high Mg (273 - 1210 mg/L), Al (up to 98 mg/L) and Si (up to 96 mg/L) concentrations suggesting that dissolution of (Mg, Al, Si)-containing chlinochlore has been the major buffering mechanism within the dump. The calculated AGR/ANRnc (ANR non-carbonate) data estimated from each of the AMD dam water samples fall within the values measured for long-term KLC tests, suggesting that the estimates made for the dump are quite reasonable. The average ratio of AGR/ANR of 1.02 indicates that the AGR was fairly close to the ANR provided by silicate minerals within the dump in 2008-2009 and that further reduction in AGR from the dump should give increased water pH in the AMD dam.

Hidden Valley Joint Venture (PNG)

A review of all previous reports on Hidden Valley (HV) waste rocks including waste classifications, site and consultants' KLC tests was completed (Gerson et al., 2014). The lithologies of the main rock types at the site are granodiorite (GD) and metasediment (MS) (the latter hosting most of the ore). The metasediment lithologies are all AMD-generating. Both lithologies can contain significant pyrite, but the HV granodiorite (HVGD) mineralogy contains calcite (11 wt.%) with the majority silicates as reactive plagioclase (anorthite with albite), chlorite, muscovite, orthoclase and quartz as well as significant pyrite content (4 wt.%). The overall ANC of the HVGD is high, *i.e.* 133 kg H_2SO_4/tonne and the ANRnc estimate from this mineralogy at pH 4 is 128 mg H_2SO_4/kg/week and at pH 5 is 30 mg H_2SO_4/kg/week delivering significant neutralization.

To test whether passivation of pyrite and AGR-ANR matching can be achieved with HVGD, KLC tests of a composite metasediment sample (2 wt% pyrite) with HVGD surface layers or in recycle from flow-through HVGD sub-columns were set up. The ANR (from effluent analysis) of the HVGD surface-layer column is initially about 50% of the AGR but the ANR matched the rapidly decreasing AGR at around 70 weeks, as the fine pyrite was depleted, but with pH still near 2.5. In the water recycle system, the effluent subsequent to both the MS composite column and the sub-column containing HVGD maintained neutral drainage and provided alkalinity up to 56 weeks. In recycle of this effluent to the MS composite column, the pH of the main recycle MS composite column in this system was only slightly increased but the acidity of the effluent was significantly lower (≈50 %) than for the MS composite control column after 16 weeks. Although recycle from the HVGD sub-column was not able to provide sufficient ANC to match the AGR of the MS composite main column, the results showed that the HVGD sub-column neutralised the acidity from the MS composite effluent in low–flow conditions. This suggested that HVGD may be useful as a flow-through reactive barrier (similar to that used at the Savage River Mine) for low-flow seeps to reduce current lime additions. To test this proposition, the effluent from a 2 kg batch of MS composite was used to flush a 1 kg HVGD sub-column in standard KLC flush conditions. The pH of the effluents from the HVGD sub-column maintained neutral to slightly alkaline pH across 60 weeks. Most of the toxic metal ions were precipitated and were below detection in the HVGD effluent except Mn. The ANR (derived from effluent concentrations) of the HVGD sub-column was slightly greater than the AGR of the MS composite up to 16 weeks but became slightly less than the MS AGR beyond 16 weeks. However, HVGD ANR is underestimated due to precipitation of gypsum (*i.e.* loss of Ca) in the HVGD sub-column, so that it is likely that the actual ANR of the sub-column exceeds the AGR of the MS column across more than 80 weeks. SEM analysis confirmed that the pyrite in the HVGD sub-column was passivated under these conditions.

This sample of HVGD had relatively high pyrite content (≈4 wt.%), twice as much as the MS composite material. However, the neutralization rate of the calcite/anorthite/chlorite in the HVGD was sufficient to enable formation of passivated pyrite surfaces within the HVGD reducing the pyrite oxidation rate. These results suggest that testing to locate HVGD lithology with lower pyrite content outside the MS areas may provide greater ANR for potentially matching AGR from MS wastes in co-disposal or layer dumping.

CONCLUSION

Most mine sites have non-value minerals capable of providing some neutralization of acid mine (rock or tailings) drainage often not considered or surveyed in primary site ore assessment or AMD dump construction. Standard assessment methods define only total acidity potential (AP) or neutralization potential (NP) of these materials, *e.g.* NP/AP ratio. This does not consider the **rates** at which acid generating and neutralising reactions may take place, although it is these relative rates in disposal of rock and tailings wastes that determine whether acid and metalliferous drainage actually occurs. Methods are now available to assess both AGR and ANR from both carbonates and reactive silicate minerals in on-site waste rock lithologies. The ratio of AGR/ANR can be followed using these assessments. These short-term, snap-shot methods can be applied at any point in the evolution of the dump or tailings from greenfield planning to operating dumping to assess current and future acid rock drainage liabilities and to make maximum use of these on-site materials. The complete definition of geochemistry and mineralogy of site materials can provide more effective and reduced-cost management of these mining wastes. Examples where neutralising waste rocks have been identified and assessed at Savage River (Tasmania), BHP Billiton Mt. Whaleback and Hidden Valley (PNG) have illustrated the value of this approach.

Acid Rock Drainage (ARD) Inhibition by Sulfite Used as Part of the Inco Process for Cyanide Removal

Leslie Hardy and Paul Morton
AMEC Foster Wheeler Environment & Infrastructure, Canada

ABSTRACT

Calcium sulfite ($CaSO_3$) has been used as an ARD inhibitor at coal ash sites for over a decade. Sulfite is considered a redox buffer and oxygen scavenger because it readily oxidizes to sulfate. Site history at a gold mine in Canada indicates sulfite can persist for decades in saturated mine tailings and inhibit the onset of ARD.

Sodium metabisulfite (SMBS, $Na_2S_2O_5$) was used as part of the Inco process to treat cyanide in 300,000 tonnes of tailings. A mass balance was developed for nitrogen, sodium, calcium and sulfur. The mass of reagents used is consistent with the mass discharging in water from the tailings, and the percentage of nitrogen discharged is lower than the other elements. Most of the nitrogen added as cyanide remains sorbed to the tailings as strong acid dissociable cyanides such as iron-cyanide complexes, and nitrogen gas is formed by biodegradation of cyanide and ammonia.

This paper discusses why the mine tailings have not become acidic as expected based on acid-base accounting or humidity cell results. The mill used approximately 270 tonnes of SMBS to treat 100,000 tonnes per year of tailings, giving a concentration of approximately 900 mg/kg as sulfur or 2,250 mg/kg as sulfite. Sulfite readily oxidizes to sulfate on exposure to air, and the ion chromatography laboratory method does not routinely distinguish sulfite from sulfate. The water concentrations reported as sulfate may actually be a combination of sulfite and sulfate. Sulfite contributes to titratable alkalinity, and the measured alkalinity versus total inorganic carbon indicates the continued presence of sulfite. Calcium sulfite has a much lower solubility than SMBS, and calcium from the lime used in the Inco process prevents depletion of sulfite from the tailings. Field observations and humidity cell results indicate that calcium sulfite in the tailings inhibits the onset of acid rock drainage.

Keywords: sulfite, sodium metabisulfite, INCO process, cyanide, acid rock drainage

INTRODUCTION

A gold mine in Canada used sodium cyanide and a carbon in pulp process to recover gold and the Inco process to remove cyanide from the effluent. The mine processed 100,000 tonnes of ore per year for three years, and the resulting 300,000 tonnes of tailings is impounded on permafrost ground behind a tailings dam constructed across a creek bed. Based on the 2% sulfide content of the tailings and some of the humidity cell test results, the tailings are predicted to create acid rock drainage. Mining and milling activities ceased in the 1990s, and most of the tailings porewater continues to have a high pH, with only preliminary indications of acid rock drainage.

Groundwater and surface water monitoring commenced in 1999, including the flow rate and chemistry of the toe seepage and decant water from the tailings impoundment. In recent years, the flow rate has increased and a conceptual remediation plan has identified that tailings relocation could be required. Based on recent monitoring data and information presented in previous reports, a revised interpretation of the mine tailings geochemistry was developed.

The hypothesis presented in this paper is that the onset of acid rock drainage is inhibited by sulfite which was added to the tailings at a concentration of 2,250 mg/kg as part of the Inco process to remove cyanide from the tailings. The inhibition of the onset of ARD by calcium sulfite was first reported by Hao and Dick (2000) who completed laboratory experiments to evaluate the geochemical mechanism. This paper presents field evidence for ARD inhibition, and is apparently the first reported observation of sulfite inhibiting the onset of ARD at a mine site.

INCO PROCESS DESCRIPTION

The mill used the Inco SO_2/Air process to oxidize cyanide in the tailings and tailings water prior to storage in the tailings pond. The following discussion about the Inco process is primarily based on Mudder, Botz & Smith, 2001, and Breuer, Jeffery & Meakin, 2011. This process description leads to an accounting of the mass of reactants used at the mill versus measured values in the tailings decant and toe seepage water.

The Inco process is based upon conversion of free cyanide and weak acid dissociable (WAD) cyanide complexes to cyanate using a mixture of sulfur dioxide (SO_2) and air in the presence of a soluble copper catalyst at a controlled pH. The specific amounts of reagents used vary between mine sites, and this mine used sodium metabisulfite ($Na_2S_2O_5$) in a liquid solution.

When the Inco process is applied to tailings liquids (i.e. homogeneous systems in chemistry terminology) all of the free cyanide and WAD-cyanide is converted to cyanate (i.e. it is stoichiometrically converted; see Breuer, Jeffery & Meakin, 2011). However, cyanide reacts very strongly with iron on tailings solids to form strong acid dissociable (SAD) iron-cyanide complexes which are not affected by the Inco process. When the Inco process is applied to tailings slurries (i.e. heterogeneous systems), most of the cyanide remains sorbed to the tailings solids as SAD-complexes. Residual metals liberated from the WAD-cyanide complexes are precipitated as hydroxides. Therefore, the Inco process oxidizes free cyanide and WAD-cyanides to the less toxic form of cyanate, but most of the cyanide remains complexed onto iron in the tailings as SAD-cyanides.

Table 1 summarizes the annual reagent usage listed in a design document for the mine.

Table 1 Design reagent usage at mill

Reagent	Formula	Design Consumption Rate (kg/tonne)	Mine Lifetime Usage (tonnes)
Sodium Cyanide	NaCN	1	300
Lime	CaO	4.6	1,400
Sodium Hydroxide	NaOH	0.18	54

Hydrochloric acid	HCl	0.18	54
Copper Sulfate	$CuSO_4*5H_2O$	0.27	81
Sodium Metabisulfite	$Na_2S_2O_5$	2.7	810

The design usage of sulfur dioxide (3.6 g/g CN), lime (8.7 g/g CN) and copper (0.13 g/g CN) is consistent with the average data presented for twelve mine sites in Mudder, Botz & Smith, 2001. The average usage is: sulfur dioxide (4.8 g/g CN), lime (3.7 g/g CN), and copper (0.1 g/g CN). The theoretical usage of SO_2 in the process is 2.46 grams of SO_2 per gram of WAD-cyanide oxidized, but in practice the actual usage ranges from about 3.0 to 5.0 grams of SO_2 per gram of WAD- cyanide oxidized. Based on the design document for the mill and the reviewed literature, the amount of reagents used at the mine is consistent with other mine sites.

Sulfite

The Inco process has been described as using sulfur dioxide, although Breuer, Jeffery & Meakin, 2011 state that the active reagent is actually sulfite which forms when SO_2 hydrates as shown in equation 1.

$$SO_2 + H_2O \text{ -----> } SO_3^{2-} + 2\ H^+ \qquad (1)$$

Sulfite (SO_3^{2-}) is a redox buffer and oxygen scavenger because it readily oxidizes to sulfate according to equation 2.

$$SO_3^{2-} + 0.5\ O_2 \text{ -----> } SO_4^{2-} \qquad (2)$$

As presented by Hao and Dick, 2000, sulfite consumes oxygen by the oxidation to sulfate according to equation 2, and this prevents the aerobic oxidation of pyrite which is the first step in the formation of acid rock drainage. Warren Dick (personal communication, 2013) stated that sulfite recovered from flue gas desulfurization at coal fired power plants has been co-disposed with pyrite bearing coal ash at several sites in the Ohio, USA, region, and more than a decade of monitoring data indicates that the sulfite is inhibiting the onset of acid rock drainage. The oxidation of sulfite to sulfate occurs slowly at low termperatures, high pH and water saturated conditions (which limits oxygen influx to the tailings), and the continued presence of sulfite in the tailings after two decades would be expected under the site conditions. However, sulfite in water samples cannot be preserved, and would be expected to readily oxidize to sulfate according to equation 2.

The source of sulfite used in the Inco process can be gaseous or liquid SO_2, sodium sulfite, or sodium metabisulfite (SMBS). This mine used SMBS based on cost and reagent handling considerations. Solid SMBS is made by evaporating a sodium sulfite solution, and when added to water, the bisulfite ion converts to sulfite. Table 2 summarizes the approximate aqueous solubility of various forms of sulfite.

Table 2 Aqueous solubility of various sulfites

Form of sulfite	Aqueous solubility (mg/L)
Sodium metabisulfite	450,000
Sodium sulfite	270,000
Magnesium sulfite	5,000
Calcium sulfite	54

SMBS and sodium sulfite are highly soluble in water, but calcium sulfite is orders of magnitude less soluble. Therefore, in the presence of high calcium concentrations in groundwater, sulfite will tend to precipitate as calcium sulfite and this is a constraint on the concentration of sulfite in water at the mine. In the tailings area, calcium is primarily derived from the 'lime' (CaO, also known as quicklime) used to control the pH for the Inco process. If calcium was not present in the tailings

water, the concentration of sulfite in the discharge would have been much higher, and the source would have been depleted more quickly.

High concentration aqueous sulfite solutions have a pH of about 9, and unlike sulfate (SO_4^{2-}), sulfite (SO_3^{2-}) can contribute to acid titrable alkalinity. The equilibrium pH point between SO_3^{2-} and HSO_3^- (i.e. the pKa) is 7.17, and when titrated to the standard alkalinity titration endpoint of pH = 4.5, sulfite buffers the addition of acid and contributes to the measured total alkalinity. Sulfate does not contribute to measurements of alkalinity because the pKa of SO_4^{2-} and HSO_4^- is 1.99 and alkalinity titrations only extend to an endpoint pH of 4.5. Therefore, in addition to carbonate alkalinity, as measured separately by total inorganic carbon (TIC), sulfite also contributes to total alkalinity. The potential contribution of sulfite is not explicitly recognized in textbook definitions of alkalinity, although weak acids such as sulfurous acid (H_2SO_3) can contribute to total alkalinity.

METHODOLOGY

Surface water and groundwater sampling commenced at this mine in the 1990s.. Tailings decant and toe seepage water samples have been collected approximately every three weeks (271 samples in 14 years) and analyzed for a comprehensive suite of analytical parameters including pH, alkalinity, chloride, sulfate, sulfide, metals, ammonia, nitrate, nitrite, and cyanides (free cyanide, WAD-cyanide, SAD-cyanide, thiocyanate, and cyanate). Groundwater has been sampled less frequently, with most locations being sampled five times since 2009. In 2013, some additional parameters and modified sampling protocols were used in conjunction with the standard parameters and methods. These modifications included the collection of unpreserved dissolved metals samples, and field measurements of sulfide in water. Additional parameters added in 2013 included total inorganic carbon (TIC), total organic carbon (TOC), and monitoring of the well headspace for biogenic gases (oxygen, carbon dioxide, and methane) using a landfill gas meter. Field parameters measured during the water sampling included pH, conductivity and dissolved oxygen.

Groundwater under flowing the tailings impoundment dam is collected by the seepage pond and the seepage is then continuously released to surface water. This seepage flow rate was measured daily using calibrated flow meters, and is consistent with water balances completed for the mine site. There appears to be minimal groundwater underflow from the tailings dam beyond that accounted for by the seepage meter because of the presence of permafrost ground. The observed seepage flow rate was approximately 50 L/min from 1999 to 2008, and has since increased to approximately 200 L/min.

Solid phase tailings samples were previously analyzed for standard acid base accounting, humidity cell testing, and field kinetic testing. The average sulfide content of the tailings was 2%, and the neutralization potential ratio of 0.5 indicates that the acid generating potential is greater than the neutralization potential. Based on these results, the tailings would be expected to generate acid rock drainage.

Sampling and analysis for sulfite in both soil and water is difficult due to the oxidation to sulfate by atmospheric oxygen and environmental analytical laboratories often cannot distinguish sulfite and sulfate when analyzing water samples by ion chromatography. The measurement of sulfite in water is also apparently limited by the formation and potential loss of SO_2 gas from water samples. There are analytical methods to measure sulfite in solids samples, although these methods are limited by the presence of sulfide minerals which can prevent the accurate measurement of sulfite.

RESULTS AND DISCUSSION

Reagent Mass Balance

The mass of a water quality parameter discharged is calculated as the volume of water times the concentration. The total mass for an element can be determined based on the various water quality parameters, and these values can then be compared to the mass of reagents used at the mill. For the

reagents listed in Table 1, water quality parameters are available to quantify the amount of sodium, calcium, sulfur and nitrogen discharged from the tailings area into the creek.

The volume of tailings water released was determined using a 10 day moving average centered on a date with water chemistry data. Graphs of the water discharged and corresponding water chemistry are presented on Figure 1 and the results are summarized on Table 3.

Inorganic nitrogen data is often reported by laboratories as mg/L-N to allow direct comparison between nitrogen species, and the total cyanide concentration as mg/L-N is calculated as shown on equation 3.

Total Cyanides as N = (14.01 g/mol) * [(CN-)/26.02+(SAD-CN)/26.02 + (OCN-)/42.02 + (SCN-)/58.08] (3)

By calculating total cyanides as N, a direct comparison with the breakdown products (ammonia, nitrate, and nitrite) can be completed as presented on Table 3. Total N is the sum of the various cyanide species (free cyanide, SAD-cyanide, cyanate, thiocyanate) and the measured inorganic nitrogen species (ammonia, nitrate, nitrite) formed by the degradation of the cyanides. WAD-cyanide is not included in this calculation as this cyanide fraction is included in the SAD-cyanide fraction reported by the laboratory as total cyanide. Note also that the measured WAD-cyanide values are higher than can be accounted for by the measured concentrations of metals that form WAD-cyanide complexes (e.g. copper) which indicate that in this case the WAD-cyanide test is actually measuring organic-cyanide complexes (Dzombak, Ghosh and Wong-Chong, 2006).

The total cyanide mass discharged reached an inflection point in about 2002 when the concentrations decreased to near non-detect levels; however, the concentration of the nitrogen breakdown products (ammonia, nitrate, and nitrite) has remained steady since monitoring began. This observation is consistent with the continued breakdown of the SAD-cyanide complexes on the tailings.

Mass balance calculations for the data presented on Figure 1 versus the mass of mill reagent chemicals used are presented on Table 3. Most (57%) of the sulfur added at the mill as sodium metabisulfite and copper sulfate is accounted for by the mass of sulfur measured in the discharge. For comparison, only 6.2% of the nitrogen added at the mill as cyanide is accounted for by the various nitrogen compounds analyzed (ammonia, nitrate, nitrite, free cyanide, SAD-cyanide, cyanate, thiocyanate). The lower value for nitrogen is consistent with the fact that most of the cyanide remains sorbed to the tailings as iron-cyanide complexes, and some nitrogen would also be lost as nitrogen gas (N_2) from the biodegradation of cyanide and ammonia. The higher percentage for sulfur may be due to the observation that this measurement is dominated by "sulfate" which is likely a combination of sulfate and sulfite, and also due to oxidation of sulfide minerals in the tailings.

Groundwater and Soil Gas Chemistry

Sample data and the calculations used to infer the presence of sulfite are presented on Table 4. The data presented is categorized as Well Series A to D, and sample data from a monitoring well representative of these categories is presented. There are approximately 30 groundwater monitoring locations.

Monitoring well headspace gas measurements show methane at percent level concentrations at four monitoring wells on the upgradient side of the tailings, and oxygen at (or above) atmospheric concentrations in the other monitoring wells within the tailings. The highest oxygen concentration measured was 23.9% using a calibrated GEM 2000 Plus. Well headspace gas monitoring was repeated three times using four different landfill gas meters. Reproducable results show the presence of methane at four wells, and that at most monitoring well locations oxygen is present at near atmospheric concentrations. These results are consistent with the presence of dissolved oxygen and lack of detectable sulfide in the water.

For monitoring wells classified as Well Series A (two wells on upgradient side of tailings), the pH is near 9, and sulfite was identified (but not quantified) in the ion chromatograms for the 2013

samples. These samples were not preserved to prevent oxidation of sulfite to sulfate, and the calculations on Table 4 show that slightly more than half of the total alkalinity expressed as $CaCO_3$ would be from sulfite, and this would represent approximately 10% of the total sulfur in the water sample.

Well Series B represent approximately 20 locations primarily within the mine tailings, and along a creek downgradient of the tailings dam. For Well Series B, the pH remains near 7.5, and the calculated sulfite concentration needed to provide the missing alkalinity ranges from 5 mg/L to 170 mg/L, with most locations having a calculated sulfite concentration of less than 80 mg/L. These calculated sulfite concentrations are consistent with the low solubility of calcium sulfite as shown on Table 2. Furthermore, the calculated concentrations of sulfite are consistent with the missing sulfur fractions when comparing the reported sulfate and total sulfur concentrations.

For monitoring wells classified as Well Series C (two wells on downgradient side of tailings dam), acid rock drainage is apparently starting in 2014. Since 2013 the sulfate concentration tripled, the pH decreased to slightly below 6, and the total alkalinity decreased to 35 mg/L. The reported 1990 mg/L of sulfate represents 651 mg/L of sulfur, and the measured total dissolved sulfur was 634 mg/L. This indicates that essentially all of the sulfur in the sample is present as sulfate. At both of these locations in 2013, acid rock drainage had not yet started, and the calculated sulfite concentration was consistent with Well Series B. At these two locations, it appears that the available sulfite has been depleted, and oxidation of the mineral sulfides has started.

For monitoring wells classified as Well Series D (four locations on or immediately downgradient of the tailings dam), the sulfate and total sulfur concentrations are low, and the amount of sulfite that would be required to provide the missing alkalinity is comparable to Well Series B. The water chemistry shown for Well D on Table 4 includes 583 mg/L of sulfate (measured on an unpreserved sample, and later confirmed by the laboratory), but only 1.6 mg/L of dissolved sulfur as measured in the acidified dissolved metals sample. In 2013, duplicate samples had reported sulfate concentrations of <5 mg/L and the dissolved sulfur concentration in duplicate samples was 1.6 mg/L. These samples are from water table monitoring wells, and the low sulfur concentration at these locations immediately downgradient of the tailings dam appears to indicate that sulfur is being lost from the water as sulfur dioxide gas.

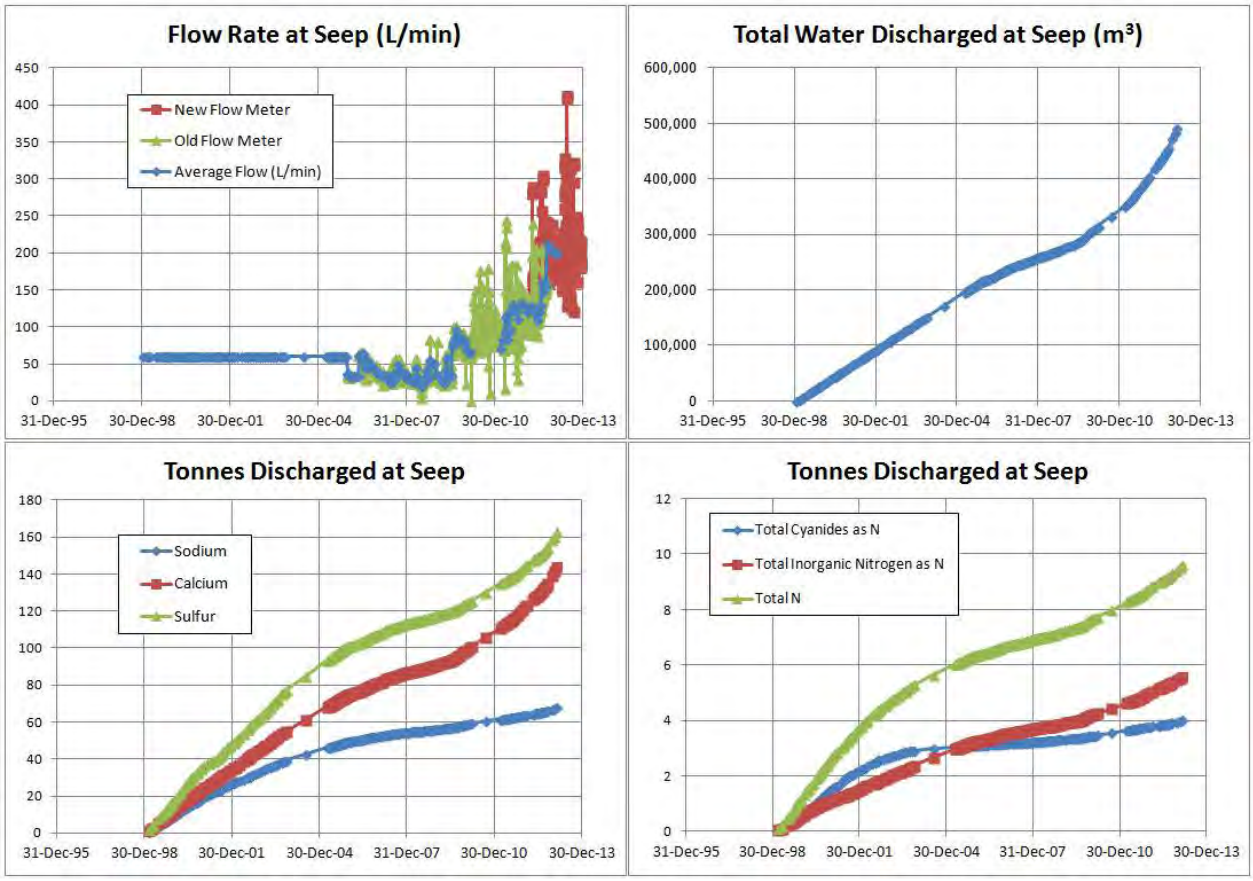

Figure 1 Graphs showing flow rate and total volume of water released from the tailings, and the total mass of sodium, calcium, sulfur and nitrogen compounds discharged

Table 3 Mass balance for mill reagents released from tailings 1999-2013

Parameter	Sodium	Calcium	Sulfur as S	Cyanides as N	Total Inorganic Nitrogen as N
Flow Weighted Average Concentration (mg/L)	139	294	331	8.7	11.3
Tonnes Discharged at Seep	68.0	144	162	4.3	5.6
Tonnes of Reagents Added at Mill	270	990	285		159
Tonnes Discharged as Percentage of Reagents added at Mill	25.2%	14.6%	57.0%		6.2%
Total water discharge from tailings from 1999 to 2013 was 490,800 m^3					

Like carbon dioxide (CO_2), when sulfur dioxide (SO_2) degases from water samples, acid is removed from the water and the pH rises. This effect is consistently seen in the monitoring data (with the exception of the two wells in Well Series A) where the field measured pH is lower than the laboratory measured pH. When CO_2 degases from a water sample, the pH rises but the total alkalinity in the sample bottle is unchanged due to the precipitation of calcite ($CaCO_3$). However, when SO_2 degases from a sample, the pH rises and sulfur is lost from the water sample as a gas. The loss of SO_2 usually occurs under acidic conditions, but several water samples collected

downgradient of the tailings dam have minmal amounts of both total sulfur and sulfate (i.e. Well Series D). This lack of sulfur in the water samples from this area could indicate that sulfur is either being precipitated as a solid, or lost as a gas.

The groundwater gradient steepens below the tailings dam, and this creates a larger surface area of water within the capillary fringe above the water table resulting in enhanced gas-water partitioning. Observations during groundwater sampling in 2013 indicate that the tailings porewater is charged with gas. This is likely to be nitrogen gas (N_2) created during the biodegradation of cyanide and ammonia. Nitrogen gas has a very high Henry's law constant (1540 L*atm/mol) and will partition from the water into the gas phase. Small amounts of nitrogen gas generated by the oxidation of cyanide and ammonia creates a high partial pressure of dissolved gas, and when the sum of the partial pressures exceeds the confining pressure, bubbles of gas can form (both in the tailings or in the sample bottle). Bubbles of gas were noted during the field sulfide testing and during the groundwater sampling. The presence of high partial pressures of dissolved gas provides a plausible mechanism to account for the lack of sulfur downgradient of the tailings dam despite the neutral pH and the high aqueous solubility and low Henry's law constant (0.8 L*atm/mol) for sulfur dioxide. Samples were flown from the mine on commercial jet aircraft, and the lower air pressure at altitude may have allowed bubbles to form which could effectively partition sulfur dioxide from the water into the gas phase.

Due to analytical limitations, there are only indirect measurements of sulfite in the soil and groundwater at this site. The presence of sulfite is indicated by the mass balance of the mill reagents, and measurements of pH, sulfate, total sulfur, total alkalinity, total inorganic carbon (TIC), and electrical charge balance. The lack of iron oxidation noted in unpreserved water samples for metals analysis collected in 2013 also indicates the potential presence of an oxygen scavenger such as sulfite. Additional calculations can also account for the alkalinity consumed by the oxidation of some of the Fe^{2+} in the unpreserved metals sample bottles. By accounting for this loss of alkalinity, the charge balances shown on Table 4 can be improved. The low dissolved sulfur and sulfate concentrations measured at locations downgradient of the tailings dam indicate the loss of sulfur from the water samples as SO_2 gas. Finally, the observation that sulfide oxidation did not occur in the humidity cell testing of untreated tailings samples even after two years, despite the 2% sulfide content, is indicative of the presence of sulfite on the tailings. Humidity cell samples that had been pre-treated with acid to accelerate the testing process produced acid rock drainage as expected, and this is consistent with the loss of sulfite from the acidified tailings samples as SO_2 gas.

CONCLUSIONS

A former gold mine in Canada used sodium metabisulfite (SMBS) as the source of sulfite (SO_3^{2-}) in the Inco process to remove cyanide. Documents for the mine show that the rate of reagent usage at the mine was consistent with other mines. A mass balance shows that approximately 57% of the sulfur added at the mine mill can be accounted for in the water discharge from the tailings, but only 6% of the nitrogen can be accounted for as the various measured nitrogen compounds. These results indicate that most of the cyanide remains on the tailings solids as strong acid dissociable (SAD) complexes such as iron-cyanide; however, biodegradation of these cyanide complexes is continuing.

As shown on Table 2, the aqueous solubility of calcium sulfite is orders of magnitude lower than for SMBS or sodium sulfite. The use of lime (CaO) to stabilize the pH in the Inco process has resulted in high calcium concentrations in the tailings, and the low solubility of calcium sulfite has limited the leaching of sulfite from the tailings. The oxidation of sulfite to sulfate (SO_4^{2-}) is slow under the site conditions (i.e. low temperature, high pH, water saturated) and the continued presence of sulfite in the tailings under these conditions would be expected. However, sulfite in water samples cannot be preserved, and would be expected to readily oxidize to sulfate according to equation 2. Furthermore, laboratory analysis typically does not distinguish sulfite from sulfate, and the reported concentrations of sulfate are likely a combination of these two sulfur species.

Calcium sulfite recovered from flue gas desulfurization inhibits the onset of ARD in pyrite bearing coal ash waste and this process has been documented in the scientific literature. The observations at this mine site are consistent with the inhibition of the onset of ARD due to the presence of calcium sulfite on the mine tailings. This paper presents field evidence for ARD inhibition, and is

apparently the first reported observation of sulfite inhibiting the onset of ARD at a mine site. If monitoring shows that sulfite is being depleted, SMBS could be injected into the mine tailings to maintain the soil and water concentrations of calcium sulphite needed to inhibit the onset of ARD.

Geochemical Study of the Interaction of Acid and Alkaline Mine Drainage with $BaCO_3$

Julio Castillo[1], Alba Gomez-Arias[1], Jan Posthumus[1], Megan Welman-Purchase[2], Esta van Heerden[1]

1. *Department of Microbial, Biochemical and Food Biotechnology, University of the Free State, South Africa*
2. *Department of Geology, University of the Free State, South Africa*

In this study the geochemical behaviour of $BaCO_3$ was investigated and the optimization of its use in acid (pH 2.93) and alkaline (pH 8.2) mine drainage (AMD) with high concentrations of sulfate (1250-1400 mg/L) and moderate to low metal concentrations (mainly Fe^{2+}> Al^{2+}> Mn^{2+}> Zn^{2+}) was determined. Batch experiments were conducted using a series of four interactions with $BaCO_3$:AMD ratios of 1:400 (0.1g:40mL), 1:57 (0.7g:40mL) and 1:160 (0.25g:40mL), 1:80 (0.5g:40mL) with $AMD_{alkaline}$ and AMD_{acid}, respectively. Each series of the experiments were composed of 15 sub-samples in which the reactions were stopped at different time intervals (0', 5', 15', 40', 2h, 6h, 12h, 24h, 36h, 48h, 72h, 96h, 120h, 144h and 168h). The neutralization process increased the pH (to 8.3 and 9.98 for $AMD_{acid/alkaline}$, respectively) through alkaline additive dissolution. The metal solubility decreased with the precipitation of $BaSO_4$ and divalent metals (Mn^{2+} and Zn^{2+}) as carbonates and poorly crystallized Fe-Al oxy-hydroxides. These precipitates acted as a sink for trace elements to the extent that the solutions reached the pre-potability requirements of water for human consumption. In all the experiments, the reactions achieved steady state conditions between 6h to 24h. The results showed 100% SO_4^{2-} removal in AMD_{acid} with an initial concentration of 1250 mg/L within a residence time of 6 hours. While in the $AMD_{alkaline}$ with an initial concentration of 1400 mg/, 86% SO_4^{2-} removal was obtained within 24 h with lower residual barium than 0.1 g:40 mL $AMD_{alkaline}$ interaction. The results showed that this ratio was optimal and could be used in the future for remediation systems. In addition, the treatment of $AMD_{acid/alkaline}$ with $BaCO_3$ removes up to 50% salinity and conductivity. The final product was $BaSO_4$ sludge with moderate to low metal concentrations, which could even be recycled and used by other industries.

Keywords: acid alkaline mine drainage, $BaCO_3$

INTRODUCTION

The Acid Mine Drainage (AMD) generated from pyrite's oxidative dissolution, typically contains high concentration of anions (SO_4^{2-}) and metal (mostly Fe^{3+}>Al^{3+}>Cu^{2+}>Zn^{2+}>Mn^{2+}) which makes it a significant environmental problem for South Africa, as well as for other mining countries (Bell et al., 1998; McCarthy, 2011).

The South African AMD is characterized by a wide pH range from acid (2.6) to alkaline (8). The main reason for this fact is that the host rock contains mainly pyrite and carbonates (such as dolomite). Therefore the AMD is characterized by having high salinity (Ca>Mg>Na), hardness and heavy metal concentrations such as Fe^{3+} > Al^{3+} > Mn^{2+} and moderate to low trace metal concentrations such as Ni^{2+} > Zn^{2+} > Cu^{2+} (Durand, 2012).

Therefore, the conventional passive chemical systems based on a $CaCO_3$ or MgO neutralization process are not completely effective for these leachates, because: (1) the acid mine drainage treatment by $CaCO_3$ or MgO allows the neutralization and removal of heavy metals. However, it increases the salinity and hardness in the treated effluent. (2) The low solubility of $CaCO_3$ at high pH limits its use in treating acid and not alkaline drainages (Maree et al., 2004; Caraballo et al., 2011; Bologo et al., 2012). Also the active systems, such as reverse osmosis or GYP-CIX, can remove salinity and hardness. However, the high maintenance costs and the brine generated by the treatment decreases the viability of these systems (INAP, 2003).

Based on hydrogeochemical characteristics of this type of leachate, many treatment systems have been showcased that are generally based on sulfate-reduction bioreactors. This technology, despite having been optimized in recent years, has not been able to completely remove the high concentration of SO_4^{2-} and it did not decrease salinity and hardness in these leachates (Du Preez et al. 1992; Moosa et al., 2002; 2005).

$BaCO_3$ was tested in simple batch experiments in the 70's due to its dissolution in a wider range of pH (0-9) and due to its capability to precipitate sulfate as $BaSO_4$, but it was not considered viable because the dissolution rate was very low at pH values of 7-10 (Kun, 1972). In the 80's, 90's and again in 2006, $BaCO_3$ was tested as a step in an active process to remove sulfate (Trusler et al., 1991; Hlabela et al., 2006). However, these studies did not optimize the $BaCO_3$ concentration, residence time nor provided relevant information about the geochemical behaviour of this compound and its use in AMD treatment.

Current studies have shown that $BaCO_3$ has a good dissolution rate between pH values of 0-6.5 and that the dissolution rate decreases when pH increases. In addition, it was also shown that $BaCO_3$'s dissolution rate increases with increasing temperature because of its endothermic nature. Moreover, previous studies showed variations between theoretical thermodynamics and experimental results regarding the dissolution of the $BaCO_3$ (Li & Jean, 2002).This knowledge is extended in this research which focused on addressing these issues by conducting a geochemical study with $BaCO_3$ and AMD that could explain both its behaviour as well as its potential to remediate these leachates. Understanding these processes will allow the optimization of $BaCO_3$ usage for sulfate removal and its contribution in removing salinity and hardness from acid and alkaline AMD.

METHODOLOGY

Starting materials

Acid and alkaline mine drainage

Two drainages with different hydrogeochemical characteristics from active and abandoned mines were collected from the South African provinces of Mpumalanga (25°42'20.4"S 29°59'28.4"E) and Gauteng (25°50'10.0"S 29°14'03.7"E) which were used as natural reagent solutions for batch experiments. The first drainage was an alkaline mine drainage (AMDE), whose hydrogeochemical characteristics conforms to the average of typical coal mine drainages (high sulphate, salinity and hardness concentration). The second drainage was acid mine drainage collected from an abandoned

mine (AMDK), which is characterized by high acidity and pollutant concentration (Bell et al., 1998; McCarthy, 2011). Each sample was taken on site in polyethylene tanks (ca. 260 L) for further experiments and part of each sample (1L/AMD) filtered through a 0.45 μm filter within 24 h for chemical analysis.

Alkaline material

Alkaline material used in this experiment was $BaCO_3$ (Protea Chemicals Company SA). $BaCO_3$ have a purity of 88.6%. These materials contain impurities including Fe and S as SO_4^{2-}, in negligible concentrations. Finally, a representative and homogeneous sample of 1 g was taken, which has been chemically and mineralogically analysed.

Batch experiment

Batch experiments were conducted to test the interaction of alkaline material with AMDE and AMDK at different time intervals (0min, 5min, 15 min, 40 min, 2 h, 6 h, 12 h, 24 h, 36h, 48 h, 72h, 96 h, 120 h, 144h and 168 h) in falcon tubes (50 mL) under continuous mixing in a rotary mixer at 12 rpm and room temperature. Four series of interactions were carried out using solid:liquid (w/w) ratios of 1:400, 1:57 and 1:160, 1:80 for experiments with AMDE and AMDK, respectively. Each interactions will be identified throughout the paper as E1 that refers to the interaction between 40mL of AMDE and 0.1 g $BaCO_3$; E2 to the interaction between 40mL of AMDE and 0.7 g of $BaCO_3$; K1 to the interaction between 40mL of AMDK and 0.25 g of $BaCO_3$ and K2 to the interaction between 40mL of AMDK and 0.5 of $BaCO_3$. At the end of each time interval, the tubes were removed from the rotary mixer and the supernatant was separated from the solid product by centrifugation at 4000rpm for 3min. Finally, the supernatant solutions were filtered through a 0.45μm filter and the solid product was dried at 40°C.

Chemical analysis

The following parameters were analysed on site from the collected samples to avoid the dissolution effects of the CO_2 (g) and O_2 (g): pH, Electrical Conductivity (EC), salinity (Sal), redox potential (Eh) and temperature (T). The pH, EC, Sal and T were measured with the ExStix®II multi-probe, while Eh was with ExStix®II ORP (Pt and Ag/AgCl electrodes) probe. The Eh measurements were then corrected to standard hydrogen electrode (SHE). Samples were filtered and acidified to pH < 2 with HNO_3 (2%) and stored at 4°C for further chemical analysis at the Institute for Ground Water Studies, University of the Free State. Sulfate concentrations were analysed by a portable Hach spectrophotometer (model DR/900 colorimeter) according to the turbidimetric method described in the Hach Procedures Manual-Method Sulfate 608. Fe^{2+} and Fe_{Total} were determined after filtration (0.45 μm) with a Hach spectrophotometer (model DR/900 colorimeter) according to the colorimetric method described in the Hach Procedures Manual-Method Ferrous iron 255 and FerroVer 265. All these chemical analysis also were carried out on site.

The neutralization potential of $BaCO_3$ was determined by treating a sample with a known excess of standardized hydrochloric acid subjected to heat treatment (95°C). Finally, the amount of neutralizing bases expressed in tons $CaCO_3$ equivalent/thousand tons of material was determined from the amount unconsumed acid by titration with standardized sodium hydroxide (Jackson, 1958).

The $BaCO_3$ was digested by an *aqua regia* solution (1HCl:1HNO_3:1H_2O) at 90°C for 1 h up to its complete dissolution (Pérez-López et al., 2010). Total Element Concentration (TEC) from the digestion, as well as the sub-samples, were analysed by inductively coupled plasma-atomic emission spectroscopy (ICP-AES; Jarrel Ash Atom comp 975). The mineralogical characterization of the final experimental products was carried out by X-ray diffraction (XRD, powder method) using a Panalytical Empyrean diffractometer under following conditions: slit fixed at 10mm, Cu/ Kα monochromatic radiation, 40mA and 45 kV. Samples were run at a speed of 2˚θ /min (5-70˚). The spectrum was obtained by Highscore software. In addition, solid samples were also studied using a scanning electron microscope equipped with an energy dispersive system (SEM–EDS; JEOL model GSM 6610).

Geochemical modelling

Precipitation of newly formed solid phases by the $BaCO_3$ dissolution could control the fate of the metal concentrations in both the acid and alkaline mine drainage, studied by the batch experiment. The results of the hydrogeochemical analysis from supernatant of each reaction (sub-sample) were modelled by PHREEQC-2 geochemical speciation model (Parkhurst and Appelo, 2005) using MINTEQ thermodynamic database (Allison et al., 1991) to predict the aqueous speciation of leachates and saturation indices of solid phases in the experiments [SI=log(IAP/KS) where IAP is the ion activity product and KS is the solubility constant]. Zero, negative or positive SI values indicate that the solutions are saturated, undersaturated and supersaturated, respectively, with respect to a solid phase.

RESULT AND DISCUSSION

Characterization of the starting materials

Acid and alkaline mine drainage (AMD)

Results of hydrogeochemical characterization of the AMDs are reported in Table 1. The main difference between the two mine water samples is the pH. The pH values of AMDE and AMDK were 8.2 and 2.93, respectively. In the case of AMDK, low pH values were related to the low carbonate concentration in the host rock, which contain high sulphide concentration. Its intense oxidation and subsequent dissolution of pyrite, produces a large amount of acidity. In the case of the AMDE it had circum-neutral to alkaline pH-values due the low content of sulphide minerals and the presence of carbonate or basic silicate minerals (Banks et al., 2002). The carbonate dissolution also contributes to lowering the water quality by increasing the hardness and salinity, which also affects the ecosystem.

Table 1 Significant physicochemical parameters of the acid and alkaline mine drainages

	AMDE	AMDK
pH	8.2	2.93
EC (mS m^{-1})	209	170
Redox potential (mV)	295	415
Ca (mg/L)	256.0	169.84
Mg (mg/L)	138.9	66.34
Na (mg/L)	12.18	41.30
Ba (mg/L)	0.040	0.028
Fe (mg/L)	0.042	34.24
Al (mg/L)	0.019	44.89
Sulfate (mg/L)	1250.0	1400
Mn (mg/L)	0.023	10.11
Zn (mg/L)	0.016	1.31

Alkaline materials

The neutralization potential of $BaCO_3$ obtained was 525 tons $CaCO_3$ equivalent / thousand tons of material. The neutralization potential of $BaCO_3$ is lower than calcite which has a high neutralizing capacity of 937.5 tons $CaCO_3$ equivalent / thousand tons of materials. However, the calcite is scarcely soluble at circum-neutral pH (6-7), while $BaCO_3$, despite having a low solubility at circum-neutral pH (6-7) is able to dissolve at pH values of up of 8-9. Total Element Concentration (TEC) confirmed the product data from Protea Chemicals, which indicated that the most significant impurities were S and Fe with values of 0.30% (total sulfur as SO_4^{2-}) and 0.004% (Fe total). The average particle size was 1-3 μm.

Preliminary batch experiments were carried out to test the dissolution capacity of the $BaCO_3$ in alkaline and acid mine drainage. The results obtained in these experiments showed a sulfate removal percentage of 90% on average and an increase to pH of 9. The $BaCO_3$ had a higher dissolution at lower pH such as 4-5, whereas, at higher pH such as 8.9 the dissolution of $BaCO_3$ was slower. However, the dissolution of $BaCO_3$ after 24 h showed the same behaviour in both AMDK and AMDE, indicating that the pH does not decrease the dissolution of $BaCO_3$ after 24 h

Hydrogeochemical study of BaCO3 dissolution with AMD

The hydrogeochemical evolution as a function of time of the physicochemical parameters such as pH, Eh, EC, Sal, as well as sulfate concentration in the four ratio (w/v) interactions are shown in Figure 1. The neutralization potential of $BaCO_3$ allowed the pH to increase from 2.93 to 8.27 for the K1 and K2 interactions (0.25 and 0.5 g of $BaCO_3$), and from pH 8.2 to 9.98 on average for the E1 and E2 interactions (0.1 and 0.7 g of $BaCO_3$), respectively. The Eh values decreased from 295 to 67 mV and from 415 to 128 mV on averages, whereas EC decreased to 942 μS/cm and 1091 μS/cm (variation ±5%), for the E1-E2 and K1-K2 interactions, respectively. The decrease in EC values reflects an improvement in the quality of AMDs that was confirmed by the decrease in sulfate concentration in the solution. In the experiments with AMDK all these parameters achieved a steady state in 6 h in both interactions (K1 and K2). The behaviour of $BaCO_3$ was different for the interactions with AMDE (E1 and E2), where a steady state was achieved after 24 h. The sulfate concentrations decreased slowly after 24 h (E 1 and E2 reached 280 and 120 ppm after of 168 h) without achieving a steady state, while in the K1 and 2 interactions, the sulfate concentration was completely removed after 24 h. $BaCO_3$ dissolution was faster in the K2 interaction where the pH increased from pH 2.93 to 6.79 and the interaction was almost immediate. However the Sal and EC evolution was slower.

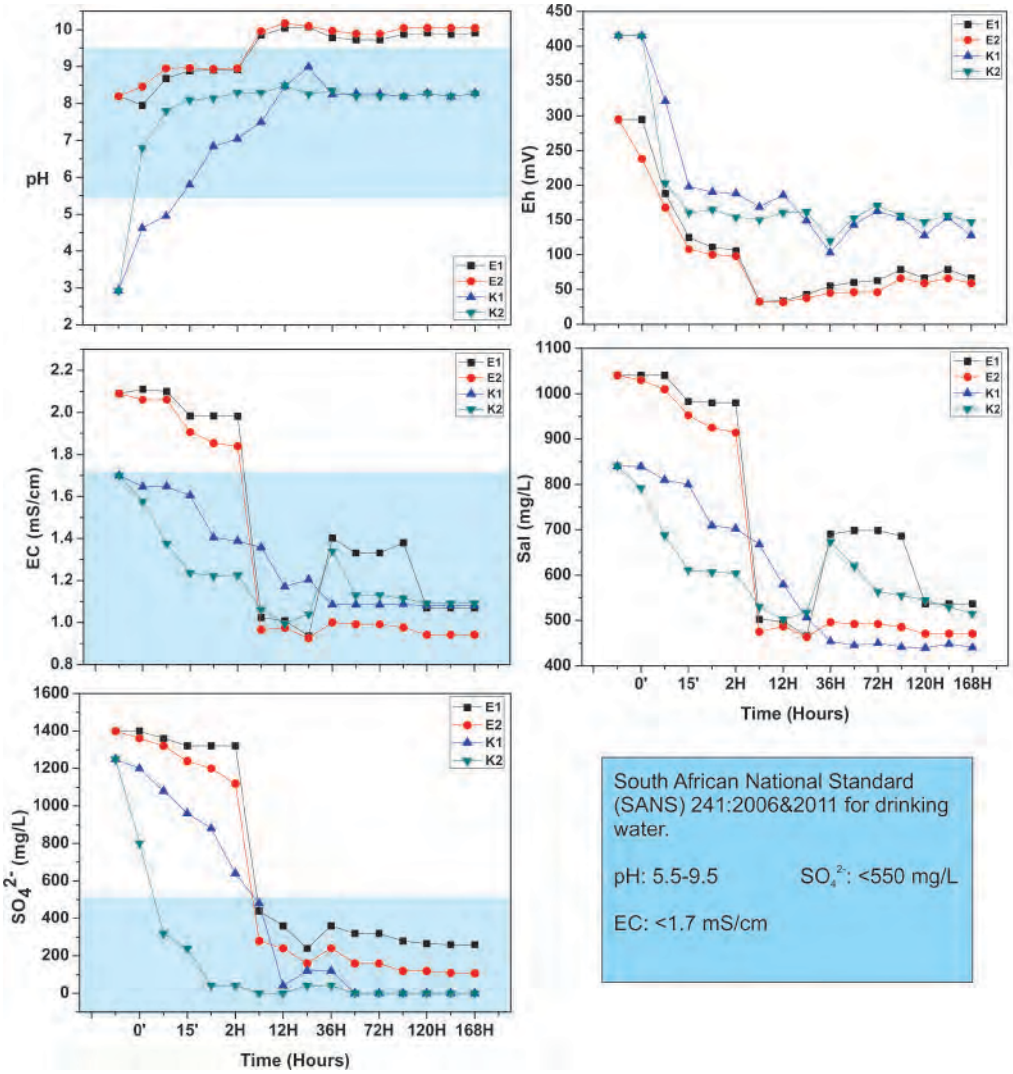

Figure 1 Temporal evolution of the physicochemical parameters from 0 to 168 h and its relation with drinking water standard (SANS 241)

The evolution of metals and sulfates are closely related to the dissolution rate and the concentration of $BaCO_3$ (Figure 2). Therefore, optimization and understanding of its behaviours is vital to assess its remediation potential. The interaction with a concentration of $BaCO_3$ larger than 0.1g (E1) showed higher concentration of dissolved Ba^{2+} at the end of the experiment (0.33, 6.7, 4.1 mg/L in E2, K1 and K2, respectively) which did not react during the experiment. Therefore, the concentration of $BaCO_3$ used in E1 can be considered as the optimum to be used in passive and active systems with a residence time of 24 hours, at most, to get an 86% sulfate removal rate.

The hydrogeochemical behaviour of the cations, such as Ca^{2+}, Mg^{2+} and Na^{+} over time was similar, between E1 and E2, as well as between K1 and K2. Ca decreased drastically within 6h, the removal reached 97 % in the E interactions, but in K interactions took 120 h to reach 51% of Ca^{2+} removal. The concentration of Na^{+} only decreased 18 % in K interactions.

The evolution of metals during the experiment will only be described and discussed with regards to the K interactions, due to the insignificant concentration of metals in AMDE. The concentration of metals in AMDK was as follow, $Al^{3+} > Fe^{3+} > Mn^{2+} > Zn^{2+}$ (44.89 > 34.24 > 10.1 > 1.3, respectively). The removal of Fe^{3+}, Al^{3+} and Zn^{2+} were 100%. However the removal of Mn was 66% in 24 h and 86% in 120 h.

Parameters such as EC, Sal and hardness decreased in all the interactions to values below the allowable limits for drinking water (SANS 241, 2006; 2011) (Figure 1). The removal of SO_4^{2-}, Ca^{2+} and heavy metals was the main reason for those parameters to decrease. Most of the passive systems are not able to remove Ca^{2+}, but increase its concentration (such as the systems based on $CaCO_3$), however this system has demonstrated its effectiveness in removing anions (SO_4^{2-}) and cations (mainly Fe^{3+}, Al^{3+}, Mn^{2+}, Zn^{2+} and Ca^{2+}) which is also reflected in the concentration of Sal and EC of the drainage.

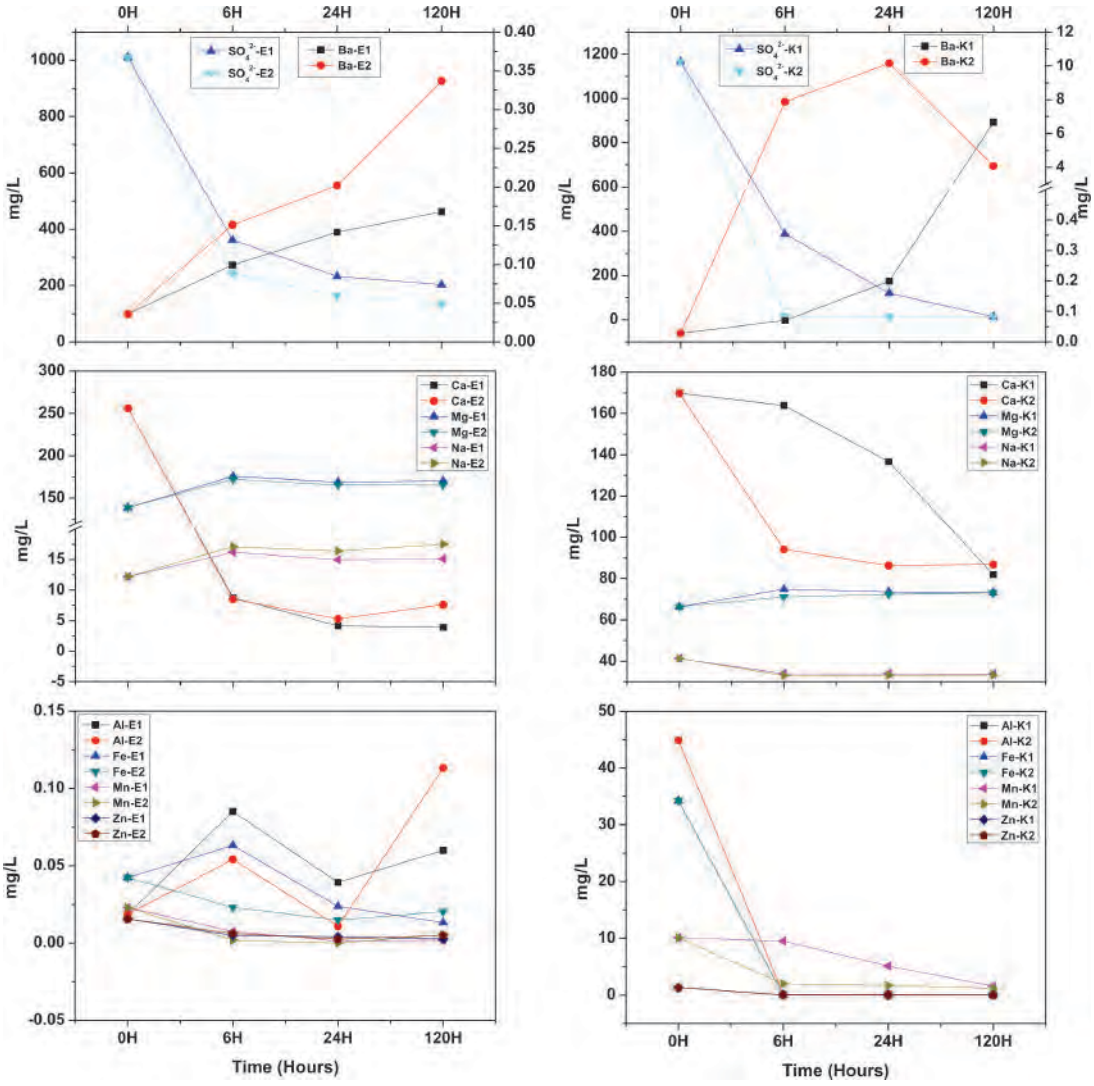

Figure 2 Temporal evolution of cations and anions from 0 to 168 h

The precipitates collected at the end of the experiment from E1 and K1 interactions, were analysed by XRD (Figure 3). The analyses showed mainly mineral phases related to the dissolution of $BaCO_3$ as well as to the precipitation of sulfate and Ca^{2+}. The geochemical processes involved in the increased of pH, as well as the sulfate, Ca^{2+}, Mg^{2+} removal, including Fe^{3+}, Al^{3+}, Mn^{2+} and Zn^{2+} has been represented by the following equations:

1. Representation of dissolution of $BaCO_3$ in AMD:

$$BaCO3s \rightarrow Ba2+(aq)+CO32-(aq) \quad (1)$$

2. pH values were increased by releasing OH^- radicals and formation of CO_2 that could act as a buffer to control the increase of pH .

$$CO32-aq+ H2Ol \rightarrow HCO3-aq+ OH-aq \quad (2)$$

$$HCO32-aq+ H2Ol \rightarrow H2CO3-aq+ OH-aq \quad (3)$$

$$H2CO32-aq \rightarrow CO2aq+ H2O(l) \quad (4)$$

3. The increased pH values would allow the trivalent and divalent metals precipitation as oxy-hydroxides and/or oxy-hydroxysulfate of Fe^{3+} and Al^{3+} and carbonates of Mn^{2+} of Zn^{2+}, respectively. In addition, the presence of carbonates and bicarbonates in solution would promote the Ca^{2+} and Mg^{2+} removal as carbonates and thus reduce the hardness of these AMDs.

$$Me+HCO3- \rightarrow MeCO3+H+ \quad (6)$$

$$Me+H2CO3- \rightarrow MeCO3+2\ H+ \quad (7)$$

The estimated percentage of those mineral phases were, according to the contact time (0h, 6h and 168 h), as follow: E1: 0h: witherite (71.2%) > calcite (15.9%) > barite (12.9%); 6h: barite (63.8%) > witherite (26.5%) > calcite (9.7%); 168h: barite (65.7%) > calcite (19.2%) > witherite (16.9%). K1: 0h: witherite (76.2%) > barite (13.5%) > calcite (10.3%); 6h: witherite (71.4%) > barite (18.9%) > calcite (9.6%); 168h: witherite (53%) > barite (28.5%) > calcite (18.5%).

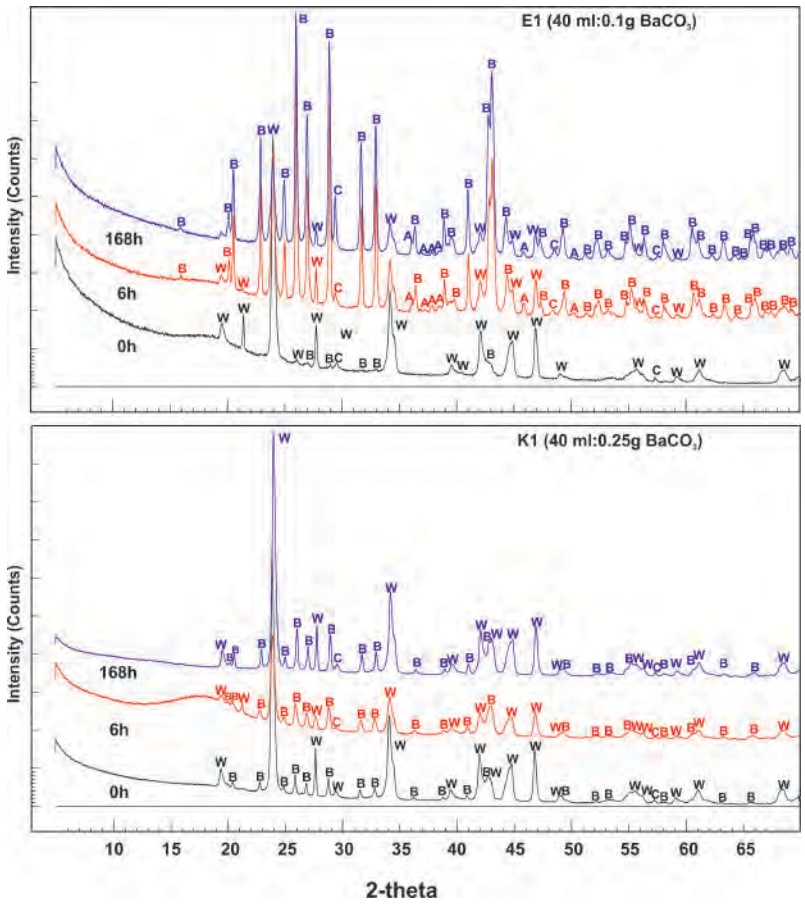

Figure 3 Difractograms of E1 and K1 at 0, 6 and 168 h. W: witherite, B: barite, C: calcite and A: aragonite

However these mineral phases could be masking other sub-idiomorphic or amorphous crystals, mainly in the K interactions, where the metal concentrations were high. This was corroborated by SEM-EDS analyses, where Fe^{3+}, Al^{3+} and Mn^{2+} were detected in the precipitates (Figure 4). The thermodynamic simulation with PHREEQC also supported this hypothesis by predicting the precipitation of Fe^{3+} and Al^{3+} as oxy-hydroxysulfate, poorly crystallized according to XRD analyses. This acted as a sink for trace elements and contributed to reaching the requirements for drinking water. The minerals phases of Mn^{2+} and Zn^{2+} were not predicted to be saturated by PHREEQC, however both metals were 100% removed from the AMDs. This again demonstrated that there are several discrepancies between the theoretical thermodynamic fundaments and the real geochemical data acquired throughout the experiment. Finally, the improvement of the quality of the AMDs used in the four interactions has been so effective that the final concentration of the sulfates was within the limit allowable for drinking water (South African National Standard 241, 2006; 2011).

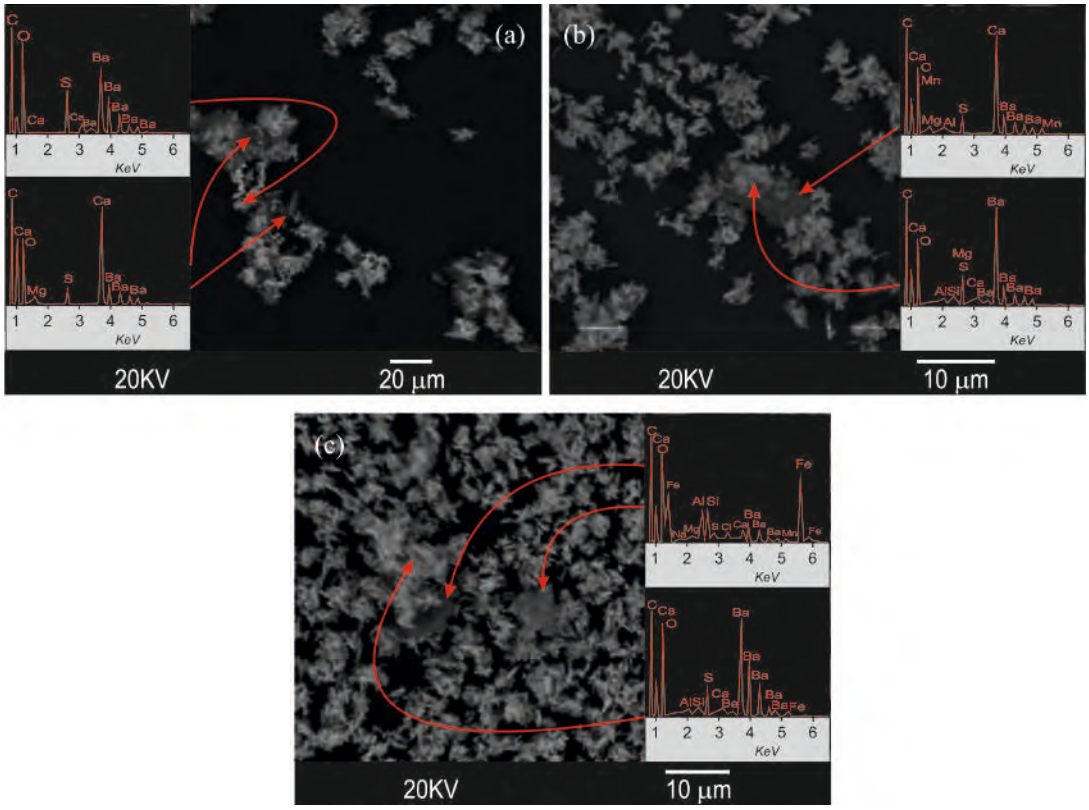

Figure 4 SEM-EDS images of minerals phase neoformed poorly crystallized

CONCLUSIONS

Batch experiments were conducted with the aim to study the behaviour and optimize the use of $BaCO_3$ in AMD remediation. Four interactions were carried out with two different AMDs and four different ratios (w/w) $BaCO_3$: AMD (1:400 and 1:57 with AMDE (alkaline) and 1:160 and 1:80 with AMDK (acid)). Each interaction was composed of 15 sub-samples, each of them with different contact time between AMD and $BaCO_3$ (from 0 to 168 h). All the samples achieved a steady state between 6 and 24 h. However the low solubility of the $BaCO_3$ at high pH slowed down the dissolution in E interactions, where the pH reached up 9.98 and the dissolution continued after 168 h. Nevertheless, E1 interaction reached a sulfates removal of 86% between 6 and 24 h. The sulfates and Ca removal were the most meaningful results in E interactions. Moreover, the total metal removal in K interactions was the determining factor for the improvement of the water quality. According to these results, the ratio used in the E1 interaction can be considered as the optimum to be used in systems with a residence time of 24 hours.

XRD and SEM-EDS analyses corroborated the sulfates and metals evolution over time by the identification of crystalline and amorphous mineral phases. The modelling also predicted the precipitation of mineral phases such as barite, calcite and Fe/Al oxy-hydroxides. However there were discrepancies between the predictions and the data acquired from the experiments, such as the removal of Zn and Mn that probably were precipitated as carbonates. Therefore the $BaCO_3$ dissolution varies according to the pH and the composition of the AMD. However, at the end of each experiment the water was within the South African National Standard for drinking water.

ACKNOWLEDGEMENTS

The authors would like to thank the Technology Innovation Agency (TIA) for funding the project, Kairos Industrial Holding Ltd. and Exxaro Resources Ltd. for samples and site access, as well as the Department of Geology and the Institute for Groundwater Studies, both at the University of the Free State, for the technical and analytical support.

ABSTRACT

The largest ever release of bauxite processing residue (red mud) into the surface water environment occurred in western Hungary in 2010 and left large areas of floodplain and river channel contaminated with a range of metals and metalloids such as Al, As, Cr, Co, Fe, Na, and V. Fluvial sediments provide an important sink, and potential secondary source for such contaminants, so there monitoring is key to assessing the health of the affected river environment. This study provides a comparative assessment of fluvial sediment quality in the Marcal-Rába catchment between post-disaster surveys (November 2010) and follow up surveys at the same locations in September 2013. The metal-rich signature of red mud apparent in initial surveys was much limited in extent in the recent surveys. These affected reaches amount to <1 km of stream, compared to the >20 km length of contaminated river in 2010. Concentrations of red mud-derived contaminants are predominately associated with fine fractions of the red mud (<8 □m). This fine-grained material has been preferentially transported out of the river system and in to the larger Danube system. These physico-chemical characteristics of the spill material, along with remedial efforts (primarily dredging), have substantially limited the within-channel inventory of potentially ecotoxic metals. As such, the legacy of the Hungarian red mud spill on the Torna-Marcal system appears to be largely overcome in a relatively short timescale since the disaster.

CHAPTER 9

COVER DESIGN AND PERFORMANCE

Incorporating Climate Variability into Cover System Design

Lindsay Tallon, Mike O'Kane, Jason Song and Amy Heidman
O'Kane Consultants, Canada

ABSTRACT

Climate is the ultimate determinant of cover system performance. Typical cover system design efforts apply average climate values as model inputs, resulting in an over-simplification of what is inherently a very complex system. The purpose of this work was to demonstrate a novel technique for separating the inherent scales of variability within a given climate signal. Long term air temperature and precipitation data from Fort McMurray, Canada were used. Air temperature averaged 0.3 °C, while the long term average precipitation was 412 mm. A moving average was used to reveal a long-term warming trend of 0.03 °C yr^{-1}. Determination of the cumulative departure from the mean for precipitation showed qualitatively periods where the annual average values departed substantially from the mean, suggesting the presence of wet and dry climate cycles. Unfortunately both techniques still operate under the assumption of data stationarity, or the assumption of a constant mean and variance, which by definition does not incorporate small scale cycles and long-term trends. Empirical mode decomposition (EMD) was used as a means of dealing with a non-linear, non-stationary dataset. The EMD technique works directly in the time domain to separate out the scales of variability inherent in the input signal, as well as to determine the contribution to the total measurement variance of each inherent scale. Air temperature was found to be dominated by the annual scale of variation, accounting for 76% of the total variance; a finding that is not surprising. However, the EMD technique was also able to demonstrate the long-term warming trend, while also uncovering high frequency variations from five to seventeen days. Precipitation had a more even contribution of high, medium, and low frequency cycles of variation. A major contribution to the total variance of the precipitation signal was at the 3 and 7 year scales, which are postulated to correspond to El Niño / La Niña cycles, and the Pacific Decadal Oscillation, respectively.

Keywords: Climate, cycles, variability, cover system

INTRODUCTION

Climate is the primary determinant governing cover system performance (MEND or INAP reference). The climate at a mine site will set the basic performance constraints, within which the cover system designer must work to achieve the design outcomes. Expected precipitation volumes and the evaporative capacity of a given location are two major design considerations that will ultimately dictate the success or failure of the entire closure landform. Given the risks involved should a closure landform not perform as designed, it is not surprising that climate data represents a critical model input during early design efforts.

Typical design approaches supply a long-term average precipitation value as a modelling input to predict future performance. However, using a single average value does not account for changing mean and variance in a climate dataset. Furthermore, applying a single average value does not allow for changes in antecedent conditions within the cover system. All periodic processes will have a range of scales of variation, from small, high-frequency changes on the order of minutes to hours, to large, low-frequency trends that can take decades to move through a single cycle. Failing to account for the many scales of variation in a climate dataset will ensure that the underlying complexities of the interactions at the soil atmosphere interface are not fully understood.

There are a number of methods for describing a climate dataset that range from very basic to extremely sophisticated. At its most basic, a characterization of the mean and variance will begin to describe the inherent qualities of the climate dataset. However, measurements of the central tendency and data dispersion soon become inadequate to properly characterize the variability of the climate model inputs. Geostatistical techniques are often employed to better understand the natural cycles of variability contained within a climate data time series. In addition, to the mean and variance, geostatistics only requires the probability distribution and the similarity between values at different temporal scales to be determined.

Geostatistics operate under the fundamental assumption that measurements made close together in time (space) tend to be more similar than those made further apart (Goovaerts, 1997). Geostatistics are used to analyze the distribution of data in a time series, and help to quantify patterns and structures within the dataset by describing the relationship between two points in time. The temporal (or spatial) structure, or the covariance, as a function of the separation, or the scale, helps to identify patterns in the dataset and major repeating processes (Si et al., 2007). Having an understanding of the structure of spatial or temporal variability in a dataset allows for better design of monitoring networks, proper data interpretation, and better assessments of simulation and uncertainty analyses (Si et al., 2008).

Whereas many common geostatistical techniques take advantage of the similarity of adjacent data points, spectral analysis transforms values from the spatial or temporal domain to the frequency domain. The result of analyzing data in the frequency domain is that the data are now partitioned wherein the total variation of the data are separated into different frequency scales. Spectral techniques then make it easy to identify dominant processes at discrete temporal or spatial scales, by simply identifying prominent spikes in frequency.

A drawback of spectral methods is that the mean and variance of the dataset do not change over time; a condition known as stationarity. For the cover system designer analyzing a climate dataset, this is problematic. Not only is it the cycles of variation within the dataset, it is the overall trend that in climate that can be of major concern. Using a single mean value for precipitation or temperature

ignores the implications of climate change in the cover system design. Spectral methods such as wavelet analysis (Torrance and Compo, 1998), Hilbert spectral analysis (Biswas et al., 2013), including empirical mode decomposition (Biswas et al. 2009) are methods that can account for nonstationary datasets. Thus, the methods are ideally suited for analyzing climate datasets when designing soil cover systems. Not only do the methods analyze high frequency, small scale climate cycles, but can also account for long term trends that span the entire dataset.

Application of geostatistics and spectral analysis to the investigation and design of unsaturated soil cover systems represents an excellent potential opportunity to define the dominant controls on performance. Too often the analysis of climate data inputs is reduced to using one mean value for the entire duration of the simulations, without consideration of the wider context of shorter term climate cycles and longer term trends. The objective of this manuscript is to demonstrate the utility of analyzing climate data inputs using geostatistical techniques.

METHODOLOGY

Dataset

The climate dataset in this analysis is the long-term Environment Canada data recorded at Fort McMurray, in the Athabasca region of Alberta, Canada. Records of precipitation extend from 1908 to 2012, while air temperature records begin in 1924 and continue to 2012. The Environment Canada data are freely available at http://climate.weather.gc.ca/. Data were initially analyzed by calculating the mean, variance, and standard deviation. Further analysis involved estimation of a 365 day moving average, and a cumulative departure from the mean (CDM). The CDM is simply calculated by summing the cumulative difference between the average value for a year, and the average value for the entire dataset.

Empirical Mode Decomposition

Geostatistical analysis was performed using empirical mode decomposition (EMD). The EMD method separates the variation in the temporal series into discrete component characteristic scales. The EMD method works directly with the dataset, rather than transforming the data into the spectral domain, as is the case with wavelet analysis. The method assumes that the temporal signal is composed of multiple components, all varying at their own specific scales of variability. The sum of all the components is equal to the dataset itself. Empirical mode decomposition is then used to sift out the component scales of variation into intrinsic mode functions (IMF) and determine their overall contribution to the total variance (Biswas et al., 2009).

The EMD method is adaptive and works directly with the data, without the need to rely on a mathematical function to transform the data, as is the case with wavelet analysis (Biswas and Si, 2011). For a complete treatment of the EMD process used to separate out the component IMFs the reader is referred to the examples shown by others (Huang et al., 1998; Biswas and Si, 2011; and Sang et al., 2012). In the present analysis, we are most concerned with the contribution of a particular temporal scale to the overall variance of the dataset.

$$\%Contribution = \left(\frac{Variance\ of\ IMF_i}{\sum Variance\ of\ all\ IMFs}\right) \times 100 \quad (1)$$

Examination of the amount of contribution of a particular IMF to the total variance allows for an estimation of the relative dominance of a particular spatial scale. The average scale of an IMF is calculated by counting the number of oscillations present in the IMF in question. For example, if over the 105 year dataset a particular IMF exhibits 5 oscillations, then the average scale of that IMF will be 105 / 5 = 21 years. This was the method used for reporting average temporal scales in the subsequent analysis. Oscillations of the IMFs can vary locally, and as such, reporting of temporal scales represents an average range for the particular scale. Therefore, the temporal scales of each IMF will be reported as a range, rather than a discrete value.

RESULTS AND DISCUSSION

Initial Data Analysis

Air temperature at Fort McMurray over the entire study period averaged 0.3 °C with a standard deviation of 1.4 °C (Figure 1). Precipitation averaged 412 mm with a standard deviation of 116 mm (Figure 2). Note that precipitation data are missing for 1911 through 1913, as well as 1947.

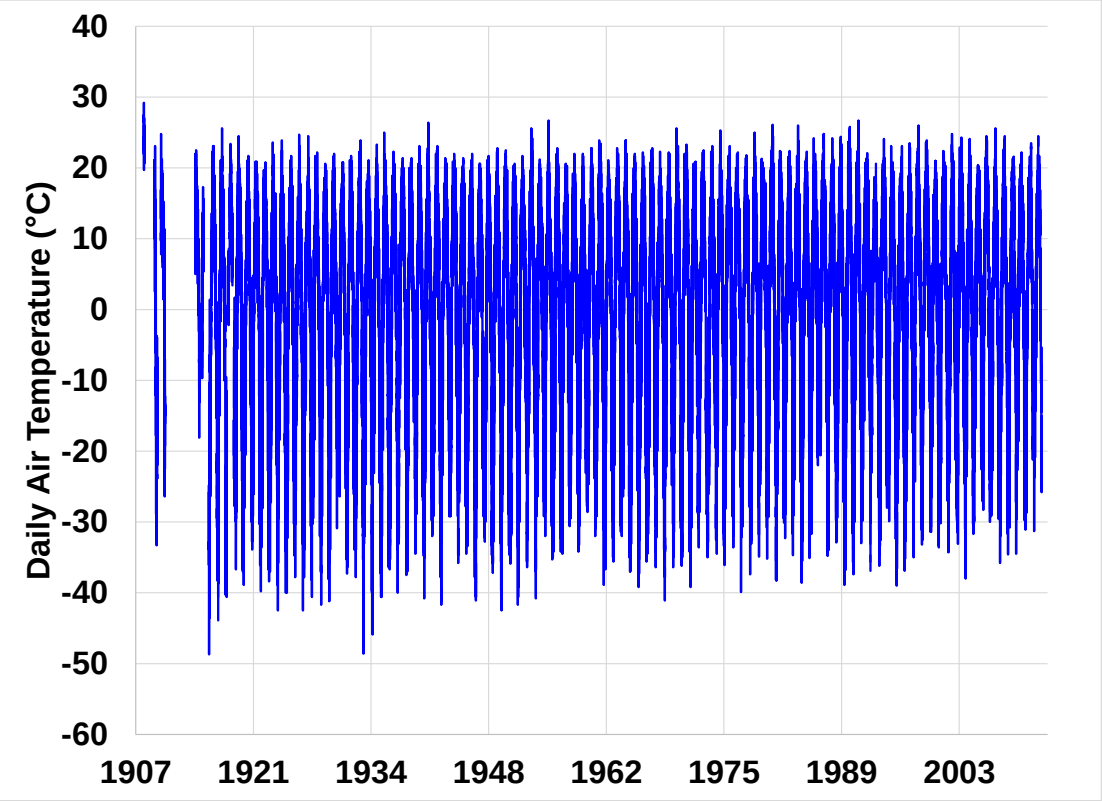

Figure 1 Average annual air temperature at Fort McMurray, 1908 to 2012.

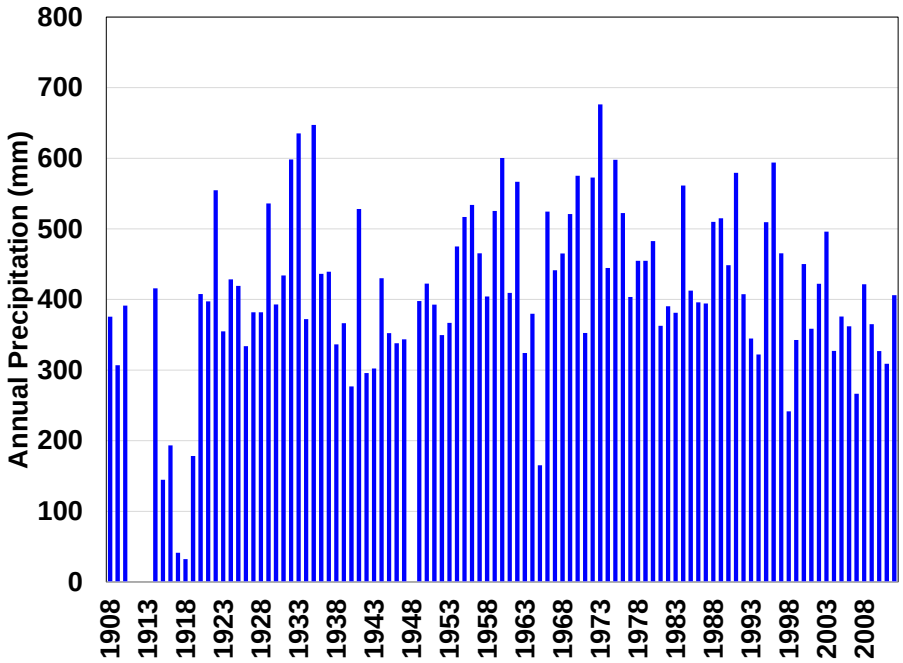

Figure 2 Average annual precipitation at Fort McMurray

Trends and cycles in the air temperature and precipitation data are not readily apparent from Figures 1 and 2. Without further investigation, the cover system designer could be satisfied that there a general annual average value for both air temperature and precipitation would be sufficient for use in modelling analyses. As will be further explored, the assumption of stationarity (constant mean and variance) may not be applicable.

A simple calculation of the average annual air temperature begins to suggest an overall trend in long term average air temperature (Figure 3). While it appears that temperatures have climbed above the mean value of 0.3 °C after 1970, the values are still within two standard deviations of the mean (± 2.8 °C).

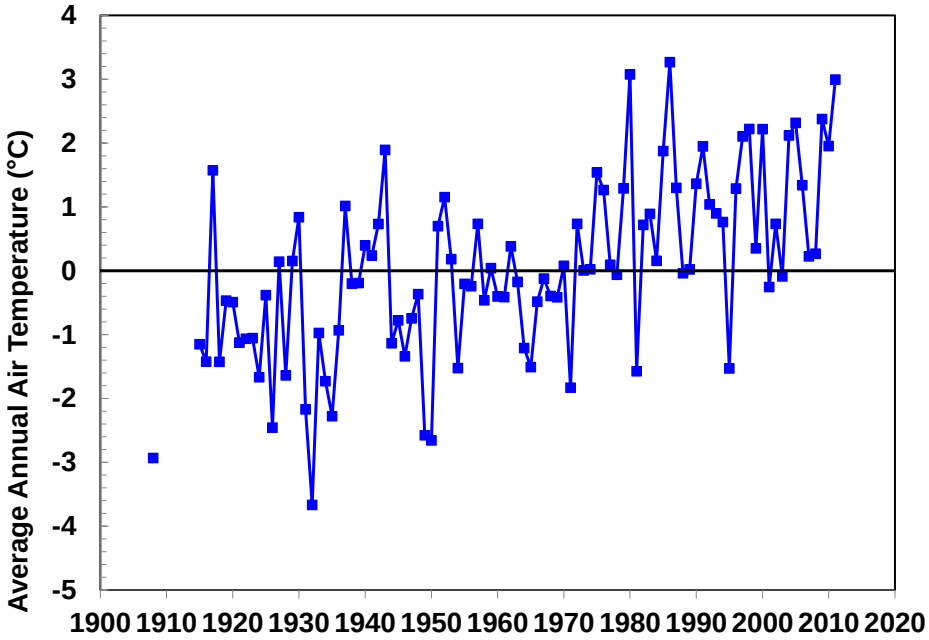

Figure 3. Average annual air temperature recorded at Fort McMuray, 1908 to 2012.

Moving Average

A common method to visualize long term trends in a dataset is to calculate a long term moving average. Three hundred sixty five day moving averages were calculated for air temperature (Figure 4).

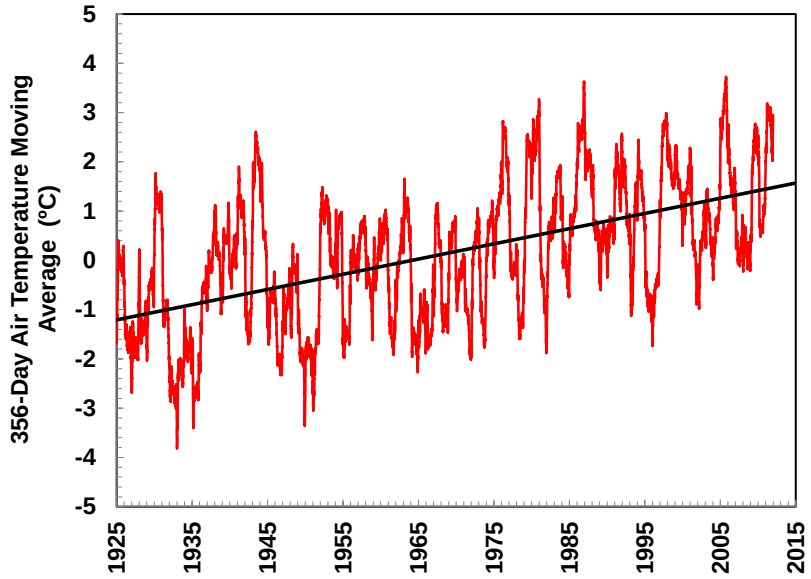

Figure 4 One year air temperature moving average.

A trend of increasing temperature is clearly evident from Figure 4. The slope of the trend line indicates a warming rate of 0.03 °C yr^{-1}. While the long term trend of the data is important, calculation of a moving average does not provide any additional information about the higher frequency, shorter duration cycles of variability within the dataset.

Cumulative Departure from the Mean

The cumulative departure from the mean of non-frozen precipitation (April through October) was calculated to demonstrate the variability of the precipitation dataset (Figure 5).

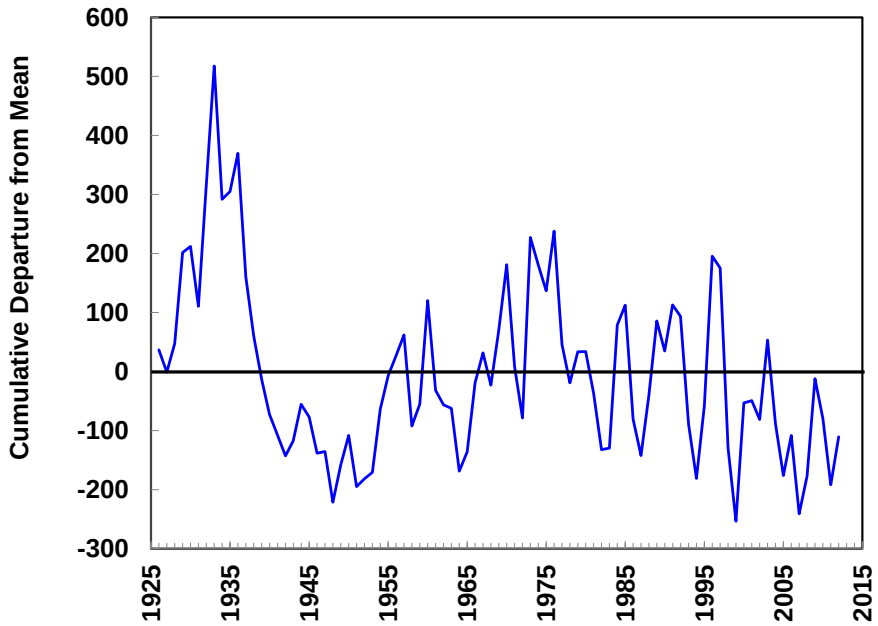

Figure 5 Cumulative departure from the mean for non-frozen precipitation.

The CDM technique is useful for demonstrating variability in a general sense. However, the technique still suffers from an assumption of data stationarity, in that the data are always compared to a single mean value. Furthermore, there is no means by which internal cycles of variability within the dataset can be elucidated.

Empirical Mode Decomposition

Empirical mode decomposition (EMD) works directly within the time domain to separate out scales of variation. The method results in a series of intrinsic mode frequencies that identify the scales of temporal variation buried within the data, as well as that scale's contribution to the total variance. Thus, an intuitive means of examining both low and high frequency variations results. Temporal variations of air temperature are dominated by the annual temperature signal (Figure 6).

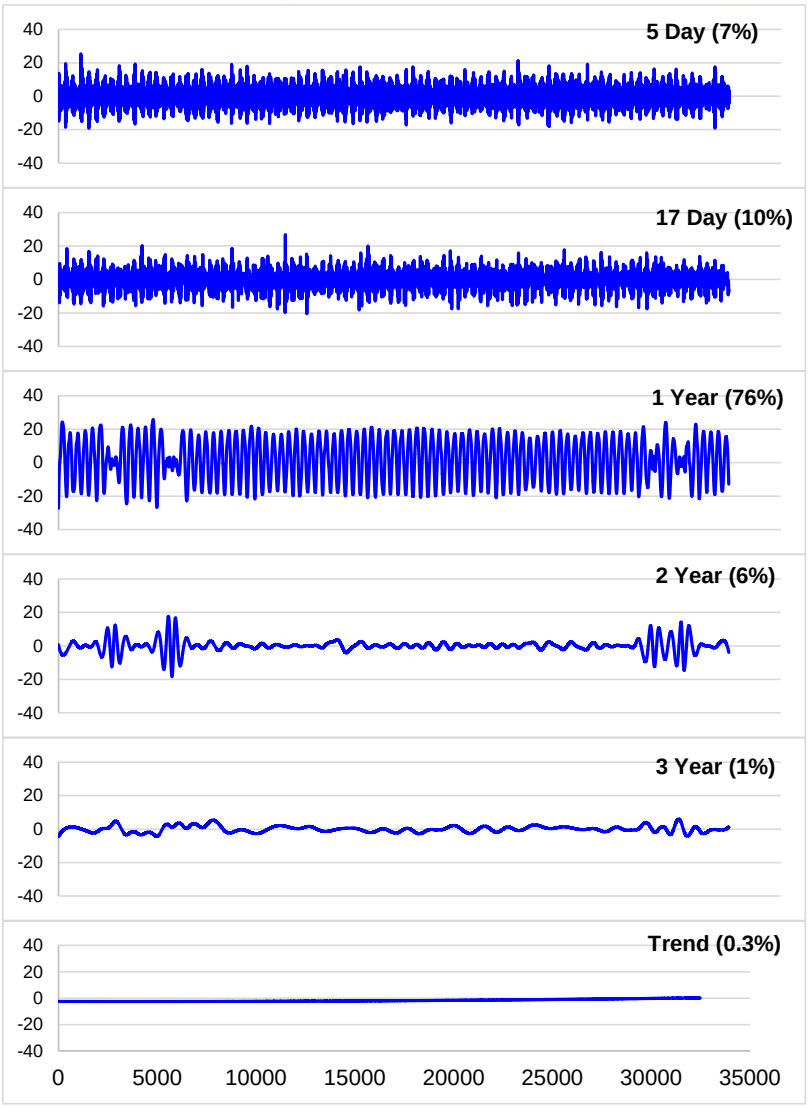

Figure 6. Temporal scales of variation intrinsic within the 1924 to 2012 Fort McMurray air temperature record.

It is clear from Figure 6 that temporal variations in air temperature are dominated by the annual signal and higher frequency signals between five and seventeen days. Also of note is the long term trend. Although the overall trend contributes very little to the total variance (0.3%), the trend is nonetheless present, thus verifying the trend that was identified earlier in the analysis. In fact, the overall trend increases at a rate of 0.03 °C yr^{-1}, providing further credence to the method.

Precipitation exhibits a more even distribution of scale contribution, relative to air temperature (Figure 7). Roughly a third of the scale dominance is contributed by the three year scale, suggesting that high frequency cycles of alternating wet and dry are to be expected in the region. It is possible that the three year cycles of variability could correspond to alternating El Niño / La Niña events.

Another major contributor to the total variance is the 7 year scale. It is interesting to note that the 7 year scale may roughly correspond to the Pacific Decadal Oscillation, another major determinant of Western Canadian weather patterns. Finally trend towards decreasing precipitation accounts for 23% of the total variance. While the EMD technique does not forecast into the future, it does elucidate the dominant cycles of variation over the timespan of the dataset. In the case of Fort McMurray for more than 100 years, the trend has been towards decreasing precipitation.

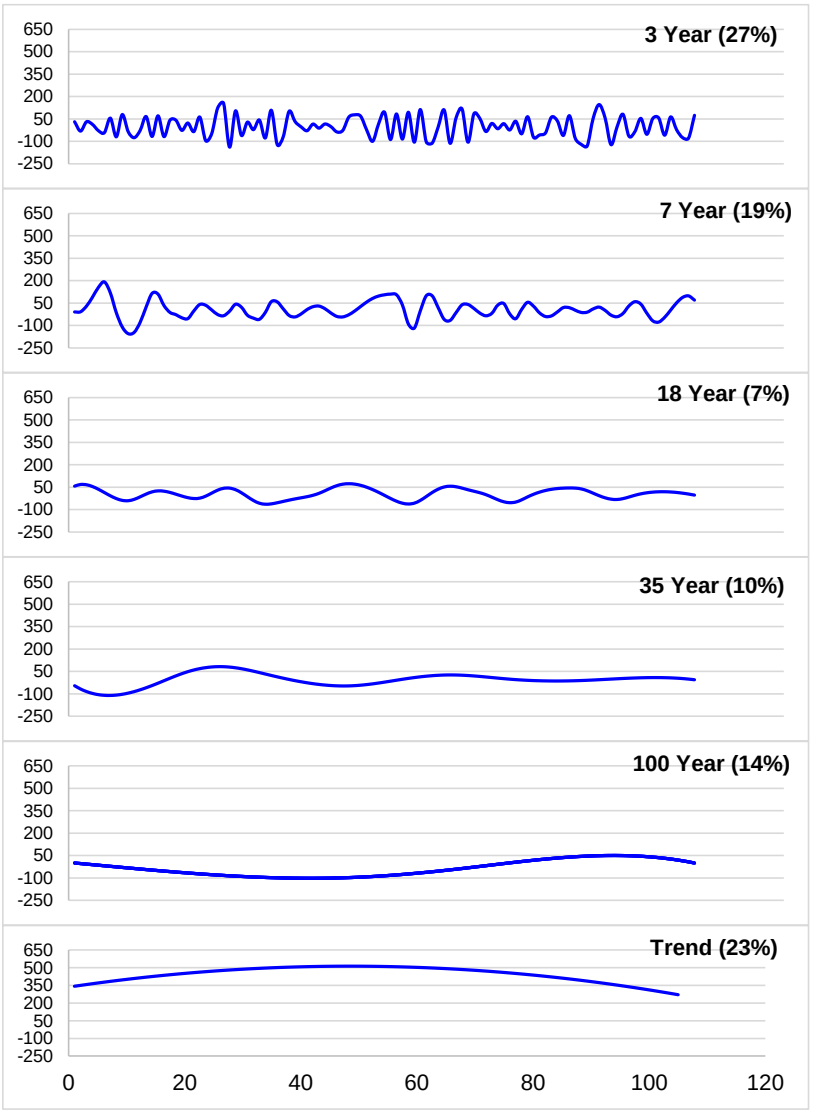

Figure 7. Temporal scales of variation intrinsic within the 1908 to 2012 Fort McMurray precipitation record.

CONCLUSION

Climate is the ultimate governor of cover system performance at a mine site. While certain cover system design parameters can be adjusted to certain degrees, the climate at a site cannot be controlled. Therefore, it is imperative that the designer understands the dominant climate at a site to the fullest extent possible. However, all too often a simple average of climate parameters is used as an input into the models used during the cover system design process. Not only does an average value of precipitation or air temperature result in an unrealistic generalization of site conditions, it fails to account for the cycles of variation that are inherent within all climate signals. Failure to examine the scales of variability within a climate dataset necessarily results in a spurious simplification of what is a very complex system.

The examples used in this manuscript demonstrate the need to have a greater understanding of the cycles of variability within a climate dataset, when designing a cover system. Long term temperature signals are not surprisingly dominated by the annual signal, but also contain a long term trend that indicates consistently rising temperatures. While the trend was not dominant, it explains why the recognition of changing temperatures is difficult to perceive. The signal of the warming trend is buried within more dominant, smaller scale / higher frequency signals.

Precipitation demonstrated that a number of scales of variation contribute to the total variance of the system. While no one signal was dominant, it goes to demonstrate that the cover system designer must be aware of all of the cycles of variation when designing the system. Determination of the cycles of variability underscores the importance of understanding where in a wet / dry cycle the system is being designed. If an average precipitation value is used from a dataset that doesn't capture the dominant scales of variability, the design of the cover system cannot be fully optimized. For instance, if a ten year average precipitation value is used to determine the optimal cover system thickness for supporting vegetation, and the average was taken from a wet cycle, the system may not be able to support vegetation throughout the entire life of the cover system. Conversely, when designing upland / wetland reclamation systems, it is critical to have a good understanding of long term climate in order to ensure that the watershed will have sufficient water supply to support wetland functions. If the watershed designer does not incorporate an analysis of precipitation trends and cycles of variability, the system will be less likely to be resilient to the cyclical changes in water supply.

ABSTRACT

A number of mining properties are present in the high-elevation (> 4 000 m) tropical Andes. The environmental conditions at these properties present challenges for mine closure. Precipitation is typically characterized by wet and dry seasons: in Peru wet season precipitation can exceed1 000 mm over a six-month period. Conversely, average potential evaporation rates are typically 60 to 80% of precipitation on an annualized basis. This precipitation and potential evaporation imbalance precludes the control of infiltration and percolation into mine waste solely via evapotranspiration cover systems.

To evaluate the efficacy of different cover systems in controlling infiltration and net percolation, cover system trials and studies have been initiated by Minera Barrick Misquichilca at their Pierina and Lagunas Norte properties. Large-scale test panels have been constructed over waste rock and heap leach facilities to evaluate different multi-layer cover systems to include the use of variable clay and topsoil depths and the use of drainage layers. Study results indicate that infiltration and net percolation is highly variable and greatly affected by surface water channeling and topographic depressions. In addition, the hydraulic properties of the cover system change over time.

The presence of a drainage layer can reduce the amount of net percolation; however drainage layers require high drain rock permeability and low permeability of the underlying layer, and are equipment and labor intensive to construct, and hence costly.

Keywords: Evapotranspiration, unsaturated flow, waste rock, ore, clay, hydraulic conductivity, drainage layer

INTRODUCTION

Peru is the leading gold-producing country in Latin America and second only to Chile in copper production. Many of the Peruvian mining properties are located in the high tropical Andes at elevations in excess of 4 000 meters above mean sea level (amsl). The climate at these locations is characterized by a bimodal precipitation pattern, cool temperatures, and high relative humidity. Precipitation is typically greater than 1 200 mm/yr, with over 80% of precipitation occurring during the rainy season which characteristically occurs between the months of October and April. Average potential evaporation rates are typically 60 to 80% of precipitation on an annualized basis.

Mines are increasingly using evapotranspiration (ET) soil cover systems to control infiltration and percolation into mine waste. ET cover systems function by storing infiltrated precipitation in the soil cover overlying the waste until it is removed by either plant transpiration or evaporation. These systems require that ET be in excess of precipitation to be effective. However, the precipitation and PET imbalance in the Peruvian Andes precludes the sole use of ET cover systems for this purpose.

In the wet environment of the Peruvian Andes, a multi-layer cover system that includes a low-permeability clay layer underneath the ET soil layer is an alternative to the single-layer ET cover system. To alleviate build-up of soil pore pressures, high-permeability drainage materials or perforated drainage pipes (suction breaks) can be placed above the clay layer on sloped surfaces to remove infiltrated water. Drainage tends to reduce pore pressures and percolation into the underlying material.

Cover system trials and studies have been initiated by Minera Barrick Misquichilca at their Pierina and Lagunas Norte properties to evaluate the efficacy of different multi-layer cover systems in controlling infiltration and net percolation. Large-scale test panels have been constructed over waste rock and heap leach facilities to evaluate cover systems comprised of variable clay and topsoil thicknesses and with or without subsurface flow manipulation. In this paper we examine the performance of the clay layer and different subsurface drainage configurations in reducing net percolation.

Site Conditions

Minera Pierina

The Pierina mine is located on the eastern flank of the Cordillera Negra, about 10 km northwest of the City of Huaraz in the Ancash Region of Peru. Elevations of the Pierina mine facilities range between 3 800 m and 4 200 m amsl. Test panels were constructed in late 2005 and monitored through 2009. Temperatures at the site rarely fall below 0° C and do not change significantly month by month; the average annual temperature is about 6° C. The recorded average annual precipitation during the 2006 to 2009 monitoring period was approximately 1 290 mm. Recorded pan evaporation and estimated reference crop evapotranspiration (ETo) averaged approximately 935 mm/yr and 745 mm/yr, respectively, for the four year monitoring period.

Two test panels, approximately 20 m by 55 m, were constructed on a 2.5(H):1(V) heap leach pad side-slope to test different clay layer construction methods. Each test panel had clay/silt borrow material placed over the waste, followed by 30 cm of topsoil material for an ET soil layer. The clay/silt material in Panel 3 was roller compacted after placement to approximately 90% of maximum Proctor density (2.07 g/cm^3) with a final approximate thickness of 35 cm. In Panel 4, only equipment traffic compaction occurred on the clay/silt material, resulting in a final approximate thickness of 55 cm. The Pierina cover system used a network of perforated drainage pipes placed at regular 10-m intervals in the topsoil layer to act as suction breaks. Surface water runoff was routed to a geomembrane-lined canal. Test panels were installed in December, 2005 and subsequently seeded with a mix of native and non-native grasses and sedges. After plant establishment, vegetative ground and canopy cover generally approached or exceeded 100%.

A cover performance monitoring system was installed and brought online in February 2006 to develop a better understanding of the capability of the cover systems to minimize net percolation into the heap leach material after closure. Monitoring nests were installed at four locations in each

panel. Monitoring system sensors included soil water potential sensors (heat dissipation sensors (HDS), and advanced tensiometers, (ATs)); soil moisture content sensors (ECH_2Os); water flux meters (WFMs); oxygen content sensors (Figaros); and surface water flumes (H-Type flumes). Drainage from the suction breaks was monitored manually on a weekly basis. Instrument cross-sections are provided in Orellana et al. (2010).

Soil water potential (HDS and AT) and water content (ECH_2O) sensors monitored the wetness of the soil cover and the removal of water through drainage and evapotranspiration. WFM measurements provided a small-scale point measurement of deep flux at each location. Oxygen sensors monitored the efficiency of the clay/silt layer in minimizing oxygen flux into the leach ore. Finally, the H-flumes provided a very precise measurement of surface water runoff. A detailed discussion of the monitoring system and installation procedures is presented in Zhan et al. (2007).

In January 2010, a test panel decommissioning program was conducted at Pierina to excavate monitoring instruments and check for functionality, conduct in-situ bulk density and saturated hydraulic conductivity (K_{sat}) tests; collect cores for laboratory testing, and, conduct a rooting survey to measure root density and thickness. Excavation trenches were typically two meters in depth.

Minera Lagunas Norte

The Lagunas Norte mine is located approximately 175 kilometers north of the Pierina mine, in the La Libertad Region. Elevations at the Lagunas Norte facilities range between 4 000 m and 4 260 m above mean sea level. Average temperatures at Lagunas Norte are slightly cooler compared to Pierina, though temperatures at the site rarely fall below 0° C. The recorded average annual precipitation during the 2009 to 2013 monitoring period was approximately 1 420 mm; estimated ETo was approximately 775 mm/yr.

Two test panels were installed in late 2008 and have since been monitored continuously. The two test panels, each approximately 42 m by 100 m were constructed on a 2.5(H):1(V) waste rock facility side-slope to test dual- and triple-layer cover systems with suction breaks. The South Panel dual-layer cover system consists of approximately 30 cm of a topsoil ET layer above approximately 60 cm of clayey material. The North Panel triple-layer cover system consists of approximately 30 cm of topsoil over approximately 30 cm of coarse-textured drainage material (gravel) overlying approximately 30 cm of clayey material. Placement of the drainage layer on top of the clay layer is intended to facilitate lateral subsurface flow through the drainage layer. In both panels a series of suction breaks consisting of gravel filled trenches were placed at the base of the topsoil (South Panel) and drainage layer (North Panel) at approximately 10-m spacing. Test panels were installed in December, 2008 with subsequent seeding using a mix of native and non-native grasses and sedges.

A cover performance monitoring system similar to that at Pierina was installed at Lagunas Norte in December 2008 and included four sensor nests for each panel. Cross-sections of Lagunas Norte monitoring nest installations for the triple layer (North) test panel are presented on Figure 1.

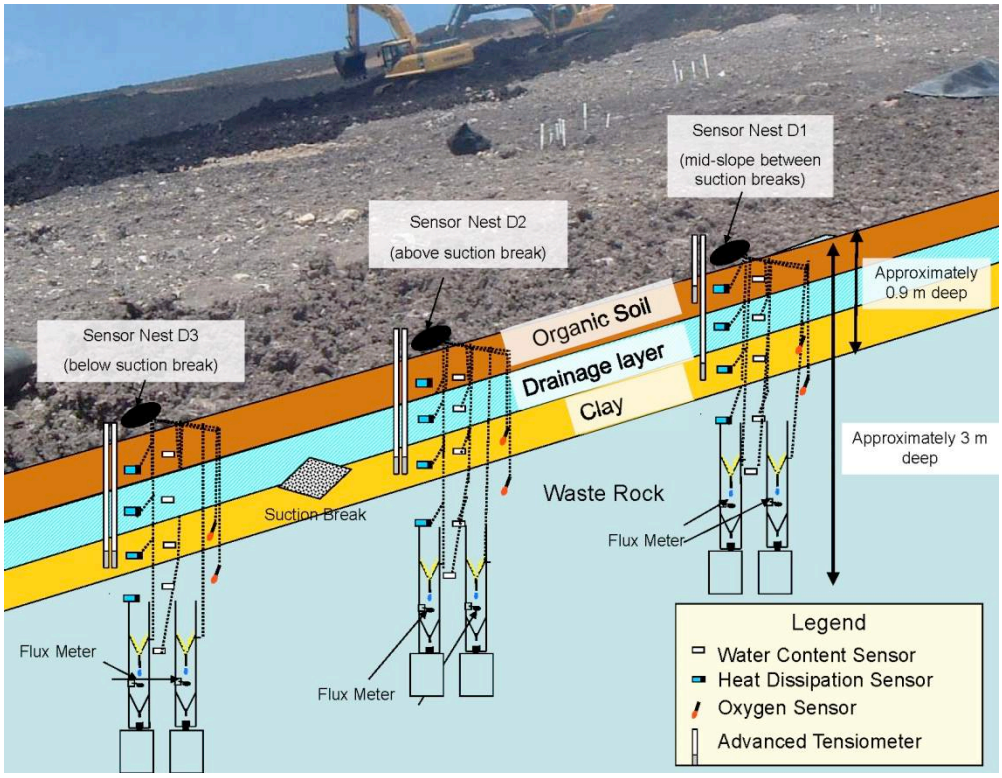

Figure 1 Cross-section of North Panel monitoring nest installation

RESULTS

For both sites the lowest precipitation rates were observed in July. Therefore, the water year was defined as the 12-month period from July 1 to June 30, and is designated by the calendar year in which it ends. For example, the water year starting July 1, 2012 and ending June 30, 2013 is called "Water Year 2013".

Surface Water Runoff and Subsurface Drainage

Measured stormwater runoff rates at the Pierina test panels were approximately 15% of precipitation (194 mm/yr). Similarly, the test panel runoff at Lagunas Norte has averaged approximately 18% of precipitation (256 mm/yr). For both sites, the observed stormwater runoff was simulated using the U.S. Soil Conservation Service (SCS) model (SCS, 1986) to estimate the approximate amount of runoff from a rainfall event in a defined area. Curve numbers (CNs) of 91 and 93 were needed to simulate the measured average panel runoff for Pierina and Lagunas Norte, respectively. Both CNs are much greater than what would be estimated using standard SCS method assumptions for hydrologic soil type and vegetative cover. These data indicate that stormwater runoff estimates using SCS curve numbers in this climate and soil types may need to be adjusted upwards to account for steep slopes and the hydrophobicity of the topsoil surface.

At Pierina, only minor amounts of drainage were recorded from the suction breaks at both panels (less than 1% of total precipitation). High topsoil and clay water content values were observed in the monitoring data. However, saturation of the topsoil is required for significant seepage from the suction breaks to occur. Low topsoil, or high clay, hydraulic conductivities could have reduced suction break efficiency. In addition, rooting around and into the geotextile material surrounding the suction break pipes could have resulted in reduced efficiency.

At Lagunas Norte, subsurface layer/suction break drainage was approximately 12% of precipitation (170 mm/yr) at the North Panel and 1% of precipitation (14 mm/yr) at the South Panel. Greater suction break flow from the North Panel indicates that the presence of a gravel drainage layer resulted in increased subsurface drainage efficiency.

Water Fluxmeter Data

WFM-measured flux at Pierina averaged 26% of precipitation (336 mm/yr) for Panel 3 and 16% of precipitation (207 mm/yr) for Panel 4. Panel 3 WFMs generally showed increasing fluxes over time.

Average WFM-measured flux greater than 250% of precipitation was recorded at the Lagunas Norte test panels during the first water year of monitoring (water year 2009), due primarily to several WFMs measuring flux in excess of 1 000% of precipitation. The high measured flux was believed to be due to topographical depressions resulting from ground settlement after sensor installation. These depressions were filled with topsoil in August 2009. The WFM-measured flux in the subsequent water years (water years 2010 – 2013) decreased, although not to rates consistent with other measurements of surface and subsurface flow.

Continued high WFM-measured flux after water year 2009 may be due to: 1) subsidence of the clay layer at the sensor nests resulting in accumulation of subsurface flow at these points, or 2) convergence of soil water flow into the WFM because of soil water potential conditions in the WFM being more negative (i.e. drier) than surrounding conditions. Based on AT data recorded during the rainy season, the soil water potential conditions are generally greater (i.e. wetter) than -30 cm, indicating that water potential conditions may be converging water into the WFM.

Water Content Data

Changes in water content over time indicate how the cover responds to seasonal climatic processes (precipitation and ET) and of the overall effectiveness of the cover system. At both sites water contents increased in response to the rainy season and decreased throughout the dry season (April through September) due to drainage and ET demand (Figure 2 and Figure 3). Wetting and drying occurred at all depths, in all panels, indicating that percolation occurs through the cover system. Water content in the topsoil layers generally decreased throughout the study period. This general drying trend is likely due to increasing vegetation and root density over the course of monitoring.

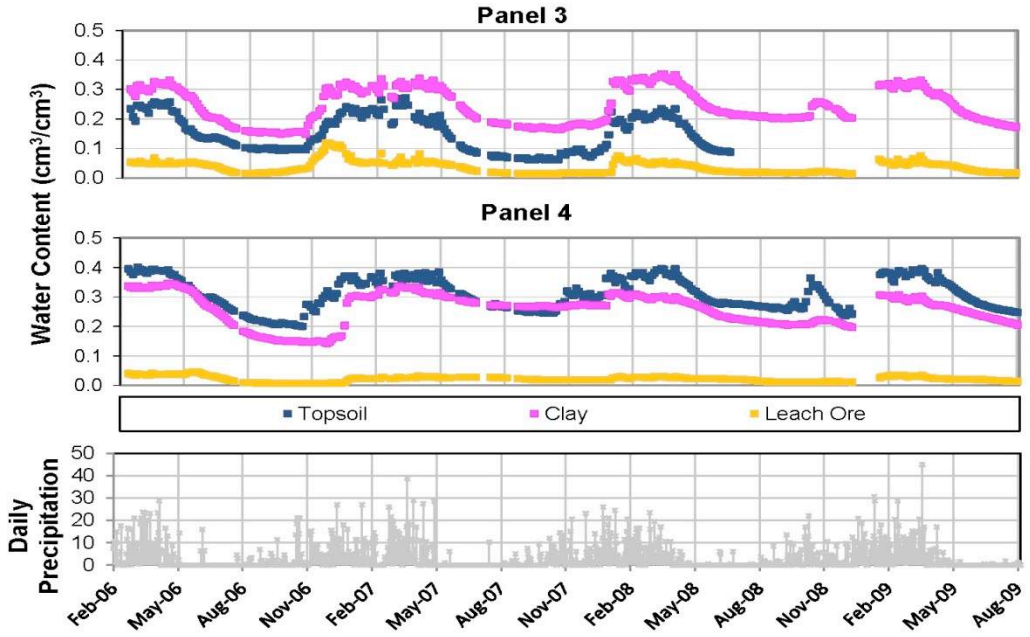

Figure 2 Pierina Mine Panel 3 and Panel 4 water content data

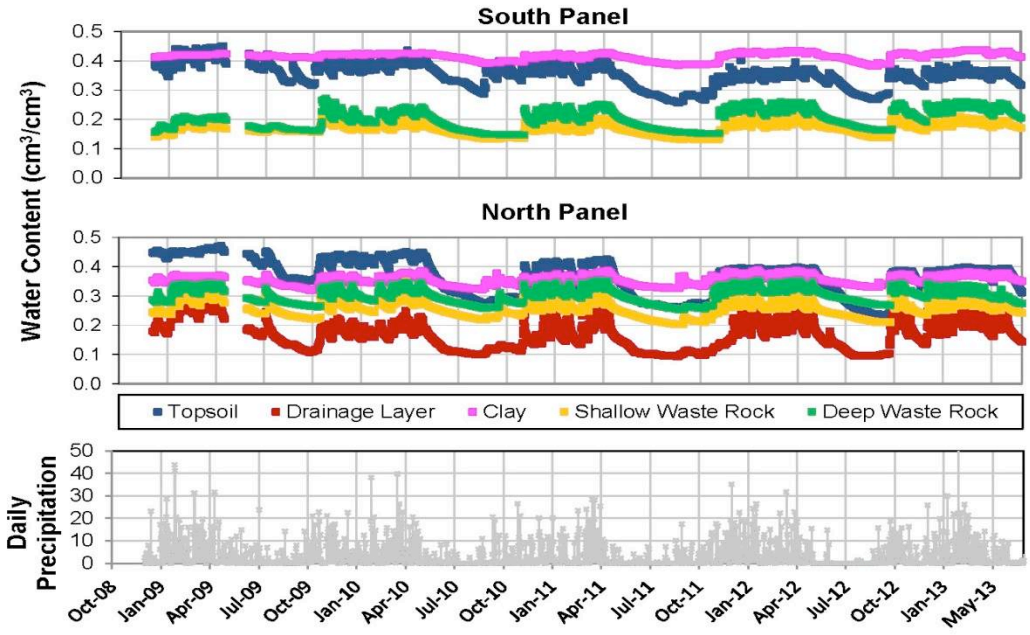

Figure 3 Lagunas Norte Mine South Panel and North Panel water content data

Clay layer wetting occurred within a short period after observed wetting in the overlying topsoil or drainage layer. Shallow and deep waste rock sensors immediately responded with little lag

compared to wetting of the overlying clay, indicating that the clay is allowing water to quickly percolate through that layer.

At Pierina, the clayey layer significantly dried out in both panels during the dry season and the ability of the clay to limit net percolation may therefore have been greater in Panel 4 due to its greater thickness (55 cm versus 35 cm). Additionally, the earlier wetting front arrival and greater water content in the leach ore in Panel 3 during each rainy season indicate that greater net percolation occurred in Panel 3.

At Lagunas Norte, topsoil sensors in the North Panel consistently recorded greater seasonal changes in water content than those in the South Panel, indicating that the North Panel drainage layer is removing water from the upper soil profile and accelerating the drying process. North Panel drainage layer sensors also showed rapid response to precipitation and subsequent drainage, which correlates with topsoil water content trends for North Panel. In general, the water potential (HDS and AT) wetting and drying trends were similar to water content sensor trends.

Estimated Net Percolation

A cover system water budget can be formulated as follows:

$$R = P - SR - AET - SB - \Delta S \quad (1)$$

where R is net percolation, P is precipitation, SR is surface runoff, AET is actual evapotranspiration, SB is suction break drainage and □S is soil storage change.

Precipitation, runoff, and suction break drainage were monitored at both sites; AET is calculated by solving Equation 1 and directly measuring or estimating net percolation. Estimated water budgets for each of the test panels are provided on Figure 4.

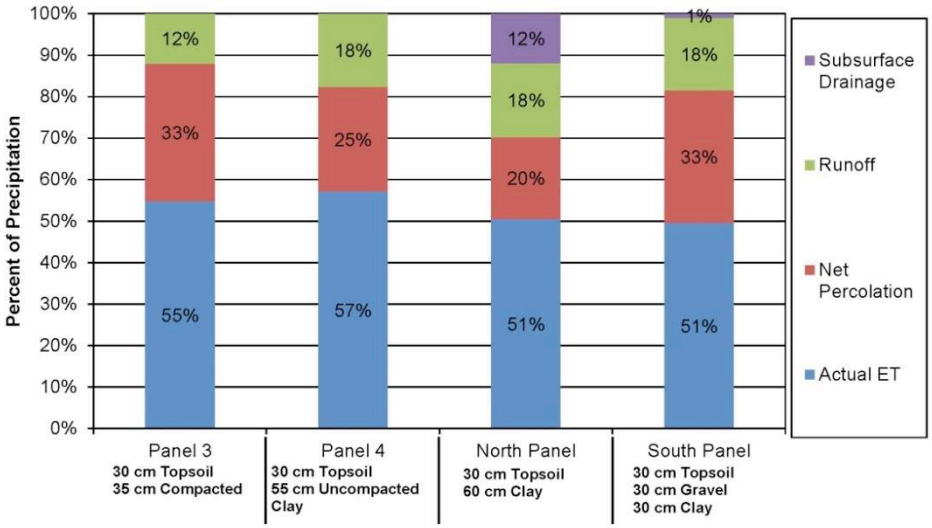

Figure 4 Estimated Pierina and Lagunas Norte test panel water budgets

Pierina Mine

At Pierina, the clay soil water potential data were used to approximate net percolation by applying the closed-form analytical solution by van Genuchten et al. (1980) to solve Darcy's law. Laboratory and field observed saturated hydraulic conductivity (K_{sat}), water content, and water potential relationships were combined to estimate van Genuchten parameters with a best fit. These parameters were further refined by comparing the predicted net percolation fluxes to the WFM-measured data and modifying the K_{sat} value until relative agreement was achieved. Additional details about the Pierina net percolation approximation are available in Orellana et al. (2010).

The Pierina test panel water budgets are shown on Figure 4. The Pierina approximated net percolation was 33% of precipitation (427 mm/yr) for Panel 3 and 25% of precipitation (324 mm/yr) for Panel 4. Applying these net percolation values and measured precipitation, surface runoff and suction break drainage in Equation 1 produced calculated AET values of 55% of precipitation (712 mm/yr) for Panel 3 and 57% of precipitation (738 mm/yr) for Panel 4.

The calculated AETs are approximately 95% to 99% of the calculated ETo for Panel 3 and 4 respectively. The high predicted AET values indicate that test panel vegetation had sufficient soil water during the dry season and/or had higher ET rates than ETo during the growing season. During Pierina test panel decommissioning extensive rooting was observed within the circum-neutral heap leach material to a depth greater than 2 m below ground surface (Orellana et al., 2010). It should also be noted that the development of vegetation in Panel 4 appeared to be more robust than in Panel 3. Consequently, the Panel 4 calculated AET would be expected to be greater than Panel 3, with potentially less net percolation.

Lagunas Norte

For estimation of Lagunas Norte net percolation the average estimated ratio of AET to ETo at the Pierina mine cover system test panel was adjusted to represent likely rooting conditions at the Lagunas Norte test panels. A numerical water balance model calibrated to the Pierina test panel monitoring data (Keller et al., 2012) predicted an approximately 5% reduction in AET to ETo when limiting the rooting depth to above the waste material compared to scenarios in which rooting was simulated within the waste material. Based on the model results and assuming rooting at Lagunas Norte is limited to above the waste material, AET at the Lagunas Norte test panels was estimated to be 92% of ETo, equivalent to 51% of precipitation (724 mm/yr).

The Lagunas Norte test panel water budgets are shown on Figure 4. Predicted water year average net percolation is 20% of precipitation (284 mm/yr) for the North Panel and 33% of precipitation (469 mm/yr) for the South Panel. The greater measured suction break drainage at the North Panel than the South Panel and lower water contents indicates that the drainage layer is contributing to increased drying of the topsoil and removal of infiltrated water.

Compared to the average net percolation measured by WFMs, the ratio of North Panel to South Panel WFM-measured flux (55%) and South Panel to North Panel water budget calculated net percolation (61%) are similar.

Hydraulic Property Measurements

The decommissioning tests at Pierina indicated a 6X and 8X increase in K_{sat} over the four-year test period in the uncompacted (Panel 4) and compacted (Panel 3) clay liners, respectively (Orellana et al., 2010). These data indicate that differences in K_{sat} values achieved via clay compaction diminish over time. Similar and even greater increases in clay K_{sat} have been observed due to wetting/drying processes and root development (e.g. Albright et al., 2006; Waugh, 2004; Taylor et al., 2003; Wilson et al., 2003). Rooting was extensive into the clay layers and heap leach materials to depths of at least 180 cm. The extensive rooting is most likely aided by the increase in clay K_{sat} and is also likely responsible for the predicted high AET rates.

CONCLUSIONS

The Pierina Mine and Lagunas Mine cover test panels tested the performance of multi-layer and low-permeability clay liner systems in reducing net percolation. Cover system performance monitoring data collected from both sites indicate that net percolation rates range from 20% to 33% of annual precipitation rates, and that the cover system performance is dynamic over time. The following trends were observed:

- Average surface runoff from the Pierina and Lagunas Norte test panels ranged from 15% to 18% of precipitation and can be modeled using the SCS equation with a CN of 91 to 93.

- At Pierina, suction breaks installed within the topsoil layer collected 1% or less of the total precipitation; relatively high clay Ksat for both the compacted and uncompacted clay liners is likely to have reduced the effectiveness of the suction breaks.
- The long-term estimated percolation through the Pierina Panel 3 compacted clay cover was 33% of precipitation; net percolation through Panel 4 uncompacted clay cover was 25% of precipitation, which indicates greater efficiency was achieved from using a thicker clay layer.
- WFM measured percolation at Pierina Panel 3 increased over time, suggesting that the effect of compaction in decreasing clay permeability decreased over time. This conclusion is further supported by observed increases in measured clay Ksat during panel decommissioning.
- The estimated net percolation through the Lagunas Norte North Panel cover, containing a drainage layer, was 20% of precipitation and net percolation through the South Panel cover system without a drainage layer system was 32% of precipitation.
- Suction break drainage averaged 12% of precipitation from the Lagunas Norte North Panel and reduced the estimated net percolation by about 40% compared to the South Panel cover system without the drainage layer.
- Numerical modeling indicates that the hydraulic conductivity of the clay layer largely influences the effectiveness of the drainage layer systems.
- Numerical modeling also indicates that, with extensive rooting into the underlying waste material, increasing cover thickness only nominally decreases predicted net percolation.

Based on these data, we conclude the following:

- There is no long-term advantage to roller-compacting a thin (30 cm) clay liner at these sites compared to a 50 cm clay layer compacted solely by the equipment used to place the clay.
- Drainage layers and/or suction breaks can significantly increase the efficiency of the cover system if there is high-drain rock permeability and low permeability underlying clay.

Integration of Climate Analysis into a Framework for Cover Design

Thomas Baumgartl, Andrea Farioli and Sven Arnold
Centre for Mined Land Rehabilitation, The University of Queensland, Australia

ABSTRACT

Successful performance of soil cover systems depends on both physical properties (including water retention characteristics, depth, and number and arrangement of materials), which define the soil cover design, and climatic conditions. While the physical properties can be addressed by site-specific selection or completion criteria and through technical means, climatic conditions are out of anthropogenic control. Climate parameters are commonly used in the first instance to plan the cover design. However, for some climates commonly used climate indices such as the rainfall to evaporation ratio or annual means of meteorological parameters oversimplify the complexity of variable and partly erratic rainfall patterns.

In this paper we present a climate-based planning framework for soil cover systems that explicitly considers climate variability. We demonstrate our approach based on a case study using historical rainfall and evaporation data from semi-arid Mount Isa (Queensland, Australia), where highly variable rainfall events are driven by monsoonal weather situations or intense convective storms. We use Hydrus-1D to simulate the seepage from two contrasting soil materials – a unimodal silt and a bimodal waste rock material. We run the model with a number of generated climate data based on the historical climate observations, and compare the seepage patterns for the two selected soil materials with uniform distributions of rainfall and evaporation.

As hypothesised, maximum seepage events and number of large seepage events were several orders of magnitude higher for the waste rock material. Interestingly, under some climatic conditions (mainly determined by its variability) the average seepage was higher for silt material. In any case, climate variability had a great impact on the seepage patterns; i.e., the median seepage, the maximum seepage events. The number of large seepage events was several orders of magnitude higher when including the variability of events compared with the control model, where rainfall and evaporation distributions were uniform. This indicates the critical role climate variability plays for the performance of soil cover systems, and the need to implement a similar approach into post-mining planning schemes.

Keywords: soil cover systems, climate variability, planning tool, soil water modeling, waste rock material

INTRODUCTION

The objective of soil cover systems, also referred to as monolithic alternative covers or phytocaps, is to minimise drainage into the underlying hazardous wastes by maximising intercepted rainfall by vegetation, soil water storage, and evapotranspiration (ET) and thereby minimising surface runoff and seepage (Salt et al., 2011). After rainfall events cease, the loss of stored soil water through ET increases the soil water storage capacity for future rainfall events (Hauser et al., 2001; Rock, 2010). Soil cover systems are increasingly accepted for the closure of mining waste facilities (Arnold et al., 2014; Gwenzi et al., 2013). Cover materials as well as cover designs vary greatly in their characteristics and complexity and may incorporate geotextile liners, multiple soil layers with selected hydrological properties, and compacted clay layers, depending on local climate and material availability (Benson et al., 2002). While the physical soil properties can be addressed by site-specific selection or completion criteria and through technical means, climatic conditions are out of anthropogenic control. Climate parameters such as long-term average rainfall or the ratio between rainfall and evaporation (aridity index) are commonly used in the first instance to design covers. However, for some climates these climate indices oversimplify the complexity of variable and partly erratic rainfall patterns (Audet et al., 2013). Consequently, the risk of performance failure of a soil cover; i.e., deep drainage and occurrence of contaminated water, is underestimated or even ignored.

In this paper we present a climate-based planning framework for soil cover systems that explicitly considers climate variability. We demonstrate our approach based on a case study using historical rainfall and evaporation data from semi-arid Mount Isa (Queensland, Australia), where highly variable rainfall events are driven by cyclonic events or intense convective storms, and the long-term average rainfall and aridity index are 423 mm and 0.13, respectively (Halwatura et al., 2014). We use Hydrus-1D (Simunek et al., 2005) to simulate the seepage from two contrasting soil materials – a silty substrate with a uni-modal pore size distribution and a waste rock dominated substrate with a bi-modal pore size distribution. Uniform, i.e., non-structured silty substrates, are classified with medium to low values of hydraulic permeabilities (Hillel, 2004), while rock containing substrate is characterized by some proportion of coarse pores, which are highly continuous and lead to high hydraulic permeabilities (Schneider et al., 2010). The water sorption capacity of substrates is used in cover design to mitigate the impact of rainfall by designing a cover around its substrate specific water storage capacity. While the storage capacity for water may be the same or similar for different materials, the intensity parameter, like hydraulic conductivity may be greatly different (Horn et al., 2002). The objective of this paper is to investigate the consequence of different values for functional parameters to realistic climatic situations and test the performance of a cover design in respect to risk and magnitude of deep drainage. For this purpose, we run the model with a number of generated climate data based on the historical climate observations, and compare the seepage patterns for the two selected soil materials with uniform distributions of rainfall and evaporation.

METHODOLOGY

We generated 35 time-series, each of 100 years length, using the LARS-WG stochastic weather generator (Semenov, 2008) and based on historical rainfall and evaporation data from Mount Isa, Australia (Bureau of Meteorology, 2014) (Fig. 1). Then we run Hydrus-1D (Simunek et al., 2005) with two soil materials (Table 1) and using the generated weather time series (Fig. 2) as atmospheric boundary condition (Appendix B). We assessed the frequency distributions of seepage for the two soil materials and compared them with the control scenario that ignored climate variability and was based on uniform distributions of rainfall and evaporation.

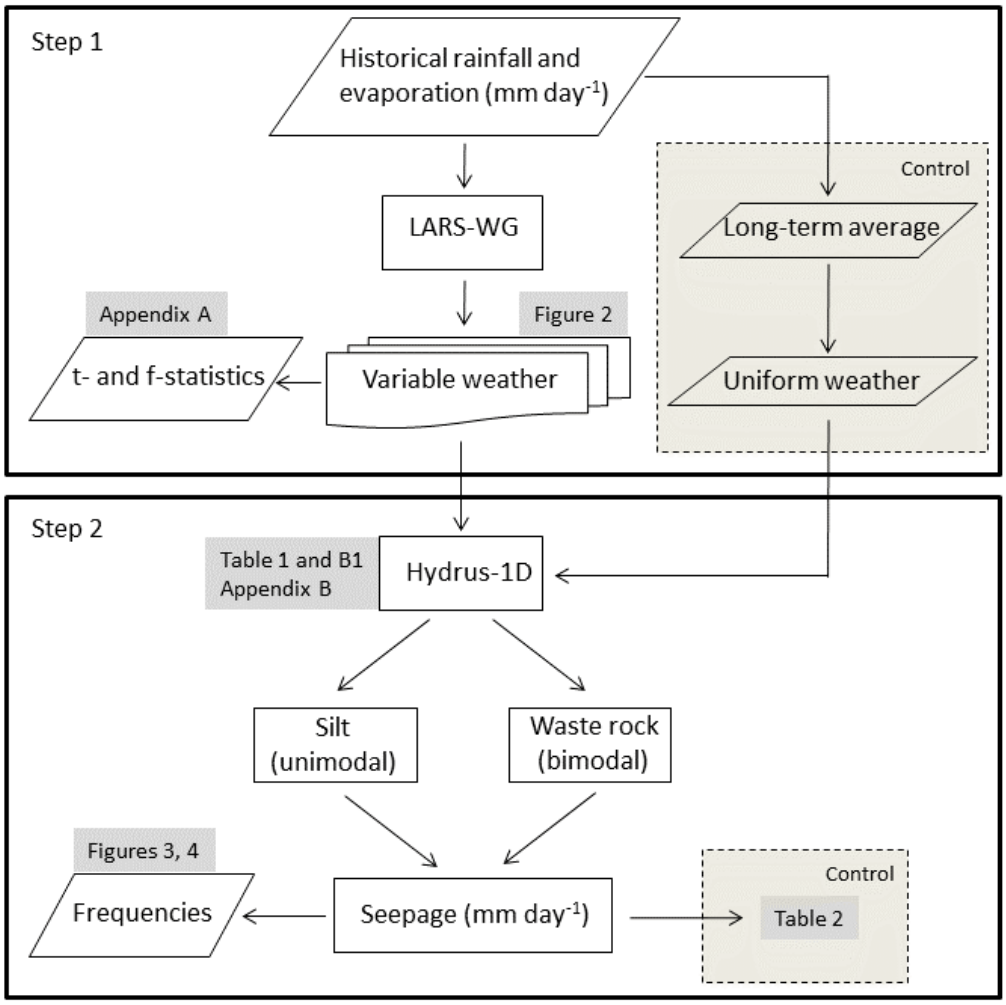

Figure 1 Schematic diagram of a climate-based planning framework for cover systems. Step 1 generates time series of rainfall and evaporation based on historical observations. Step 2 uses the generated weather data to assess frequency distributions of seepage based on selected soil materials. In total, we generated 35 time-series, each of 100 years length.

Generated rainfall and evaporation values (step 1)

The LARS-WG stochastic weather generator generates time-series of daily weather at a single site (Semenov, 2008). Here we used 100 years of historical rainfall observations from Mount Isa, Australia, to generate 35 time-series of rainfall that have the same statistical properties (mean and variance) as the empirical observations. Likewise, we generated time-series of evaporation based on 25 years of historical records. While the generated and observed rainfall values were not significantly different (Appendix A), the generated evaporation was underestimated (Fig. 2b). Therefore we corrected each generated time-series i of evaporation as:

$$E^{corr}_i = (E^s_i)^{1.22}, \quad (1)$$

where E^{corr}_i (mm day^{-1}) is the corrected evaporation used for further simulations, and E^s_i (mm day^{-1}) is the evaporation generated by LARS-WG. The ensemble mean and standard deviation of all E^{corr}_i values were 4% higher and 5% lower than the observed values.

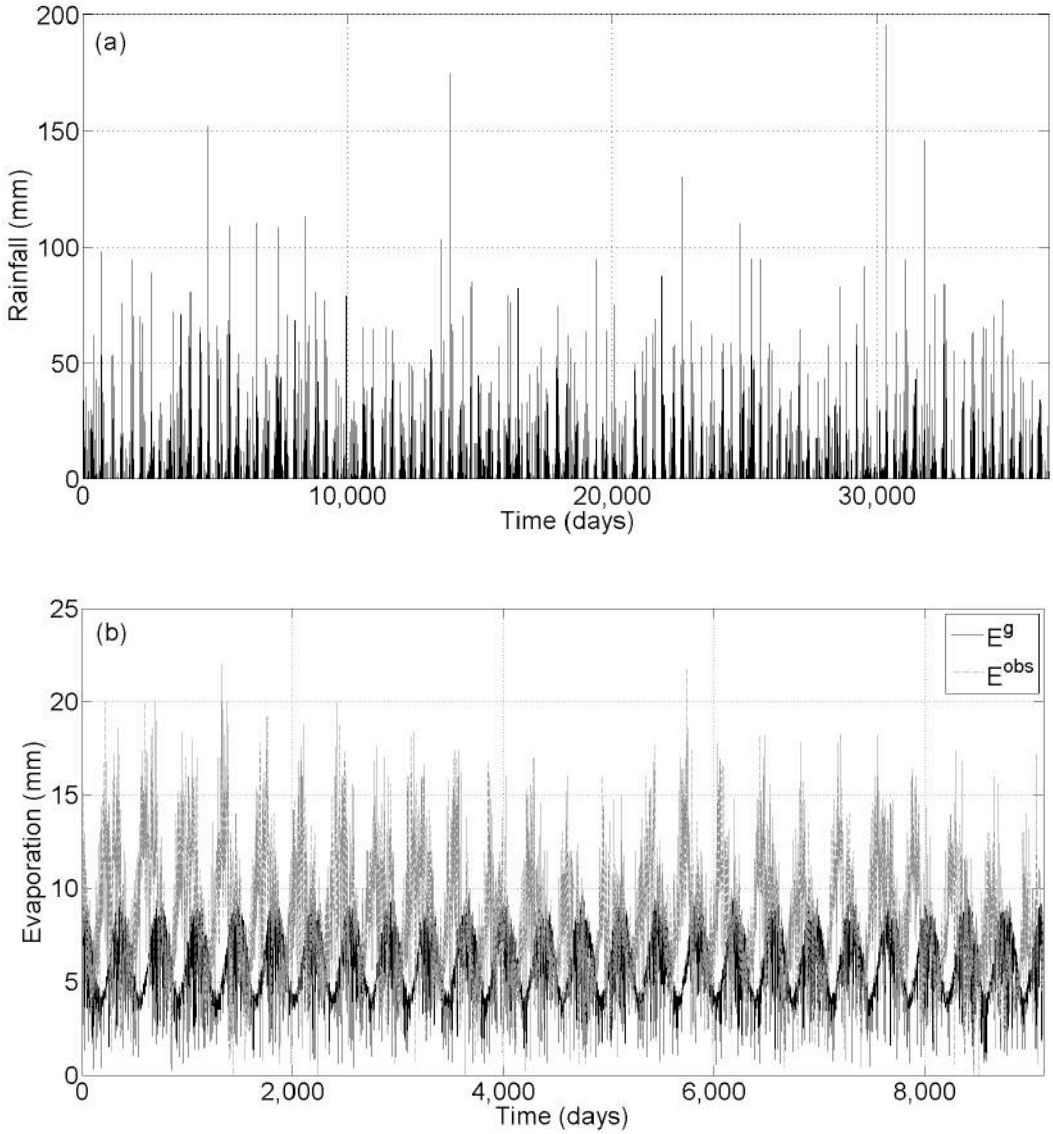

Figure 2 Examples of generated time-series of daily (a) rainfall and (b) evaporation values based on historical weather observations in Mount Isa. The generated evaporation values E^g underestimated the observed evaporation values E^{obs}.

Soil water modeling (step 2)

We used the generated time-series of rainfall and evaporation values as atmospheric boundary condition in the water flow and solute transport model Hydrus-1D (Simunek et al., 2005). We ran the model with two contrasting soil materials – a unimodal silt material reflecting a substrate with a very high water storage capacity and a bimodal waste rock material, representing a substrate with pronounced coarse and continuous pores (Table 1) – to assess the seepage patterns over a simulation period of 100 years at daily time steps. Further, we ran a control model with uniform distributions of rainfall and evaporation based on the long-term average daily records to assess the impact of climate variability on the seepage patterns of the two soil materials. For the control model, the daily rainfall and evaporation were 1.16 and 8.36 mm day^{-1}, respectively. More details on the configuration of the Hydrus-1D model are provided in Appendix B1. For each soil material

and each generated weather situation (i.e., expressed through rainfall and evaporation values), we calculated the median seepage, and recorded the maximum seepage as well as the number of seepage events greater than 1 mm day^{-1}, which occurred over 100 simulated years.

Table 1 Hydraulic parameters of selected soils, based on (van Genuchten, 1980).

Soil Parameter	Silt	Waste rock (dual porosity)
θ_r (m^3 m^{-3})	0.034	0.05
θ_s (m^3 m^{-3})	0.46	0.28
α (cm^{-1})	0.016	(1) 1, (2) 0.01
n (-)	1.37	(1) 6, (2) 1.15
K_s (cm day^{-1})	6	1000
w_2 (-)	-	0.4

RESULTS AND DISCUSSION

Impact of climate variability on seepage

For both soil materials, climate variability had a great impact on the seepage patterns. While under uniformly distributed rainfall and evaporation the median seepage ranged between 2.84 10^{-5} and 1.42 10^{-4} mm day^{-1} (Table 2), the median seepage was several orders of magnitude higher when climate was variable, and ranged between 0.01 and 0.05 mm day^{-1} (Fig. 3). Likewise, the maximum seepage events were several orders of magnitude higher under climate variability and ranged between 0.5 and 200 mm day^{-1} (Fig. 4) compared with 2 10^{-4} to 0.06 mm day^{-1} under uniform weather conditions (Table 2). Finally, the impact of climate variability was most dramatic when comparing the number of seepage events greater than 1 mm day^{-1} between uniform and variable distribution of rainfall and evaporation. While no such events occurred under uniform conditions (Table 2), under climate variability their number increased up to 1750 events within 100 years of simulation (Fig. 5). These distinct patterns are the consequence of the different daily rainfall amounts, which are only 1.16 mm day^{-1} under uniform conditions, but can be up to 200 mm day^{-1} under variable conditions (Fig. 2a) as observed over the last 100 years (Bureau of Meteorology, 2014).

Table 2 Seepage of the control model with uniform rainfall and evaporation of 1.16 and 8.36 mm day^{-1}, respectively.

Soil material Seepage	Silt	Waste rock
Median (mm day^{-1})	2.84 10^{-5}	1.42 10^{-4}
Maximum (mm day^{-1})	0.06	2 10^{-4}
Number of event greater than 1 mm day^{-1}	0	0

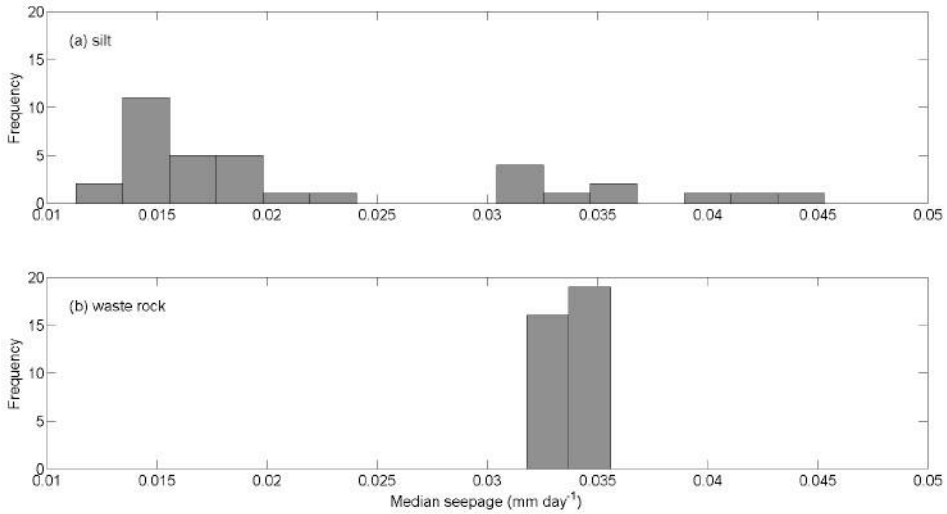

Figure 3 Frequencies of median seepage for (a) unimodal silt and (b) bimodal waste rock material and variable climatic conditions (based on 35 generated time-series, each of 100 years length).

Seepage patterns of two contrasting soil materials at variable climatic conditions

In general, seepage was lower for silt than for waste rock material. While for most of our simulations the maximum seepage for silt material was less than 1 mm day^{-1} (Fig. 4a), for waste rock material the maximum seepage ranged between 140 and 200 mm day^{-1} (Fig. 4b). Consequently, the frequency of seepage events greater than 1 mm day^{-1} ranged from 10 to 70 for silt (Fig. 5a), and from 1450 to 1750 for the waste rock material over the period of simulated 100 years of variable rainfall (Fig. 5b). The high number of seepage events >1 mm in the waste rock is a consequence of the bimodal pore system, consisting of a small proportion of wide and continuous pores and a majority of pores of medium to fine size. Water flow in coarse pores may only occur at rainfall events, which are sufficiently intensive to saturate these pores. For the majority of rain events these pores will not be filled and may not participate to downward flow because they function as a capillary barrier. Only if the soil is saturated or close to saturation, these pores will participate in the water flow. When averaging rainfall events across a large time scale, high intensive rainfall situations will be overlooked. For pore structures with a bimodal pore system and macro-pore flux, the consequences of water flow at saturated conditions will be ignored (i.e., higher maximum seepage events for silt rather than waste rock material (Table 2)).

At annual time scale, the median seepage ranged from 7 to 23 mm year^{-1} for silt (2-5 % of annual rainfall), and 175 to 229 mm year^{-1} for waste rock (44-50 % of annual rainfall). Interestingly, at a daily time scale, the median seepage ranged from 0.01 to 0.05 mm day^{-1} for silt (Fig. 3a), and 0.03 to 0.35 mm day^{-1} for the waste rock (Fig. 3b). That is, on a daily time scale and under same climatic conditions (variability), the average long-term seepage was higher for silt than for waste rock material. This finding is critical for the planning of soil cover systems and underpins the importance of using well-defined target parameters or closure criteria; i.e., whether average seepage or single seepage events should not exceed threshold values. In this regard, our case study of the climate in Mount Isa depicts that silt material much better reduces the probability of large seepage events (Figs. 4 and 5) at the expense of potentially higher average long-term seepage (Fig. 3).

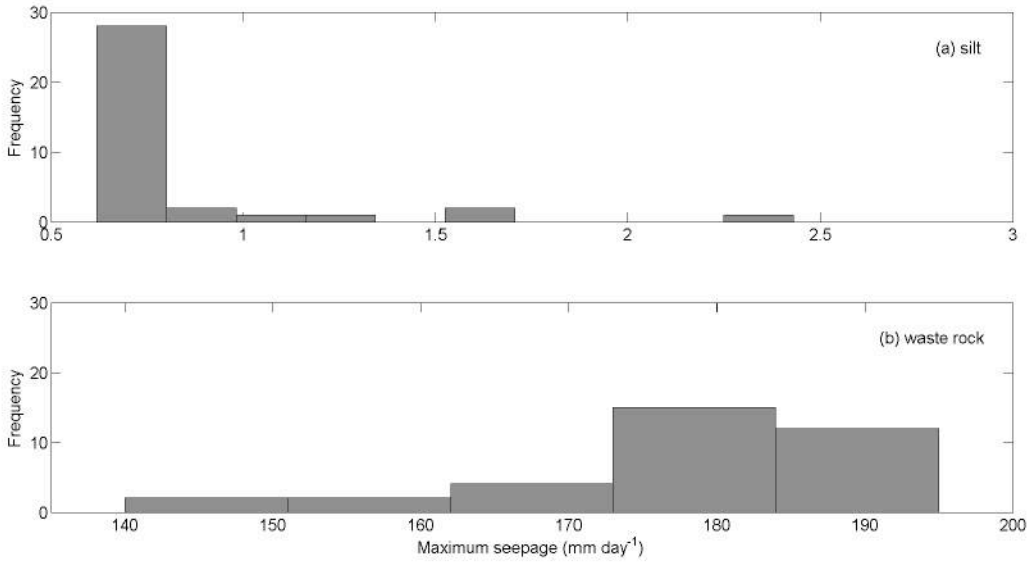

Figure 4 Frequencies of maximum seepage for (a) unimodal silt and (b) bimodal waste rock material and variable climatic conditions (based on 35 generated time-series, each of 100 years length). Note the scale differences.

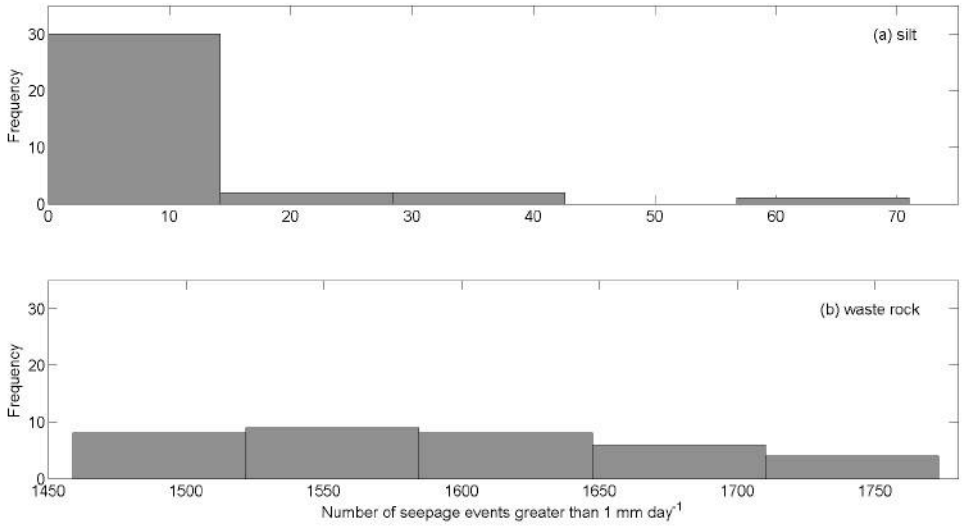

Figure 5 Frequencies of number of events with seepage greater than 1 mm day^{-1} for (a) unimodal silt and (b) bimodal waste rock material and variable climatic conditions (based on 35 generated time-series, each of 100 years length). Note the scale differences.

CONCLUSION AND FURTHER DIRECTIONS

A main consideration of our analysis is that the regional intensity, seasonality, and extremity of rainfall should represent a primary determinant of the design of soil cover systems. Our case study of climate in Mount Isa, Australia, indicates the critical role climate variability plays for the performance of soil cover systems, and the need to implement a similar approach into post-mining planning schemes (Audet et al., 2013). Based on our approach (Fig. 1), the strategy of: (i) using historical rainfall and evaporation data to generate statistically identical weather time-series, and

(ii) assess soil cover designs regarding seepage patterns when being forced to climate variability could be readily applied to other locations that are similarly affected by variable/erratic rainfall events and used to guide initial cover design planning.

ABSTRACT

In arid and semiarid climates, acid mine drainage (AMD; also called acid rock drainage, ARD) generated by mine tailings can be controlled by reducing water percolation. The use of store-and-release (SR) covers with capillary barrier effect is emerging as the most effective way to prevent water percolation through tailings under these climates. Four instrumented experimental cells made of phosphate wastes, as SR covers, were constructed on top (flat surface) of the abandoned Kettara mine site (near Marrakech, Morocco). Results confirmed the potential of phosphate mine waste as SR cover material to control water percolation. However, significant uncertainties remain about the influence of inclined conditions on the hydrogeological behavior of a SR cover at the mine, as the mine wastes at Kettara mine site are retained by dykes that reach a height of 10 m. Due to the slope inclination, water can accumulate above the tilt interface during extreme precipitation events, which could create a breakthrough of the capillary barrier; at this location, the cover is no longer effective to control water infiltration into the mine wastes. A field investigation was conducted to evaluate the influence of the slope on the Kettara SR cover's performance. An experimental field cell (10 m wide by 8 m long) inclined at an angle of 14.5 degrees was constructed on-site. The SR cover retained is made of 0.8 m of phosphate waste, placed over a capillary break layer made of coarse-grained materials. Cover performance was monitored using lysimeters, Tensiometers, suction and soil moisture sensors installed at four stations and at different depths. The paper presents the design, the construction and the instrumentation of an inclined SR covert. Preliminary results of the monitored parameters under natural conditions are also included. The field test showed that the slope influences water distribution in the cover with more water at the bottom of the slope. The inclined SR cover still effectively limited water percolation under natural conditions.

INTRODUCTION

Acid mine drainage (AMD) from mine wastes is the main environmental problem facing the mining industry. It is a common practice to construct single or multi-layered engineered cover systems to control AMD from waste rocks and tailings. In dry climates, where the potential evaporation rate exceeds the annual precipitation, these cover systems are usually used to limit water percolation into mine waste disposal (e.g., Albright et al., 2004; Hauser, 2008). These covers use the physical process of evaporation or evapotranspiration to control water percolation into the reactive wastes (e.g., Morris and Stormont, 1997; Albright et al., 2004; Rock et al., 2012, Bossé et al., 2013). These cover systems are known as alternative covers, evapotranspiration (ET) covers, water balance, or store-and-release (SR) covers; this terminology (SR cover) will be used throughout this paper. The technology of SR covers has been applied with success to several mine sites such as Kidston Gold Mines (Australia) and Barrick Goldstrike Mines (Nevada, US) to control acid mine drainage (AMD) generation from sulfidic mine wastes (Zhan et al., 2001, 2006; Williams et al., 2006). The concept of this approach is to control water percolation by using a moisture-retaining layer (MRL) that acts as a sponge or a reservoir by storing water during precipitation events, and then releasing it back to the atmosphere by evaporation (e.g., Rock et al. 2012, Bossé et al., 2013). The water storage capacity in the MRL can be increased by the implementation of a capillary break layer (CBL) below the MRL. If the hydrogeological contrast between the two materials (MRL and CBL) is sufficient, capillary barrier effects (CBE) will control the water flow at the layers interface and increase the water storage capacity of the MRL. More details on CBE can be found in Morel-Seytoux, (1992) and Bussière (1999).

The abandoned pyrrhotite mine site, Kettara, is one of several abandoned AMD-generating mine sites in Morocco. The site is located in an arid climate (Bossé, 2014) approximately 35 km north-northwest of Marrakech (31°52'15"N–8°10'31"W). The region's climate is characterized by a bi-modal precipitation pattern with wet (October-April) and dry (May-September) seasons. The annual cumulative rainfall and the potential evapotranspiration (PET) are estimated at 334 mm and 2,178 mm respectively. The tailings pond area contains approximately 1,800,000 tons of mine wastes (Lghoul et al., 2012). These wastes were deposited at the surface without any concern about the environment (Hakkou et al., 2008, Bossé, 2014). This mine waste is considered as highly acid-generating, with negative net neutralization potential (NNP) values ranging from -453 to -22.5 kg $CaCO_3$/t (more information on Kettara mine waste characterization can be found in Hakkou et al., 2008). Indeed, this contaminated drainage is a source of pollution in this region that affects the surrounding ecosystems as well as the people living nearby the mine site (e.g. Khalil et al., 2013). One of the most promising reclamation options to control AMD generation at this Kettara mine site is the use of a SR cover system that integrates CBE. A very helpful factor facilitating the mine rehabilitation is the availability of alkaline mine wastes, generated by phosphate mines located nearby to be used for the MRL.

Four instrumented experimental cells (1D), made of phosphate wastes as SR covers, were constructed on top of the Kettara mine site to evaluate the use of the phosphate mine waste as MRL in the SR cover (Bossé, 2014). Results confirmed, for 1D conditions, that the phosphate limestone has the appropriate properties to become part of an efficient SR cover to reduce rainfall percolation and control AMD. However, uncertainties remain about the influence of inclined conditions on the hydrogeological behavior of a SR cover at the mine, as mine wastes at the Kettara mine site are retained by dykes (coarse mine wastes) that can reach a height of 10 m. Due to slope inclination, water can accumulate above the tilt interface during precipitation events, which would increase the water pressure at this location. When the pressure exceeds the water-entry value of the coarse-grained material, a breakthrough of the capillary break can occur at the interface, and the cover becomes no longer effective to control water percolation into the AMD-generating mine wastes (e.g., Ross, 1990; Steenhuis et al., 1991; Bussière, 1999; Aubertin et al., 2009; Maqsoud et al., 2011). In order to investigate the slope effect for the SR cover at the Kettara site, an experimental inclined SR cover was constructed. The objective of this article is to present the design and construction in the field of an instrumented inclined SR cover, and the preliminary results accumulated during the first months of monitoring. As mentioned earlier, one of the originalities of this work is mainly related

to the use of phosphate limestone wastes generated by a sedimentary phosphate mine, located close to the abandoned Kettara mine site, to construct the cover system.

FIELD EXPERIMENTAL CELL DESCRIPTION AND MATERIALS CHARACTERIZATION

Design and construction

The work was initiated during March 2014 at the Kettara mine site to evaluate the slope effect on the hydrological behavior of a SR cover system. The tested SR cover is made of two layers: a MRL made of 0.8 m of phosphate mine waste placed over CBL made of Kettara's coarse grained mine waste. The slope is approximately 14.5 degrees and the field cell area is about 10 × 34 m (Fig 1). A 3D schematic representation of the inclined field instrumented SR cell is presented in Fig 1.

The field experimental cell was constructed directly on the retention dyke. The dyke is 8 meters high and made of the reactive coarse-grained material at Kettara mine site (Fig 1).

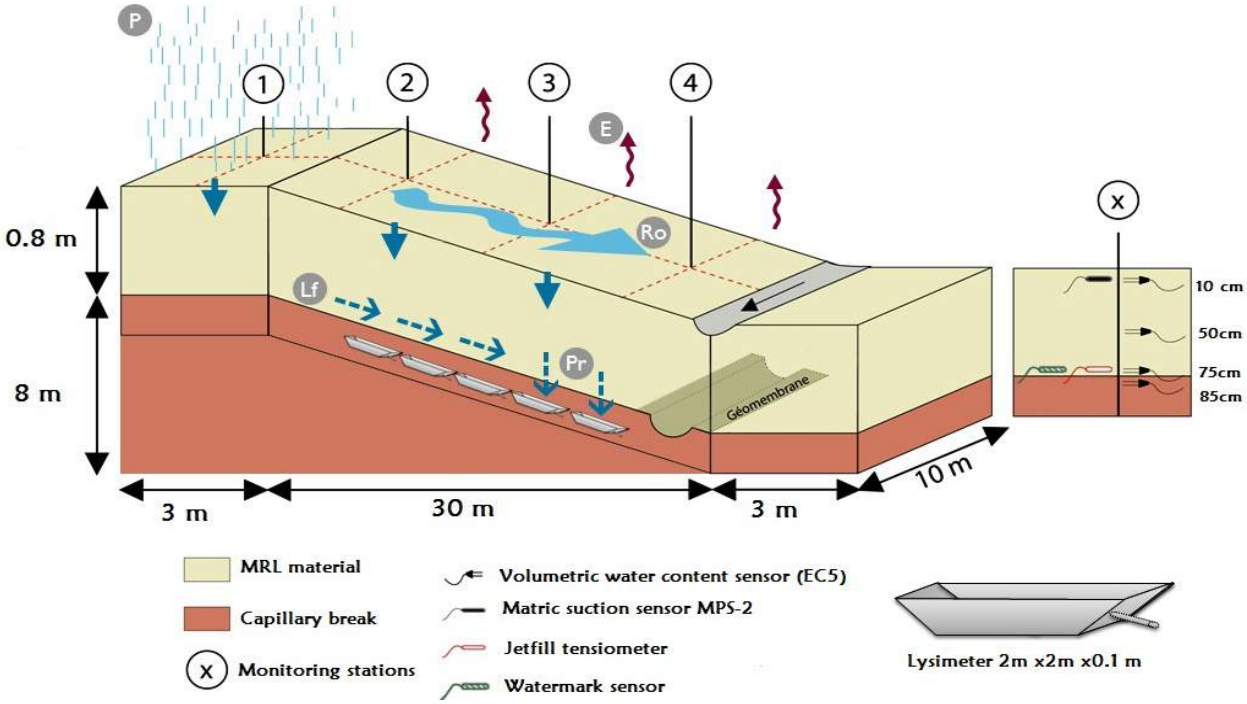

Figure 1 3D schematic representation of the field instrumented cell (E: evaporation; P: precipitation; R0: runoff; Pr : percolation; Lf: lateral flow); locations 1 to 4 on the slope are the monitoring stations

The MRL material was placed and compacted with a manual compactor to a dry unit weight of 15 kN/m^3. The experimental cell was constructed in different steps. The slope was first flattened and compacted (Fig 2-step 1) to a targeted porosity (n) of approximately 0.37 m^3/m^3 (dry unit weight = 18.3 kN/m^3). Five lysimeters were installed in the CBL material to monitor water percolation at the base of a cover system (Fig 2-step-2). The water collected may drain out of the lysimeters through a pipe by gravity. The phosphate limestone wastes were then placed and compacted at their natural water content (w ≈ 4%) to a porosity of approximately 0.41 m^3/m^3 (Fig 2–step-3). The material was compacted in successive lifts of about 20 cm thick to ensure a uniform density. Surface and lateral drainage systems were installed at the toe of the slope (Fig 1). The lateral drainage consists of the water that flows at the interface between the CBL and MRL due to the capillary barrier effects

(Fig 3.e). The surface drainage collector was installed to quantify the runoff water and to facilitate the calculation of the water balance (Fig 3.f).

Field instrumentation and monitoring

Field performance of the tested inclined SR cover is monitored by measuring the percolation through the CBL, the changes in moisture conditions (ΔS) within the cover layers, the internal lateral flow, run off and climatic conditions. Five lysimeters (2 m x 2 m x 0.1 m) were installed to measure water percolation into the underlying mine wastes at a depth of 90 cm from the cover surface (fig. 2 step 2). Daily precipitation (rainfall) i measured using an automated weather station (HOBO U30-NRC) installed at the Kettara mine site (fig 5.c; see Bossé, 2014 for more details). Changes in ΔS are estimated using ECH2O volumetric water sensors (EC5) (fig 3.a) and measured indirectly by matric suction sensors (MPS-2) (fig 3.b). Tensiometers and Watermark sensors are also used to measure matric suction in the inclined SR layers (fig 3.d). Tensiometers can measure suction between 0 and 80 kPa with an accuracy of 1 kPa, while the suction range of Watermark sensors is from 0 to 200 kPa (Bussière, 1999). The MPS-2 can measure suction between 10 kPa and 500 kPa (Bossé, 2014). Note that the three instruments (MPS-2, Tensiometers, and Watermarks) were soaked in water before installation to improve early measurements.

Before installation, EC5 sensors were calibrated for each material in the laboratory. The Tensiometers were inserted carefully at the required depth (75 below the surface) to ensure good contact between the high air-entry ceramic cups of the Tensiometers and the MRL material. Four EC5 sensors were placed at depths of 10, 50, 75 and 85 cm into the cover system, and a matric suction sensor (MPS-2) was placed at depth of 10 cm. To be able to compare measurements, JetFill tensiometers and Watermark sensors were placed beside each other at each monitoring station at a depth of 75 cm (close to the interface between the MRL and CBL). All monitoring stations were placed near the central axis of the cell. Manual monitoring of the Tensiometers and Watermark sensors is done three times per week while the monitoring frequency for the EC5 and MPS-2 sensors is a measured every 30 minutes

Materials characterization

The main properties of the inclined SR cover components (the phosphate limestone wastes, and Kettara coarse-grained mine) used in the experimental cell are summarized in Table 1. Material particle size distribution was determined using a Malvern Mastersizer laser particle size analyzer and by sieving (ASTM D 6913-04 2009). The specific gravity (Gs) was estimated with a Micromeritics Accupyc 1330 helium gas pycnometer (ASTM D5550-06 2006). The liquid limit (w_L), plastic limit (w_p) and plasticity index (PI) of materials were determined by Bossé et al., (2013) using ASTM standards (ASTM 4318-10-2010).

Step 1 Step 2 Step 3

Figure 2 Photos illustrating the field inclined SR cover construction steps

The specific gravity (Gs) and the percentage of fines (< 80 µm) of the phosphate limestone wastes were respectively estimated at 2.85 and 15%. The liquid limit wasless than 50%, the plasticity index was estimated to be 0.8 and the material is categorized as a non-plastic sandy silt according to the USCS classification (e.g., McCarthy 2007). The air-entry values (AEV- pressure at which the material starts to drain) of the phosphate and coarse tailing were-40 kPa and -0.1 kPa respectively. The water-entry values (WEV-pressure at which the water starts to enter) were -2000 kPa for the MRL material and -0.4 kPa for the CBL material (Bossé et al., 2013). The saturated hydraulic conductivity (k_{sat}) of the coarse-grained material (5.9 cm/s) was substantially greater than the one of the fine-grained material (5.7×10^{-6} cm/s; see tab 1). This important contrast in hydraulic properties between the two materials with different textures restricts water flow at the interface and enhances the water storage capacity of the fine grained layer (e.g., Khire et al., 1999). More information on phosphate limestone waste characterization can be found in Bossé, (2014)

PRELIMINARY RESULTS

After the construction of the experimental field cell, an important wetting event was simulated using drip irrigation tubes connected to a pump and installed on the inclined SR cover surface. Approximately 100mm of water over a period of 48 hours was applied to the tested area, to assess the behavior of the water diversion capacity of the cover. The hydrogeological behaviour of the inclined SR cover after the wetting event was also monitored.

Hydrogeological behaviour of the inclined SR cover during the wetting event

This section presents the behavior of the experimental cell test during the simulated wetting event. Figure 4 shows the fluctuation of volumetric water content (θ) within the inclined SR cover at 75 cm depth (fig 4.a) and 50 cm depth (fig 4.b) for the four monitoring stations (station 1 is located at the top and station 4 at the bottom; see fig. 1). The fluctuations of matric suction (ψ) measured with the watermark sensors (fig 4.c) and JetFill tensiometers (fig 4.d) are presented and compared for the 75 cm depth (close to the interface of the CBL and MRL). Note that a significant rainfall event occurred during construction which led to an increase in the moisture content in station 1, especially at the depth of 75 cm. The observed θ results at 50 cm and 75 cm depth are quite similar. During the wetting event, it took about 2 days to notice an increase in volumetric water content at station 2, 3 and 4 with a water arrival first at station 2, followed by station 3 and 4.

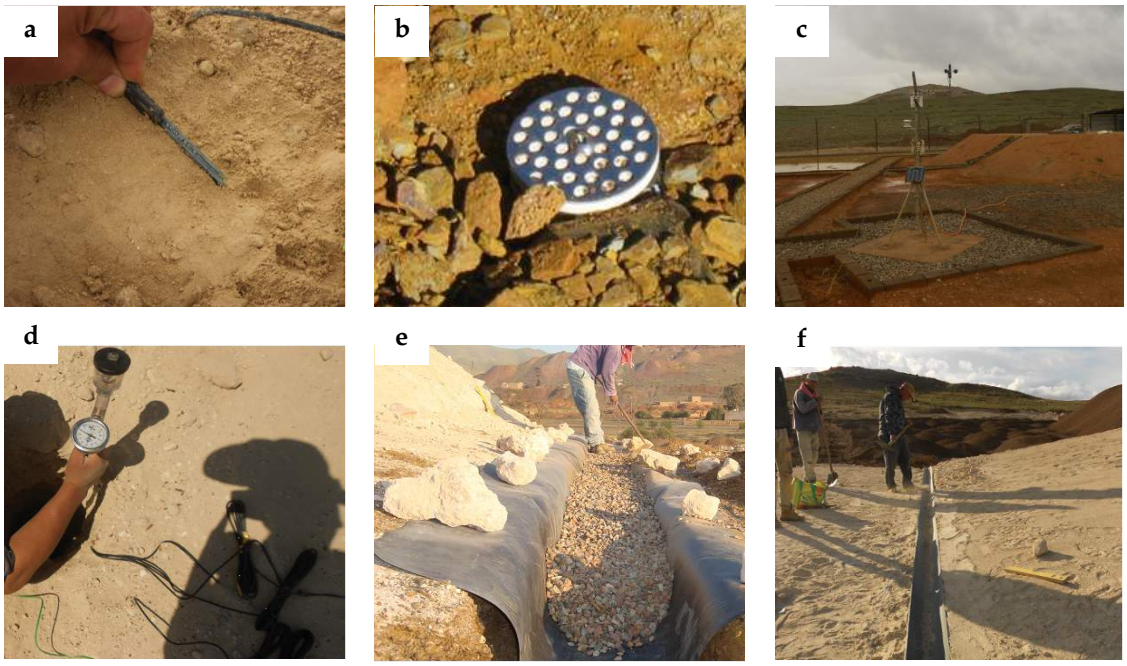

Figure 3 Photos illustrating the instrumentation used for the monitoring of the inclined SR cover: (a) Volumetric water content sensors (EC5) (b) Matric suction sensors (MPS-2) (c) Weather station (d) JetFill tensiometers (e) Lateral drainage collector (f) Surface drainage collector

Table 1 Basic properties of MRL (Phosphate limestone waste) and CBL (Kettara coarse-grained waste) materials

Parameter	Phosphate limestone waste	Kettara coarse-grained waste
Specific gravity	2.85	2.90
D_{60} [mm]	0.31	6.3
D_{10} [mm]	0.07	1.13
Fines content (< 80µm) (%)	15	7
w_L(%)*	26.4	-
w_p (%)*	25.6	-
*PI (%)**	0.8	-
k_{sat} (cm/s)*	5.7×10^{-6}	5.9
AEV (kPa)*	-40	-0.1
WEV(kPa)*	-2000	-0.4
Classification (USCS)*	Sandy silt	Poorly graded gravel with sand
Mineralogy by order of importance**	Calcite/fluoapatite/ Dolomite/quartz	Pyrite/pyrrhotite/ chlorite-serpentine, quartz, talc

* Values from Bossé et al., (2013); ** Values from Hakkou et al., (2009)

The wetting event did not have an impact on θ values at station 1 because water accumulates above this elevation; this behavior was also observed by Bossé, (2014) in a similar cover built on a flat surface. The magnitude of the volumetric water content increase is more pronounced at 50 cm than 75 cm depth but the MRL material didn't reach the saturation value (= porosity) of 0.41. It can also be observed that, as expected, the θ values are usually higher close to the bottom of the slope

(station 3 and 4; typically between 0.30 and 0.35) than close to the top. This behavior is due to the diversion capacity of the inclined SR cover; theoretically, water flows along the interface between the MRL and CBL until the MRL become nearly saturated and the pressure at the interface reaches the water entry value of the CBL material (e.g. Steenhuis et al., 1991; Aubertin et al., 2009). Note that no water flow was observed in the different lysimeters and no change in terms of θ in the CBL was detected; confirming that the tested inclined SR cover was able to divert the water during the wetting event. Field lysimeter is a very important tool to evaluate the performance of cover systems. The design involves different parameters such as the geometry of the lysimeter, hydraulic properties of the backfill material, and boundary conditions (Bew et al., 1997). Suction inside and outside the lysimeter must be similar to avoid preferential outward flow. It is worth mentioning that during another wetting event of 155mm/48h simulated in November 2014, water percolation was detected in the 5 lysimeters (Knidiri, 2015). These results prove that even if the height of the lysimeters is small (0.1 m), the lysimeters function well enough to detect a breakthrough of the capillary barrier.

The trend of ψ evolution during the wetting event close to the interface between the CBL and MRL is similar for the four stations. After the wetting event, the ψ value starts to decrease from values between 40 and 85 kPa to values below 20 kPa due to water accumulation. The lowest values were observed near the bottom of the slope where θ increased the most (station 3 and 4). It is interesting to note that both equipments tested (Watermark sensors and Jetfill tensiometers) gave similar trends even if the absolute values can be slightly different.

The hydrogeological behaviors of the inclined SR cover during summer 2014

Figure 5 illustrates hydrogeological behavior of the tested inclined SR cover exposed to natural climatic conditions after the wetting event; rainfall measured during this period is presented in red. Results indicate a decrease of the θ few days after the wetting event due to evaporation during the dry summer conditions. The daily air temperature during this period ranged from 15°C to 33°C with an average of 23.5°C. The fluctuation of θ is more pronounced at 10 cm depth than at 50 cm and 75 cm depth; this is due to atmospheric forcing that affects essentially the surface of the inclined SR cover. However, the effect of evaporation is also present at 50 and 75 cm, particularly for stations located close to the bottom (station 3 and 4) where a constant decrease of the volumetric water content is observed. Hence, the inclined SR cover is presently regaining its full capacity to store further precipitations by transferring water to the atmosphere via evaporation.

In summary, preliminary results show that the hydraulic behavior of the inclined SR cover is influenced by the inclination of the slope. θ in the inclined SR cover is greater at station 3 and 4 which are located in the lower slope positions of the inclined cover. No lateral flow and no percolation were observed during this wetting event. Water accumulated and was diverted by the capillary barrier effects at the interface of the two layers (CBL and MRL) to the bottom of the slope. The suction results indicate that the breakthrough of the capillary barrier (or the Down Dip Limit (DDL), Ross, 1990) was nearly reached at the bottom of the tested inclined SR cover with suction value close to 0 at station 4. These preliminary results also indicate that the cover is presently releasing the water stored during the wetting event to the atmosphere via evaporation.

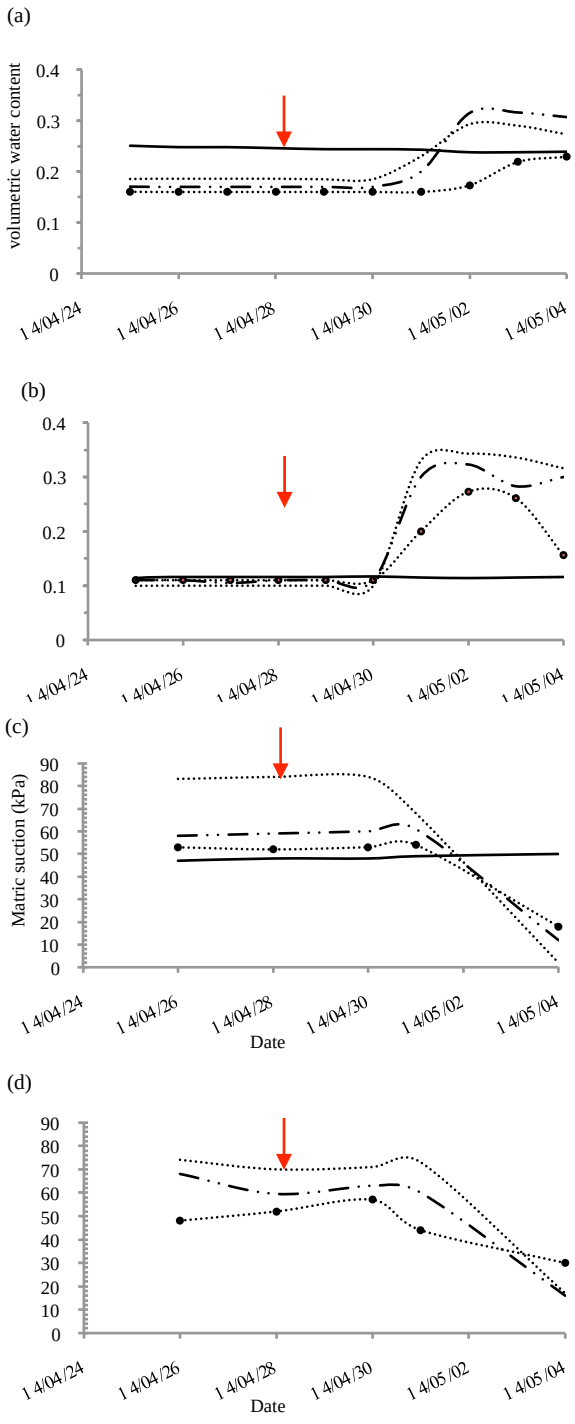

Figure 4 Measured volumetric water content at depths of 75 cm (a) and 50 cm (b) and measured matric suction at the depth of 75 cm with Watermark (c) and Jetfill (d) stations (the arrow in the figure indicates the wetting event)

FINAL REMARKS

The construction of an inclined SR cover in Kettara (Morocco) designed to investigate its slope effect was completed successfully and preliminary results confirm that the SR cover system is working properly to control water percolation. At this stage, measurements indicate that:

- Volumetric water content and suction obtained during the wetting event show that the sensors at 10, 50, 75 cm were affected by this event but the inclined SR cover was able to divert the water flux applied at inclined SR cover surface (100 mm per 48h) where no water percolation was collected in the lysimeters.
- Water was successfully diverted and stored within the phosphate limestone wastes, and is being presently released to the atmosphere during the dry summer period.

The hydrogeological monitoring of the system is underway. In addition, other wetting tests will be performed to investigate the diversion capacity of the tested inclined SR cover. A particular attention will be put on the DDL of the system. Numerical modelling will be also performed to better understand the hydrogeological behavior of inclined SR cover exposed to arid conditions.

ABSTRACT

The Boliden Aitik copper mine is located outside Gällivare, northern Sweden. Since mining started in 1968, more than 500 Mt of waste rock have been deposited in waste rock dumps (WRDs). In the 1990s, a dry cover system was designed to reduce oxygen diffusion to the underlying waste rock and limit the subsequent formation of metal leaching and acid rock drainage (ML/ARD). The original cover system (applied to WRD5 and parts of WRD2) consists of 1.0 m compacted till placed in two lifts covered by 0.3 m organic material. Recent studies concluded that predicted annual diffusion flux estimates based on calibrated soil-plant-atmosphere modelling were similar in magnitude, but greater than, rates predicted in the 1996 design. Therefore, to increase the level of water retention within the compacted till and reduce oxygen ingress to the underlying waste rock, increased compaction from the current practice is required.

Multiple field and laboratory studies were completed to evaluate the cover system design and performance. Field compaction trials conducted in 2012 confirmed that increased compaction would enhance water retention characteristics within the cover system. A field study of freeze / thaw effects on the compacted till highlighted frost penetration to the compacted layer as an area of concern for long term performance of the cover system. Cover system trials implemented in 2013 were instrumented with monitoring instrumentation that will allow performance to be evaluated over time under site-specific conditions, providing essential insight into cover system response to climatic variations in terms of temperature and water storage dynamics.

Keywords: field performance monitoring, water retention capability, oxygen ingress

INTRODUCTION

The Boliden Aitik copper mine (Aitik) is located outside Gällivare, in northern Sweden. Since mining started in 1968, more than 500 Mt of waste rock have been deposited in waste rock dumps (WRDs). The Aitik site is located in a seasonally humid environment, subjected to frozen conditions for approximately half the year. Major seasonal weather events include spring snow melt and heavy rains in the late fall. In the 1990s, a dry cover system was designed to reduce oxygen diffusion to the underlying waste rock and limit the subsequent formation of metal leaching and acid rock drainage (ML/ARD). The original cover system consists of 1.0 m compacted till placed in two lifts covered by 0.3 m organic material. As part of ongoing reclamation activities at Aitik, this dry cover system design has been applied to WRD5 and parts of WRD2.

Recent studies found that predicted annual diffusion flux estimates based on calibrated soil-plant-atmosphere modelling were similar in magnitude, but greater than, rates predicted in the 1996 design. It was hypothesized that increased compaction from the current practice was a feasible option to increase the water retention capability of the compacted till layer, and reduce oxygen ingress to the underlying waste rock. To test this hypothesis, a compaction field trial program was completed to evaluate the relationship between compaction methods and achievable water retention characteristics (as determined by measurements of *in situ* dry density and hydraulic conductivity). Based on this relationship, an improved cover system design was developed. To improve understanding of the *in situ* performance of this cover system, cover system trials were designed, constructed, and instrumented.

METHODOLOGY

Methodology for this study involved compaction field trials, completed in September 2012, to measure achievable *in situ* dry density and hydraulic conductivity. A follow up testing program was completed in May 2013 to determine the effect of a freeze / thaw cycle on the compacted till layers. Cover system field trials were then designed using results of the compaction field trial program to determine optimum compaction methodology for the compacted till layers. Instrumentation installed in the cover system field trials allow for assessment of the cover system performance under site-specific conditions.

Compaction field trials

Compaction field trials were conducted in September 2012 for the purpose of determining the optimal method of construction and achievable level of compaction in terms of *in situ* dry density and minimum field permeability for a compacted till layer at Aitik. The previous methodology for constructing compacted till layers at Aitik consisted of compacting six passes with a 6 ton smooth-drum roller over ~50 cm lifts. The purpose of the compaction trials was to replicate and assess the level of compaction achieved for a compacted till layer using the previous construction methodology and evaluate the level of compaction achieved on a 50 cm lift compared to that achieved on a thinner 30 cm lift. Additional testing evaluated alternative compaction equipment (a 10 ton smooth-drum roller, and 6 ton pad-foot roller) on the 30 cm lift.

The compaction trials were established in an area approximately 60 m x 40 m wide on a surface of compacted, relatively smooth, waste rock that included both a relatively flat and a sloped surface. Each trial pad was approximately 60 m in length and 10 m in width, which accommodated the compaction equipment to create at least a three-pass-wide compacted surface.

For the reason that a significant potential exists for the permeability of a compacted layer to increase as a result of freeze / thaw cycling, a follow-up test program was implemented in the spring of 2013 to assess the effect of one freeze / thaw cycle on *in situ* density and field permeability of the compacted layers. Following completion of the compaction trial test program in 2012, the trial area was covered with a geotextile fabric and a layer of overlying till approximately 0.5 m thick. The fabric was placed immediately over top of the compacted layers to allow for differentiation between the overlying till and the compacted till layer.

Sampling and Laboratory Analyses

Two large samples (~40 kg) of till were collected from each compaction trial pad. Laboratory analyses included determination of particle size distribution (SS-EN 933-1, 2012), compaction testing (SSEN 13286-2, 2010), Atterberg limits (ASTM, 2010), and determination of specific gravity (ASTM, 2010). Distributions of particle sizes larger than 75 µm were determined by sieving, while the distributions of particle sizes less than 75 µm were determined by a sedimentation process using a hydrometer. Standard Proctor and Modified Proctor compaction tests were conducted on each sample to determine compaction characteristics.

In Situ Testing

A nuclear densometer was used to measure *in situ* density and water content (ASTM D 2922, 2005). During the 2012 compaction trials, 86 nuclear densometer measurements were taken at the surface (from a depth of 0 – 20 cm), while 12 nuclear densometer measurements were taken at depth on the 50 cm trial (20 – 40 cm). Small samples of till were collected throughout the testing program for laboratory determination of gravimetric water content (ASTM D2216, 1992); the primary purpose of this sampling effort was to use gravimetric water content results to correct *in situ* dry density measurements taken with the nuclear densometer. A total of 32 additional nuclear densometer tests were completed during the 2013 testing program (after freeze / thaw). Three techniques were used to measure *in situ* permeability, or field saturated hydraulic conductivity (K_{fs}) of the compacted layers: a Guelph permeameter (described in Mohanty et al., 1994) a pressure infiltrometer (described in Reynolds and Elrick, 1990), and borehole permeameters (ASTM, 2011).

Cover system field trial design and construction

Two cover system trials were constructed in the summer of 2013 over waste rock on WRD6. Based on results obtained during the compaction field trial program, a maximum till lift thickness of 0.3 m was implemented for construction of the compacted till layers, compacted at 1 – 2% wet of optimum water content to increase dry density through the lift profile and minimize hydraulic conductivity. In terms of methodology, a minimum of six passes with a 10 ton smooth-drum roller (using maximum vibratory action) was used. Cover System Field Trial # 1 was constructed using the 'preferred' design alternative: 0.3 m compacted till, overlain by 1.0 m non-compacted till, overlain by 0.3 m till and organic mixture. Cover System Field Trial #2 is the 'conservative' design alternative, consisting of 0.3 m compacted till, overlain by 1.5 m non-compacted till, overlain by 0.3 m till and organic mixture. Both trials are comprised of relatively flat plateau sections approximately 50 m wide by 50 m in length, and sloped areas (~3H:1V). The total footprint of the cover system field trials is approximately 1 ha.

The purpose of the cover system field trials is to track the evolution of the cover systems in response to site-specific processes (physical, chemical, and biological) to enhance understanding of key characteristics and processes that control cover system performance, and to assess and compare performance of the two cover system design alternatives. Cover system performance will be assessed in terms of susceptibility of the compacted till layer to freezing, the degree of saturation through the cover system profile, and net percolation to the underlying waste rock. To evaluate cover system performance, the cover system trials were instrumented with:

- A meteorological station, including:
  - a tipping bucket rain gauge for continuous monitoring of rainfall at the site;
  - a net radiometer to record daily totals of net solar radiation;
  - a sonic ranging sensor for continuous monitoring of snowpack depth; and
  - an air temperature sensor.
- Automated monitoring stations for measuring *in situ* volumetric water content, matric suction (i.e. negative pore-water pressure), temperature, and oxygen concentration in the cover system / upper waste rock profile every six hours.
- Manual gas sampling stations for monitoring the oxygen content within the cover system and upper waste rock materials using a portable gas detector.

RESULTS AND DISCUSSION

Laboratory test results

Results of particle size distribution testing indicate that the till used for the compaction trial program was generally well-graded from 1 to 30 mm and deficient in the range of particles smaller than 1 mm. The samples collected contained a range of 30 - 50% gravel, 33 - 52% sand, 15 - 20% silt, and less than 1% clay (Figure 1). The till material was screened to a maximum particle size of 100 mm. Atterberg Limits testing indicated that the till material is non-plastic.

Both Standard and Modified Proctor tests were employed for determining the compaction characteristics of the till material. The average maximum dry density and corresponding optimum water content as determined by the Standard Proctor test were 2.13 t/m^3 and 6.8%, respectively. The higher compaction energy of the Modified Proctor compaction test resulted in an average maximum dry density of 2.20 t/m^3 and a corresponding optimum water content of 6.2%. Density testing during the field program indicated that the higher compaction energy of the Modified Proctor test is more representative of the level of compaction achieved in the field.

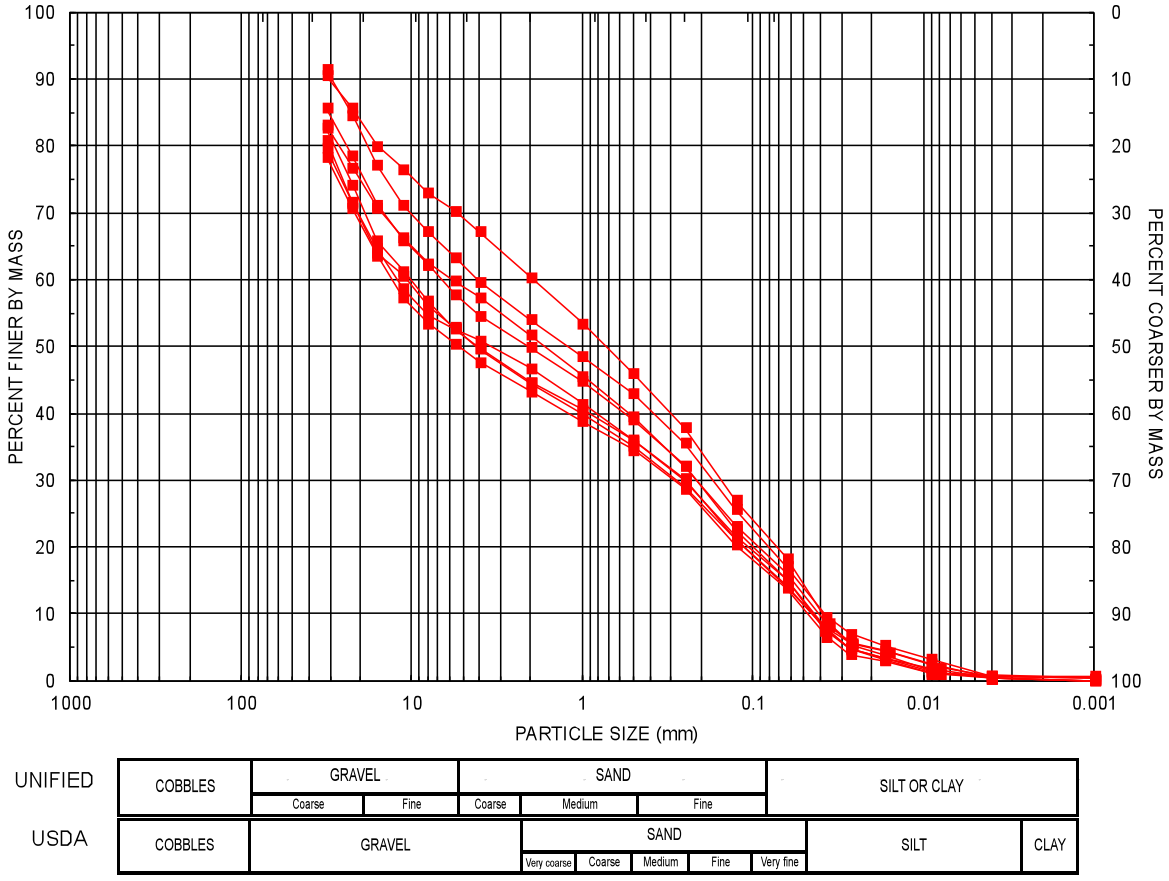

Figure 1 Particle size distributions for till used in compaction trial test program

Evaluation of compaction methodology

Results of compaction testing are summarized in Table 1. Six passes were sufficient to reach a maximum dry density for each test pad. Average dry density and water content values are

presented for each test surface. Unless otherwise noted, nuclear densomer measurements were taken at the surface (0 to 20 cm depth).

Table 1 Average in situ nuclear densometer measurements after various compaction treatments

Lift thickness	Compaction treatment	Plateau ρ_d (t/m³)	W.C. (%)	Slope ρ_d (t/m³)	W.C. (%)
(~50 cm)	6 t smooth-drum roller	2.09 ±0.03	9.1±1.0	2.10±0.05	8.4±1.0
	6 t smooth-drum roller (20 - 40 cm depth)	2.03±0.07	8.6±1.0	2.01±0.07	7.7±1.5
(~30 cm)	6 t smooth-drum roller	2.18±0.07	9.2±1.5	2.13±0.04	9.1±0.7
(~30 cm)	6 t pad-foot roller	2.14±0.05	8.8±0.9	2.18±0.03	7.9±0.7
(~30 cm)	10 t smooth-drum roller	2.23±0.09	8.2±1.3	No data	

Dry density in the 50 cm compacted layer was found to decrease with depth (Figure 2); this is attributed to the dissipation of compaction energy over the thicker lift. Results show that a higher dry density was achieved on a 30 cm lift compared to a 50 cm lift when subjected to the same compaction methodology (six passes with a 6 ton smooth-drum roller). It follows that the bottom 20 – 25 cm of material in the 50 cm compacted layer would not add any value in terms of increased cover system performance, and would therefore be more beneficial as part of the overlying till layer.

Evaluation of alternative compaction equipment on 30 cm lifts showed that compaction with a pad-foot roller was not beneficial in terms of achieving a higher dry density. The highest average dry density was achieved with a 10 ton smooth drum roller on the 30 cm lift (Figure 3).

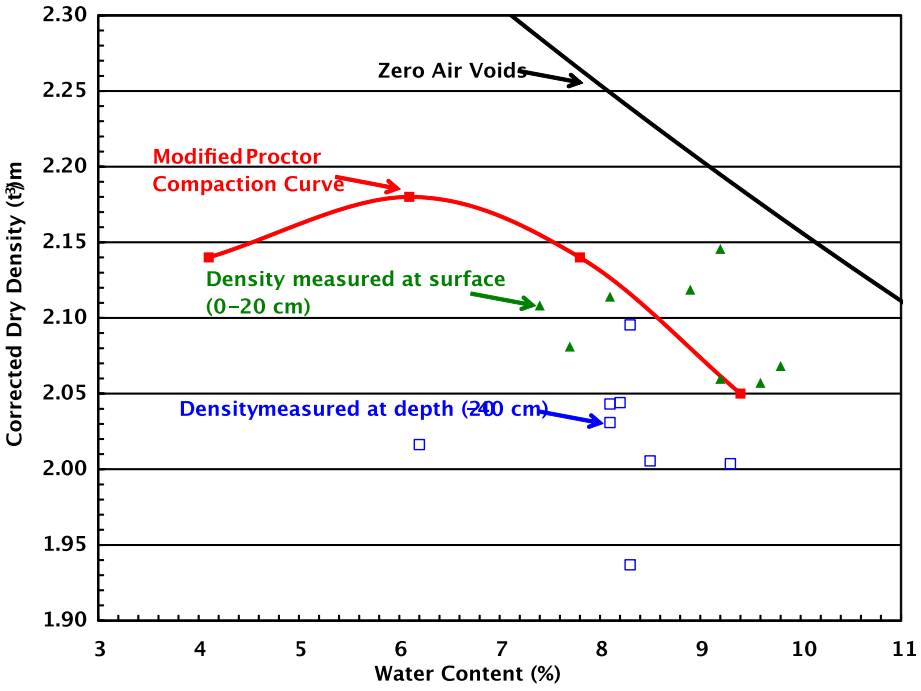

Figure 2 Comparison of in situ density measurements at surface – 20 cm and 20 – 40 cm depth within 50 cm lift

The zero air void line shown in Figure 2 and Figure 3 represent the theoretical line at which the till layer is 100% saturated (i.e. pore space is occupied by water). The zero air voids line is an approximation based on a specific gravity value of 2.74 (based on laboratory results), but it is still useful for illustrating trends. It is apparent from Figure 3 that compaction of a 30 cm lift resulted in reduced porosity (void ratio), and thus would potentially result in a higher degree of saturation and be more beneficial to performance of the cover system.

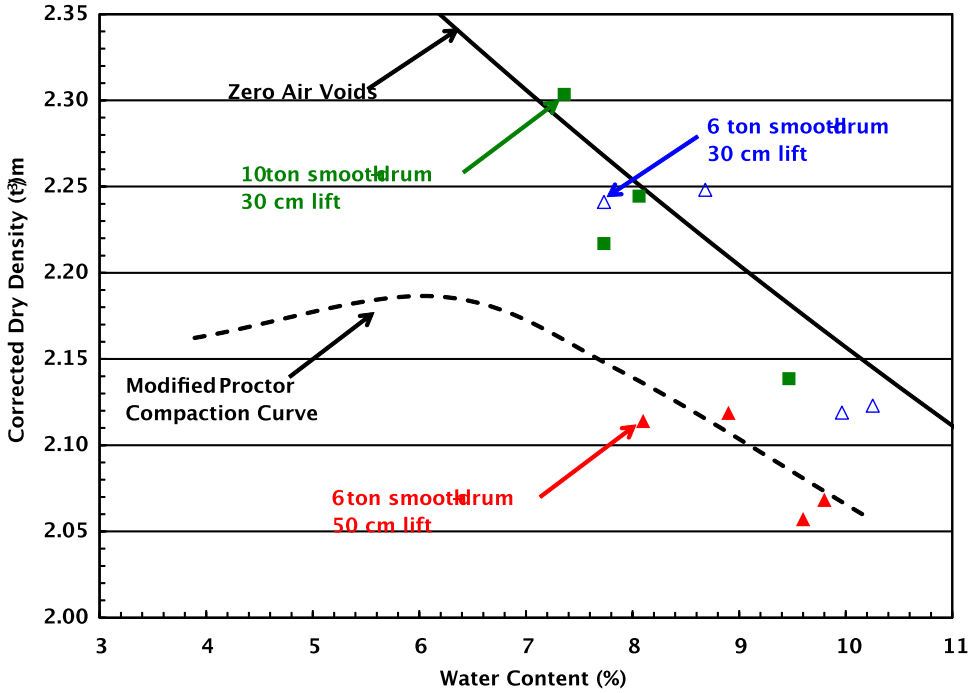

Figure 3 Comparison of dry density measurements on plateau surfaces

K_{fs} measured on the 30 cm thick test pads were in the range of 3 – 5 x 10^{-6} cm/s, while values measured on the 50 cm thick test pad were in the range of 6 – 8 x 10^{-6} cm/s. The lower K_{fs} values measured on the 30 cm test pads compared to the 50 cm test pad were expected because of the higher density measured on the thinner lift. Compaction increases material dry density by decreasing void space within the compacted material. Decreased void space within the compacted till layer increases the tortuosity and, as a result, there are fewer open paths for water (or gas) to move through. For a compacted soil layer, an inverse relationship exists between the capacity to retain and transmit water (i.e. a lower K_{fs} will generally result in higher levels of saturation). Thus, increased compaction achieved on the 30 cm lift leads to increased levels of water retention (degree of saturation) and lower rates of oxygen ingress.

Follow-up testing on compaction field trials to assess effect of one freeze / thaw cycle

A follow up test program in the spring of 2013 evaluated how the compacted layers were affected by a single freeze / thaw cycle. Results of density testing showed that average dry density did not substantially increase or decrease after one freeze / thaw cycle for any of the compaction trial test pads. Results of K_{fs} testing showed that the mean K_{fs} did increase for each test pad, and maximum K_{fs} increased by more than an order of magnitude for each test pad. Figure 4, a histogram (cumulative percentage) of K_{fs} measurements before and after the freeze / thaw, shows that before the freeze / thaw, 100% of measured K_{fs} measurements were lower than 6 x 10^{-6} cm/s, while in 2013, 0% were lower than 6 x 10^{-6} cm/s. The measured increase in K_{fs} is attributed to the effects of freeze / thaw processes on internal structure of the compacted layer.

Svensson and Knutsson (2012) investigated how hydraulic conductivity in till at Aitik changes upon freezing and thawing in a laboratory setting. Results showed little change in hydraulic conductivity after four to eight freeze / thaw cycles for samples that were well compacted prior to freezing, and hydraulic conductivity never exceeded 2×10^{-5} cm/s. When soils are subjected to freeze / thaw cycling, layers of soil are separated by volumetric expansion of ice lenses that form during freezing. In a cohesive soil these fractures may not close fully during thawing; however, in a non-cohesive soil, some degree of self-healing will take place and hydraulic conductivity can be re-established. Therefore, a smaller increase in hydraulic conductivity is expected to result from freeze / thaw cycling in non-cohesive soils compared to cohesive soils (Eigenbrod, 1996; Viklander, 1998). Viklander (1998) found that the hydraulic conductivity of initially dense silty till generally increased by a factor of less than two when subjected to repeated freeze / thaw cycling. Viklander notes, however, that if the till includes stones there is a potential for the soil structure to be affected by movements of the stones during the freeze / thaw cycling.

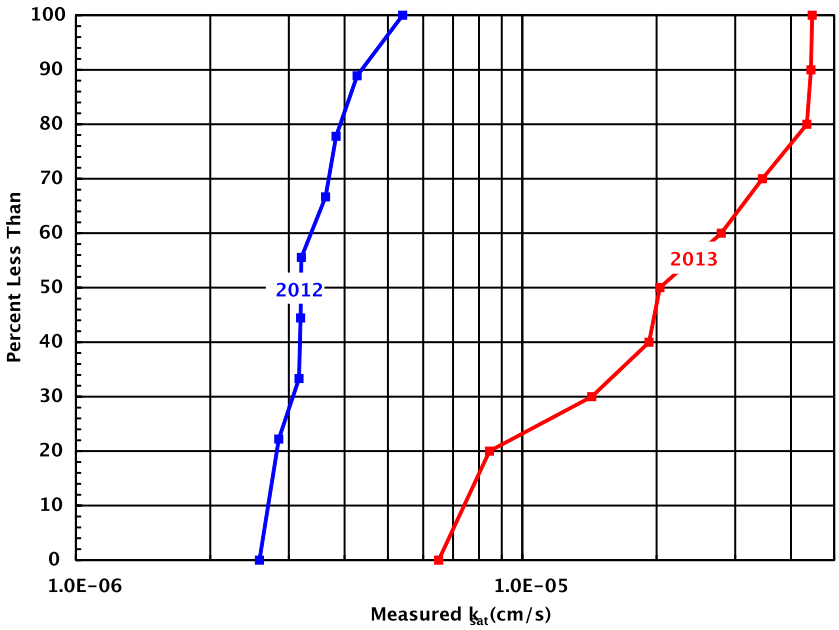

Figure 4 Cumulative histogram of Kfs values measured on compacted till layers in 2012 and 2013

In a compacted layer composed of non-cohesive till (such as that at Aitik) with stone inclusions, there is a potential for a single freeze / thaw cycle to result in an increase in hydraulic conductivity that would not have otherwise occurred in the same soil without stone inclusions (Viklander and Eigenbrod, 2000). Till used for the compaction trial study included stones of varying sizes; results of particle size distribution testing indicate that materials greater than 30 mm comprised, on average, 16% (by mass) of the till material. The presence of stones and the subsquent alteration of structure within the compacted layer caused by freeze / thaw processes was identified as a contributing factor to the measured increase in hydraulic conductivity on the compaction trial pads. Susceptibility of the compacted till layer's hydraulic conductivity to increase as a result of a single freeze / thaw cycle should be highlighted as a potential area of concern for the long-term performance of the cover system.

Depth of freezing front

Findings from the compaction trial study highlight the importance of designing appropriate overlying layers and construction sequencing to complete construction of the cover system before freezing temperatures can alter the structure of the compacted layer. Temperature monitoring of the WRD6 cover system trials using profiles of thermal conductivity sensors show *in situ* temperatures within the cover system and waste rock profile for the first year of monitoring (Figure 5 and Figure 6). Data shows that the freezing front did not reach the compacted layer of either of the cover system trials during this period. While neither compacted layer was affected by frost penetration in this scenario, it is evident that there is an increased buffer zone for Cover System Trial #2 provided by the additional covering layer thickness compared to Cover System Trial #1.

The average air temperature for the winter of 2013-14 (November to April) was -5.4°C, which is significantly ($p > 0.05$) higher than the 5 year site average measured at the WRD5 monitoring station (-6.9°C). It should be noted, however, that penetration of freezing temperatures for a given soil is not dependent solely on air temperature. Additional factors include, vegetative cover, snow cover, and antecedent water content within the cover system profile. The cover system trials were completed in the summer of 2013, providing time for the overlying layers of the cover system to wet up in response to climatic events, and for some vegetation to become established. The compacted layer is likely to be particularly susceptible to freeze / thaw cycling in the first year following construction as vegetation coverage will not be fully established before winter. Snow is an effective insulator, inhibiting the transfer of energy out of the cover system that would be necessary to decrease temperatures within the cover system profile. Lack of vegetative cover during the first winter following installation of monitoring instrumentation, and consequent lack of snowpack would contribute to lower temperatures within the cover system profile. High water contents within the cover system profile may result in a greater amount of energy required to be released for the cover system profile to freeze. If the cover system performs as designed, water content within the profile will remain high, resulting in higher *in situ* temperatures for a longer period of time relative to a cover system with a lower water content. Monitoring of *in situ* water storage dynamics and thermal regimes as well as meteorological parameters at site is necessary to confirm the cover system is performing as designed.

CONCLUSIONS

Multiple field and laboratory studies have been completed at Aitik to achieve the overall objective of developing a reclamation design for the WRDs that will provide the necessary control on oxygen diffusion rates to waste rock material over the long term. Recent studies found that predicted annual diffusion flux estimates based on calibrated soil-plant-atmosphere modelling were similar in magnitude, but greater than, rates predicted in the 1996 design. It was hypothesized that by improving the methodology of compaction for the compacted till layer within the cover systems at Aitik, increased levels of water retention (degree of saturation) could be achieved, reducing potential oxygen ingress into the underlying waste rock. This hypothesis was tested by completing compaction field trials in 2012. Findings from this study confirmed the hypothesis; results showed that dry density was higher and K_{fs} was lower in a 30 cm layer when compared to a 50 cm layer when subjected to simliar compaction energy.

Two cover system field trials were designed based on results of the compaction trial testing. The cover system trials included various monitoring instrumentation that allow the performance to be evaluated over time under site-specific conditions, providing essential insight into cover system response to climatic variations in terms of temperature and water storage dynamics., thus providing greater confidence in full-scale cover system design.

Results of a field investigation in 2013 showed that increased K_{fs} as a result of freeze / thaw processes should be highlighted as a possible area of concern for the long term performance of the cover system. The potential for the freezing front to penetrate to the compacted layer is dependent on factors such as air temperature, snowpack, antecedent water content, thickness and composition of the overlying layer, and vegetative cover. First year monitoring data from the cover system field trials show that the freezing front did not reach the compacted till layers. Continued monitoring of meteorological and water balance components is necessary to determine an accurate representation of *in situ* cover system performance.

A Field-Scale Performance Evaluation of Erosion Control Measures for Slopes of Mine Tailings Dams

Francis Amponsah-Dacosta
Department of Mining & Environmental Geology, University of Venda, South Africa

ABSTRACT

Erosion is a serious problem at mine tailings disposal sites, particularly if the surface is left unprotected. Dust from the tailings dams can be harmful to human, animal, and plant life. Water erosion of the slopes of tailings dams is a considerable and costly maintenance and pollution problem. At present, erosion prevention and control in the short term is very often a process of trial and error and very little information exists on performance of erosion protection measures for long periods. The purpose of this study was to conduct a field-scale investigation into effectiveness of different erosion control measures. This involved creating erosion control panels on a typical slope of tailings dam with surface treatments ranging from simple vegetative techniques to fairly civil engineering erosion protection covers using fragments of rock. A series of measurement of erosion rates were made using measurement of sediment trapped in catchment paddocks and measurement by means of steel pegs to provide a quantitative basis for identifying effective and more economical erosion protection measures. Results of the erosion measurement have shown that erosion from the unprotected slope for the period of the experiment ranged from 257 to 316 tons/ha/year. These losses are alarmingly high and the surface loses its aesthetic appeal with time. On the other hand, any forms of vegetative and physical stabilization of the slopes can significantly reduce erosion of tailings and minimize environment problems at the tailings storage facility. The results of the field experiment have demonstrated that a protective treatment for slope surface takes a number of years to show its value. It has been shown that non-vegetative treatments such as fragments of rock are very effective in resisting erosive forces of nature, providing long-term stability and keeping maintenance to minimum.

Key words: Mine waste, tailings dams, erosion protection, rock fragments, vegetative techniques

INTRODUCTION

Mining and mineral processing result in generation of large quantities of waste such as overburden, waste rock, and tailings. These large volumes of mine waste are expensive to manage, and are frequently cited as an obstacle in the environmental sustainability of mining. Tailings are finely ground rock and mineral waste products of mineral processing operations. The tailings are usually mixed with water to form slurry which is then transported hydraulically into tailings ponds or dams.

Mine tailings are potentially subject to wind and water erosion, acid generation and the release of heavy metals. Dust generated from tailings dams on windy days can be a major problem especially where such dams are located near population centres (Fahey & Newson, 1997). Besides the visual impact of such dust clouds, there are also many potential public health and environmental problems associated with dust. Erosion of the slopes of tailings dams by rainwater runoff is a considerable and costly maintenance and pollution problem (Blight & Steffan, 1979). Cumulative and subsequent erosion down the slope of waste deposits results in gullies that can damage embankment and subsequently lead to instability of part of a slope (Bromhead, 1986). Gullies are also difficult to control and arrest and are not aesthetically pleasant, especially for unprotected slopes. The cost of repairing damages caused by erosion processes can be very high and of great concern to the mining industry.

A major environmental issue facing the mining industry is the rehabilitation options for tailings dams. Successful rehabilitation of mine waste deposits is a major problem, particularly in arid and semi-arid climates, and cannot be attained without substantial outlays of effort, money and innovative techniques (Stiller, Zimpfer & Bishop, 1980). Experience has shown that, of all the rehabilitation purposes, stabilising the impoundment against long-term wind and water erosion is often the most technically problematic and difficult to achieve (Vick, 1983). The need to prevent pollution, improve safety and the appearance of the environment has led to the use of various control and stabilisation techniques.

In South Africa, establishment of grass cover is by far the most common and usually the preferred stabilisation option for tailings impoundments. Vegetation not only serves to reduce wind and water erosion, it also stabilises slopes and results in improvement in the aesthetics of a tailings area. However, mine tailings are generally inhospitable medium for growth and are difficult to vegetate due to their characteristics such as the presence of acid and metals, deficiency in nutrients, lack of agglomerating material and extremes of moisture content (Gorber *et al*., 1978). In arid climates and for tailings having high concentrations of heavy metals or salts, establishment of vegetation may be a lengthy, difficult, and costly process.

It should be possible to identify potential rehabilitation options for a particular site well before the actual rehabilitation programme is implemented based on experience of long-term monitoring of alternatives and comparing their performance. This approach to rehabilitation assessment will provide more assurance that the rehabilitation programme will be successful. In this regard, a large-scale field experiment was designed and constructed to monitor the performance of various slope protection options.

RESEARCH METHODS

Experimental design

The experimental site was a south-facing slope with a slope angle of 16^{o} over the lower two-thirds of the slope length of 20 m and 28 ^{o} over the upper one-third. The slope was divided into 11 panels each measuring 20 m long (upslope) by 10 m wide. Each panel was separated from its neighbour by means of a 0.5 m metal sheet partly dug into the tailings surface to form a low vertical wall. The toe of each panel terminates in a catchment paddock to capture and hold solids removed from the slope by water erosion. Figure 1 shows a plan of part of the experiment.

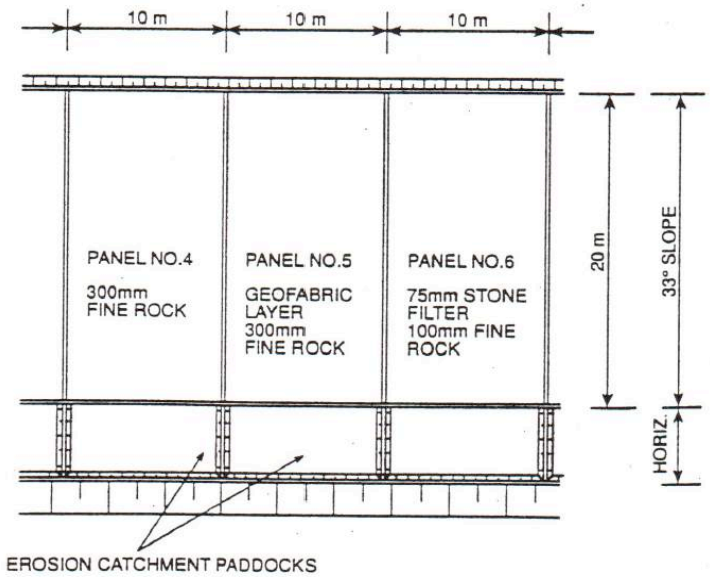

Figure 1 Part layout of erosion protection experiment

Design considerations of slope protection methods

The major design objectives were to utilise simple and low-cost control measures that prevent wind and water erosion, provide long-term stability, and require minimal maintenance to assure performance. A number of options identified for this experiment were rock armouring, revegetation and a combination of these two to take advantage of the benefits of each approach. These erosion protection methods range from very simple changes in vegetative methods to fairly civil engineering works. For any alternative surface treatment to be accepted, it will have to be demonstrated to have long-term durability.

Vegetation is by far the most common and usually the preferred stabilisation option for tailings impoundments. Vegetative stabilisation involves establishment of vegetation on top of a deposit, either by planting directly into the tailings material or by first covering the surface with a layer of top soil of suitable thickness. According to Blight (1989), where continuously maintained, fertilised and watered as needed, a good growth can establish. Physical stabilization involves covering the top and slopes of embankment of tailings dams with suitable thickness of soil, sand or broken waste rock or other restraining material to prevent and control erosion. The use of soil often has a dual advantage in that effective cover is obtained and a habitat is provided for local vegetation to encroach. Crushed rock for stabilisation purposes may be readily available at many mine sites in the form of mine waste or stripped overburden.

Cost estimation of erosion control options

The cost of erosion protection methods was determined only in terms of initial capital outlay without any maintenance cost component. This was to enable the most resilient surface treatment over the long-term without any maintenance to be determined. The cost components considered were: raw materials, direct labour and earthwork activities such as levelling and compacting. Raw materials (such as grass seed, rocks, soil fertiliser, and geofabric) are those materials that actually become part of the product which is the control measure. The cost of labour is the straight wages paid to the employees during construction of the control measure. Some of the surface treatments required levelling and compacting whilst others needed levelling only.

Erosion assessment of slope protection methods

Two methods were used for determination of erosion rates from the erosion protection panels. These were measurement of sediment trapped in catchment paddocks and measurement by means of steel pegs. Each panel was originally equipped with a sprinkler irrigation system to simulate rain, 3 rain gauges and a set of 10 surface pegs. Simulated rain was used to obtain initial results and for the next five years the slopes were exposed to natural weather. It should be noted that the erosion rates were measured differently for phases I to 2 and 3 to 5 of the experiment.

Phase 1 involved a five-week period of simulated rain during the dry winter season of the first year of the experiment. The sprinkling periods were carefully controlled by observation of the rain gauges, thereby ensuring an equal distribution of simulated rain on each of the panels. At the end of the five-week period, all eroded material captured in the catchment paddocks was extracted and weighed. Phase 2 comprised of measurements taken for two wet seasons. At the end of each wet season all eroded material accumulated in the catchment paddocks was measured by determining the in situ volume and unit weight of the captured material.

During phase 3 (cumulative erosion for 4 wet seasons), an unusually heavy rainstorm caused tailings to be washed onto the test slopes from above, thus rendering the origin of the mass of caught material questionable (Blight & Amponsah-Dacosta, 1999a). For this reason, erosion for phases 3 to 5 was assessed by measuring the retreat of the slope surface against the surface level pins. According to Toy (1983), this erosion pin technique is the most extensively used erosion measurement technique. It is also a more reliable method of measurement of soil losses from constructed slopes and gives an indication of the distribution of the soil loss from the slope. From the average measured surface retreat on the selected slopes and measured dry density of the material of the slope surface, the annual rate of erosion in tons/ha was determined. It should be noted that phase 4 and phase 5 represent cumulative erosion for 6 wet seasons and 8 wet seasons respectively.

Cost-effective evaluation of erosion control alternatives

The erosion control measures were assessed in terms of cost and likely effectiveness. This assessment is based on combination of considerations, including reported experience gained and relevant work undertaken by the contractors.

RESULTS AND DISCUSSION

Table 1 records the type of surface protection and its relative cost, actual erosion rates in tons/ha/year, relative erosion rates and a cost effectiveness number represented by the product of relative cost (C) and relative erosion rate (E). The most cost-effective treatment would be the one with the least value of the cost-effective number.

Table 1 Cost-effectiveness evaluation of slope protection methods

Panel Number	Treatment	Level & compact	Level only	Relative Cost/ha C %	Erosion Rate (tons/ha/year)			
					Phase 2	Phase 3	Phase 4	Phase 5
1	Conventional grassing	√	—	100	164	164	164	192

11	100	100	100	100	0	0	0	0	11	11	11	11

Rates of erosion from unprotected slopes of tailings dams can be frighteningly large. Erosion from the unprotected slope for the period of the experiment ranged from 257 to 316 tons/ha/year. According to COMSA (1996), losses of tailings from unprotected gold tailings dams in South Africa of over 500 tons/ha/year are quite common. Blight & Amponsah-Dacosta (1999b) have also recorded erosion exceeding 1000 tons/ha/year on some unprotected slopes of tailings dams in South Africa. Results of the erosion measurement also shows that protecting the slope, by armouring it with crushed rock or covering it with vegetation, increases the surface shear strength and this helps to reduce erosion considerably by dissipating the energy of the erosive forces of wind and water.

On the basis of cost-effectiveness for phase 2, conventional grassing ranks just above no treatment at all and a soil layer covered with grass sods (Panel 10) rated top. However, the grass sods have visibly deteriorated with time and most of the grass has now died. Only the presence of the grass roots has maintained the effectiveness of the treatment. Although establishment of grass cover is the most common means of stabilising tailings disposal sites in South Africa, there are several situations where vegetation is relatively or completely ineffective in protecting a slope from erosion. An important factor, which must be considered in any vegetation programme, is the related equipment necessary to neutralise, fertilise and seed the tailings. According to Gober et al. (1978), the finer fractions of the tailings when wet, is not capable for supporting the heavy equipment normally used for these purposes, and special techniques are required to vegetate these areas. Blight (1989) has also pointed out that grassing does reduce wind erosion but has much less effect on water erosion.

On panel 9, which has a thicker soil layer, and was expected to perform better than Panel 10, the grass has died and the panel rating has dropped from 2 to 8. The conditions of the surface of the various panels after six years are shown in Figures 2 to 4.

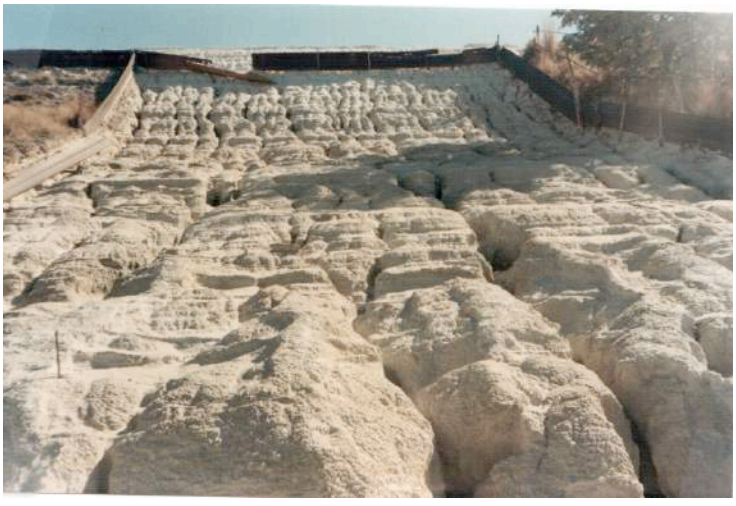

Figure 2 Devastating effect of erosion on unprotected slope (Panel 11)

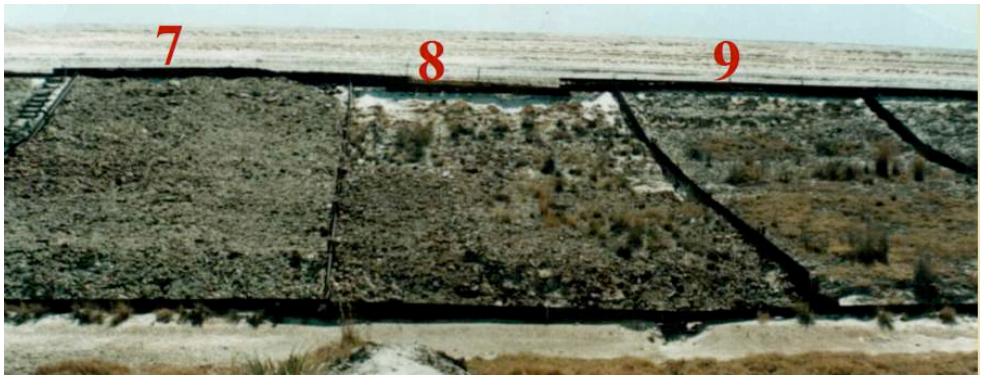

Figure 3 Slope protection panels 7 – 8

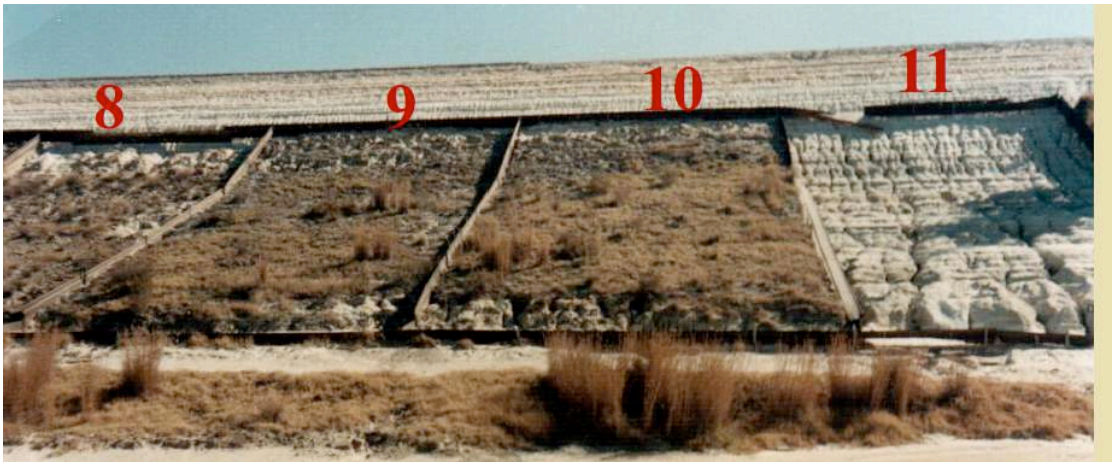

Figure 4 Slope protection panels 8 – 11

It is observed that unprotected panel shown in Figure 2 is highly eroded compared to the other panels which have some form of surface cover. Thus, physical roughness in the form of vegetation and crushed rock play an extremely important role in controlling erosion. Bare slopes of tailings dams experience accelerated erosion whilst any measure that provides cover significantly retards tailings loss and minimise erosion. These qualitative results reinforces the results of the quantitative erosion assessment by repeated measurements of surface elevation using pins driven into the slope surface as reference points and by sediment collection from paddocks that surface cover plays an extremely important role in controlling erosion from slopes of tailings dams.

Table 1 shows that non-vegetative treatments occupy 6 of the first 9 places in the ranking, and should therefore be seriously considered for use in future. The presence of riprap, coarse fragments of rock, on the tailings surface act as mulch. The size and mass of the riprap material absorbs the impact energy of rain drops, while the gaps between the riprap traps and slows the flow of water, lessening its ability to erode the tailings. Rock mulches significantly reduce erosion potential when a large percentage of the tailings surface is covered but this can be an expensive undertaking. The effectiveness of riprap to stabilise soil against erosion is evidenced in nature by the development of a desert pavement, a surface layer of pebbles that forms an effective erosion-resistant surface for long periods of time (Vick, 1983).

This experiment has demonstrated that a protective treatment for a slope surface takes a number of years to show its true value. According to Waugh & Richardson (1995), when earthen materials are

placed in an environment that is not harmonious with the surrounding system, rapid changes in characteristics of the placed material occurs as nature begins to bring the entire system into equilibrium. This point is further illustrated by Figure 5 which shows how the performance of six of the panels has changed with time, with the performance of some remaining relatively static, some improving and others deteriorating with time. It should be noted that season 1 represents application of irrigation and 100% corresponds to erosion of unprotected panel.

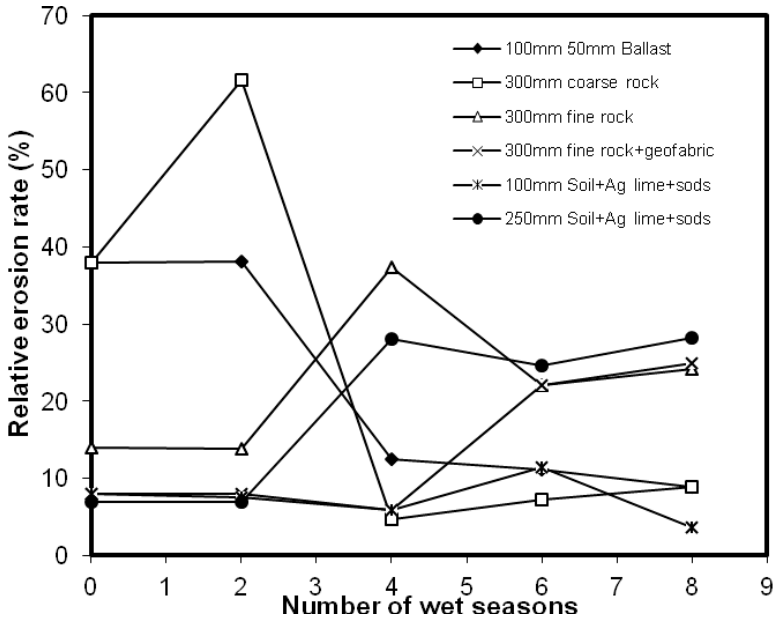

Figure 5 Variation of erosion rate with time (in wet seasons)

The successful long-term stabilization of mine tailings dams is a difficult and complicated process. Erosion prevention and control measures selected must be based on a thorough understanding of the characteristics of the tailings, site-specific properties, how they will react to various treatments, and how the erosion protection covers will change with time. The fundamental principle currently used associates erosion control of tailings dams with revegetation. However, erosion control of tailings dams by means of grassing or revegetation alone has indeed proved challenging to the mining industry. The actual amount of vegetation cover required for adequate erosion protection depends on several factors, including the amount and intensity of rainfall, length and angle of the slope to be stabilized, and erodibility of the tailings material.

This field experiment has shown that rock fragments over slopes of tailings dams are very effective in resisting erosive forces of wind and water. Tailings covers designed with crushed rock, gravel/cobble mixtures, or riprap have several advantages over vegetative covers. Large particle sizes are more resistive to movement by water and wind and have higher shear strengths compared with the smaller soil particles required for revegetation. However, the rock to be used for erosion protection should be geochemically analysed to ensure that it does not cause environmental pollution and evaluated to determine its suitability for providing the necessary long-term erosion protection.

CONCLUSION

Tailings and other mine residues are potentially subject to wind and water erosion. Unprotected surfaces of tailings dams offer little or no resistance to erosive forces and therefore experience accelerated erosion with time. Slope surfaces without cover are aesthetically unpleasant. From

mechanics of the detachment and transport of tailings by rainsplash, runoff and wind, it follows that the best way to minimise the potential adverse effect of tailings erosion on the surrounding environment and hasten the restoration of the area is to cover the surfaces of the tailings dams to protect it from raindrop impact and increase surface roughness to reduce the velocity of the runoff and the near-surface velocity wind.

The need to prevent pollution, improve safety and the appearance of the environment has led to the use of various control and stabilisation techniques. Observation of the various erosion protection panels indicates that nature is attempting to alter some panels in the short time they have been in existence. Some of the panels intended to protect tailings for long time periods experienced severe deterioration over only six years of the cover performance monitoring. Nevertheless, the experiment has enabled continual performance data to be compiled.

It is evident from the results that cost-effective slope protection can be achieved using non-vegetative methods. The rock fragments have potential field applications to mitigate erosion on tailings dams for longer-term period. However, guidelines need to be developed for system design and potential applications, taking into consideration the size of the fragments, the thickness of the cover and the durability of the material. Research to determine the optimum percentage of materials such as boulders, cobbles, gravels, and coarse sands for erosion resistance for a given slope gradient and length also need to be conducted.

Improving Till by Adding Green Liquor Dregs in Sealing Layers to Control AMD – A Pilot Study

ABSTRACT

A common solution to minimize the formation of acid mine drainage (AMD) in sulphide-bearing mine waste is to use a conventional cover. The cover is usually constructed by using natural soils, in the boreal zone often till. Shortage of fine-grained till close to mines suitable as sealant material is often an issue. In the last years, considerable research has been carried out to use residual products from other industries in the control of AMD. Green liquor dregs (GLD), an alkaline and inorganic residual product generated by the sulphate pulp and paper mills, has shown desirable properties such as low hydraulic conductivity, high water retention capacity as well as long term sustainability, to be a candidate for constructing sealing layers in cover system designs. However, the geotechnical strength of the material is insufficient for engineering applications. If this issue can be overcome, developing a cover system with GLD would be possible. The challenge remains of finding a solution that is viable in regards to logistics and transport economics. To reduce transportation costs but take advantage of the physical properties of the residual product, GLD was blended with two types of till in a pilot scale study with the aim to optimize the use of GLD in a sealing layer application. 5-15% (wet weight) GLD was found sufficient to take full advantage of the physical properties of the residual product and to minimize transportation costs. Different mixing techniques were also evaluated. The results show that the quality of the till in regards to hydraulic conductivity and water holding capacity could be improved with the addition of only 5% GLD. A short and efficient mixing was preferred since mixing the material too vigorously released the bounded water resulting in increased water content and a reduction of the compaction efficiency. It results in a material that is difficult to apply and use in sealing layer constructions. Transportation, mixing and application costs are comparable or lower than of fine-grained till.

INTRODUCTION

Mining generates mainly two types of residues: waste rock and tailings. Waste rock is the material that lacks economic amounts of mineral and is removed to access the ore, while tailings are finely ground material that has been processed in the mill. Mine waste from sulfide ores has the potential for a significant environmental impact because it often contains iron sulfides such as pyrite and pyrrhotite. Acidification caused by oxidation of these minerals occurs when they are exposed to atmospheric oxygen (Höglund et al. 2004). If no alkaline material is present to consume this acidity, water entering the waste transports the oxidation products. This leachate is called acid rock drainage (ARD) and often contains high levels of heavy metals. ARD is one of the most significant challenges when dealing with sulfidic, pyrite rich mine waste. One common technique to mitigate the formation of ARD is to apply a barrier made of soil (in Sweden often till) on top of the mine waste that has a high degree of water saturation to limit oxygen diffusion and a low hydraulic conductivity to reduce water percolation. A protective layer is placed on top of the barrier to protect its integrity. Using till in barriers, or so-called sealing layers, is often associated with large costs due to the long distances that the material has to be transported, as finding till of suitable quality that can function in sealing layers and is located close to the mine is seldom possible. If the costs can be kept low, modifying the till available at the mining area may, therefore, be an alternative. To achieve a till that complies with the qualifications of a sealing layer (a highly saturated layer with a low hydraulic conductivity $<10^{-8}$m/s) to reduce oxygen ingress. One way to reduce the heterogeneity and increase the sealing properties of the till is to adjust the particle size distribution and change the porosity. It can be done by removing bigger rocks and adding a fine-grained material of suitable quality.

One potential candidate is the non-hazardous industrial residual waste Green liquor dregs (GLD) that has been characterized previously (Mäkitalo et al. 2014). GLD is the largest waste fraction retrieved in the chemical recovery cycle at sulfate pulp and paper mills and the production in Sweden is ~240 000 t per year. The material has small particle size (clay-silt fraction) and high porosity (>75%). In addition, it showed favorable qualities such as low hydraulic conductivity and high water retention capacity for use in sealing layers to reduce oxygen ingress in the prevention of AMD (Mäkitalo et al. 2014). However, GLD has low shear strength (Mäkitalo et al. 2014) making it difficult to use in engineering applications. It would also be expensive to transport GLD due to the large quantities needed per m^2 and its high water content. However, adding GLD to modify and improve the till to a grade where it can be used as a sealing layer could be an economically viable solution.

Mixing large volumes of **material** poses the risk of inadequate **mixing, therefore,** the mixing of selected proportions of till/GLD was conducted under both laboratory and field conditions. In the field, two different techniques, a loader with a crushing bucket and a mobile asphalt plant, were used in the frame of a pilot scale experiment. The aim was to find a mix that had decreased hydraulic conductivity and increased water retention capacity compared to till to decrease the oxygen influx through the material. The ability to be compacted under field conditions was also an important criterion.

METHODOLOGY

Material

GLD was obtained from the Smurfit Kappa sulphate pulp and paper mill in northern Sweden. Till was excavated at the Ragn-Sells waste management site at Brännkläppen, Sweden, referred to as Till A herein. The till was screened for a particle size of <20mm and had a content of 30% of particles <0,063mm. Another till, from BDX Material, Sweden, with the same maximum particle size, but with the content of <10% of particles <0,063mm was obtained and used to compare the tills. The till is referred to as Till B.

Method

Compaction properties such as maximum dry density, porosity and the optimum water content of till/GLD mixes blended in the laboratory with the proportions 90/10, 80/20, 70/30 and 50/50 were carried out by an accredited laboratory (MRM, Luleå, Sweden) with a standard procedure (EN 13286-2, 2010). Eight mixes of Till A or Till B blended with 5-15% GLD using either a Loader with a crushing bucket (Allu Group Inc.) (Figure 1) or a Mobile Asphalt Plant (Figure 2) were prepared. Total volumes of 10-60 tons were mixed to evaluate the ability to obtain a homogenous product and the production efficiency. The composition of the different mixes and the total amount mixed are shown in Table 1. The production speed of the machineries was recorded to get an estimation of the production costs. Compaction properties of till/GLD blended in the field, and 95/5, 90/10 and 85/15 blends carried out in the lab was determined using standard proctor compaction test. The compaction energy was 2.65 J*cm-3 according to the Swedish Standard SS 027109 (SIS, 1994) and was obtained by filling the column with three layers of material, compacting each layer with 25 blows with a Proctor hand hammer.

Figure 1 Loader with a crushing bucket

Figure 2 Mobile Asphalt Plant

A hydraulic conductivity test was carried out according to the Swedish standard (SIS, 1989) using Darcy's equation. Water was pressed through the column from below and collected in sampling bottles using constant water head. The amount of the permeated water was monitored by weighing. The density was calculated by weighing and water content could be calculated after the material was dried at 105°C for 24h. Water retention capacity (WRC) was measured on sample 4:3 (n=3) and on sample 1 (n=1). The samples were compacted in cylinders and saturated from below. The cylinders were then placed on a ceramic plate, and pressure was applied using a pressure plate apparatus (Soilmoisture Corp., Goleta, CA, USA).

RESULTS AND DISCUSSION

To identify the required amount of GLD that may improve the properties of till without losing the compaction properties, proctor experiments were carried out. A maximum of 20% GLD could be mixed with till. At higher additions of GLD, the plastic behavior prevented compaction by proctor. GLD has a water content of 120 - 150 % (by weight %). Its liquid limit, w_L, is ~132 %. It means that GLD at higher water content than 132 % will transform from a plastic to a liquid consistency. Based on this, 5-15% GLD was mixed with till for further analysis. The composition of the mixes is summarized in Table 1. The productions speed of the asphalt plant was 90 tonnes/h using a mixing time of 45s. The speed could be increased. The loader's capacity was 180 tonnes/h (mixed one time).

Table 1 The composition of the blends, mixing equipment, mixing time and the total amount generated are shown as well as the hydraulic conductivity (k), density (ρ) and water content. The results are given as mean ± SE (n=3).

Mix nr	Composition, mixing equipment, time	Total amount (tonne)	k (10^{-9} m/s)	ϱ (g/cm^3)	Water content (%)
1	10% GLD/Till A, asphalt plant, 45s	60	10.4 ± 9.4	2.0 ± 0.0	N/A
2	15% GLD/Till A, asphalt plant, 45s	30	12.5 ± 4.9	1.9 ± 0.0	21.4
3	10% GLD/Till A, asphalt plant ,2x45s	10	9.8 ± 3.2	2.0 ± 0.0	18.4
4 1	10% GLD/Till A, Loader, 1 run	30	61.4 ± 51.6	2.0 ± 0.0	19.1
4:2	10% GLD/Till A, Loader, 2 runs	30	4.9 ± 3.9	2.1 ± 0.0	N/A
4:3	10% GLD/Till A, Loader, 3 runs	30	4.8 ± 3.5	2.1 ± 0.0	N/A
4:4	10% GLD/Till A, Loader, 4 runs	30	32.7 ± 13.1	2.0 ± 0.0	19.1
4:5	10% GLD/Till A, Loader, 5 runs	30	55.7 ± 29.5	2.1 ± 0.1	16.1
5	5% GLD/Till A, asphalt plant ,45s	30	30.9 ± 31.7	2.1 ± 0.0	13.1
6	5% GLD/Till A, asphalt plant, 2x45s	30	13.7± 3.2	2.0 ± 0.0	16.4
7	10% GLD/Till B, asphalt plant, 45s	30	21.2± 26.7	2.1 ± 0.0	13.6
8	10% GLD/Till B, asphalt plant, 2x45s	30	8.17± 3.6	2.1 ± 0.1	13.8

A large difference in porosity and density of GLD and till was observed. GLD had substantially higher porosity, 83±3% vs. till 36±1%. The density of GLD and till was 1.21±0.05 g/cm^3 and 1.80±0.04 g/cm^3 respectively. The density for all blends was 1.9-2.1 g/cm^3. The average hydraulic conductivity of the blends was $3x10^{-8}$ m/s. It is a substantial decrease compared to till without additives that generated a hydraulic conductivity of $3.9x10^{-7}$ m/s (Table 1). The results indicate that longer mixing time may decrease the hydraulic conductivity. Only for Mix 4:4 and 4:5, the opposite applies. It is hypothesized that the multiple mixing times resulted in the inclusion of coarser till material from the ground in the blends due to the mixing technique (loader) causing the increased hydraulic conductivity. A decreased particle size of a material is usually correlated to a decreased hydraulic conductivity (Sivapullaiah et al. 2000; Benson & Trast 1995). Mixing 10% GLD with till having a silt content of 30% is sufficient to achieve a hydraulic conductivity of 10^{-8} -10^{-9} m/s (Table 1).

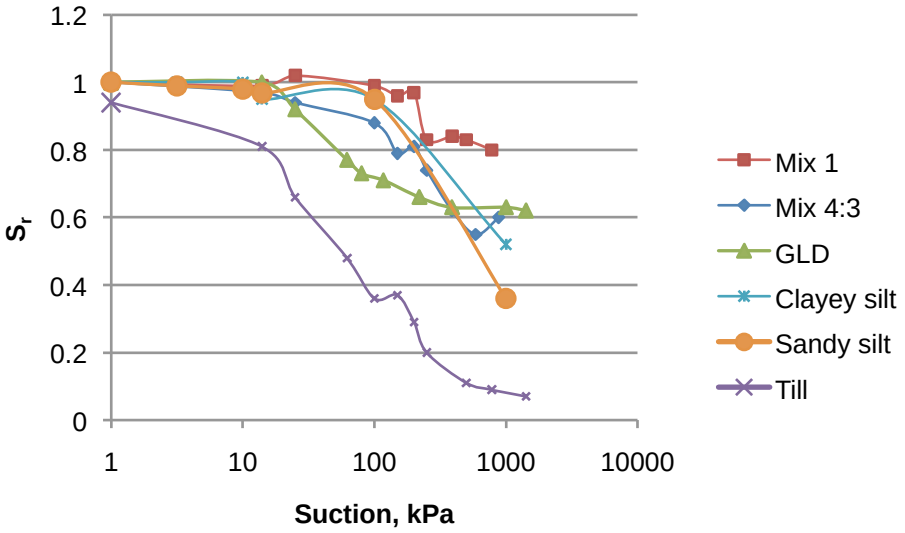

Figure 3 Water retention curves of Mix 1, Mix 4:3, GLD, clayey silt, sandy silt and till.

The water retention capacity for both the tested mixes was high (Fig. 3). Mix 1 and Mix 4:3 were of the same composition (10% GLD) but were blended with different techniques (asphalt plant respectively crushing bucket). Mix 1 blended with the asphalt plant had higher water content (*w)* and lower dry density compared to Mix 4:3, blended with the crushing bucket. It also had higher porosity. One hypothesis is that Mix 1 has undergone more intensive mixing resulting in different physical/geotechnical properties compared to the less disturbed Mix 4:3. The results indicate that intensive mixing of GLD releases bounded water. It increases the porosity and the *w* whilst the dry density decreases. A greater WRC can then be achieved. It has previously been shown that water content at field capacity (-10 or -33 kPa) is affected by macroporosity and structure (Sharma and Uehara, 1968). On the other hand, the water content at the wilting point (-1500kPa) is not dependent on the structure since the majority of the water is held with adsorption (Aina and Periaswamy, 1985). This may be the reason for the difference in WRC between Mix 1 and 4:3 decreases at this suction.

To enable the use of GLD as an additive, the factors affecting the retrieval of the finished product should be understood. Sufficient mixing could be achieved with both the loader and the Mobile Asphalt Plant. Comparing the compaction properties of the tested samples, it shows that the amount of GLD influences the degree of compaction. The 5% GLD blend achieved the highest degree of compaction, i.e. the mix that could achieve the highest dry density and lowest porosity and water content. The amount of GLD in the mix and the mixing energy/time that is applied to the samples are negatively correlated to the degree of compaction (Figure 4). The water content is dependent on mixing technology of the material and is negatively correlated to dry density. The mixing time may affect the properties of the blends and is correlated to the water content and silt content of the till/GLD mixtures. A longer mixing time increases the porosity of blends with high silt content whilst the opposite is noted for blends with low silt content. Using a till with high silt content can, therefore, increase the production process speed and efficiency. To obtain a product suitable for sealing layer purposes, the observed variations of the feed materials (GLD and till) has to be taken into account and the proportions and mixing energy should be adjusted thereafter. A guidance manual for end users is currently under construction.

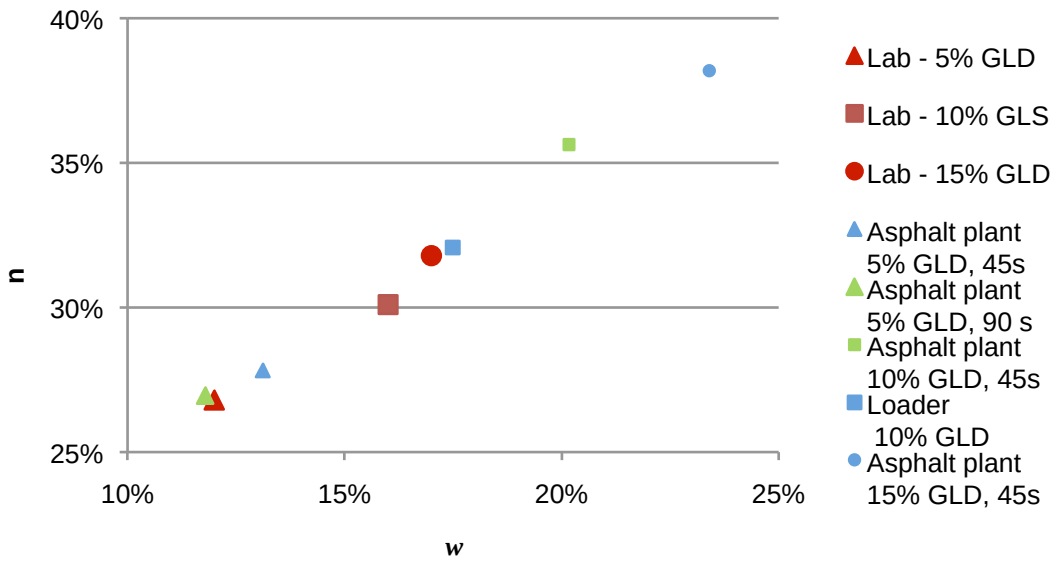

Figure 4 Correlation between water content and porosity of till/GLD samples.

GLD addition as a remediation method is a viable option and may generate decreased costs, better result or both compared with traditional remediation solutions. An assessment of transport economics, transport logistics, handling and management and other surrounding cost have been published (Mácsik and Maurice, 2014). The largest costs are concerned with transportation distances and the mode of transportation. The report showed that using GLD as an additive (addition of 10%) to till available close to the remediation site, is an economical alternative to consider if the distance to till that fulfill the requirements for sealant material is larger than ~10 miles and assuming GLD can be obtained within a reasonable distance (maximum ~500 miles).

CONCLUSION

The aim of the project was to produce mixes of till and GLD, with a hydraulic conductivity lower than 10^{-8} m/s and a high water retention capacity. This study shows that it is possible to produce homogenous mixtures under field conditions and achieve a material that can qualify as a sealing layer. Till blended with 10% GLD by using an asphalt plant showed a higher water retention capacity than till without addition of GLD, but also higher than sandy silt and even clayey silt. This is partly due to highly water saturated conditions in the compacted till/GLD mixtures. Water retention capacity and hydraulic conductivity are related to the mixtures porosity/dry density. Thereby the compacted Till/GLD blends dry density is a good measure of their function as a liner. The quality of the till, such as particle size and water content, as well as the quality of the GLD, such as water content and liquid limit, are important factors influencing the compaction and the hydraulic conductivity of the Till/GLD mixture. The amount of GLD and the mixing energy should be adjusted depending on the geotechnical properties, mainly particle size and water content.

ONGOING RESEARCH

This pilot-scale experiment creates the basis for the remediation of a part of a former mine (4.5 hectares) with a sealing layer made of GLD/till that will take place in 2015. A guide on how to design a sealing layer of till and GLD including mixing techniques, recipes, economics, etc. is currently under process and will be published during 2015. Another pilot scale experiment has been set up where the selected proportion (10%) of GLD/till has been used (based on this current

study) to construct a dry cover system to simulate the mine aimed for remediation. The cover system will be monitored during the next five years and is funded by Boliden Minerals and Vinnova.

ACKNOWLEDGEMENTS

ABSTRACT

Environmentally safe disposal of reactive sulphidic tailings is one of the major management challenges facing the mining industry. Consequently, there are a broad range of tailings rehabilitation strategies suitable for a variety of climates. One option is placement of tailings under a water cover to reduce oxygen influx. However, for sites in Australia that lie in a cool temperate climate, the suitability of engineered water covers is not well documented. The Old Tailings Dam (OTD) located at the Savage River Mine, Tasmania provides a unique opportunity to evaluate water covers as a rehabilitation strategy. The OTD extends roughly 1500 m northeast to southwest and 170 m east to west at its widest point (Hassell, 2005). The northern end is submerged under water, as the OTD was constructed on a natural gradient. Therefore, up to 0.2 km^2 are permanently submerged under water (maximum depth of 10 m) with some seasonal variation. In contrast, the southern portion in contrast has been exposed since 1982. Tailings from 14 trenches and 11 sediment cores were collected across the OTD. Selected samples were subjected to geochemical testwork and also used in mineralogical studies whereby a modified sulphide alteration index was developed. Results revealed a complex, heterogeneous sediment architecture with ten facies observed. From this, four zones were defined (A, unsaturated and coarse-grained, B- unsaturated and fine-grained, C- intermediate saturation and D- saturated). Geochemically, Zone D was identified as the lowest risk, with Zones A to C classified as having a high to extreme acid forming nature, which concurred with bulk mineralogy evaluations showing relatively high quantities of unoxidised pyritic tailings (5 to 9 wt. %). Sulphide alteration index assessments allowed for oxidation to be observed on a micro-scale, and indicated that a minimum water cover depth of approximately 1 to 1.5 m would be sufficient to significantly retard oxidation. Ultimately, a phased rehabilitation strategy which requires geotechnical earthworks and installation of flow-through reactors in combination with a water cover should be developed to successfully reduce AMD from this site.

Keywords: acid mine drainage, rehabilitation, tailings, Australia, mineralogy

INTRODUCTION

Uncontrolled sulphide oxidation can lead to the generation of acid mine drainage (AMD) - characterised by metal-laden acid-sulphate waters (Jambor *et al.* 2003). Impacts of AMD on the environment can occur throughout the life of mine (LOM) with many examples published in the scientific literature; e.g., Harris *et al.* (2003), Edraki *et al.* (2005), Parbhakar-Fox *et al.* (2014) and Candeias *et al.* (2014). As lower grade ore deposits are now being exploited for a range of commodities (c.f. Mudd, 2007), the management challenges are ever increasing as a consequence of the increased volumes of waste (Lottermoser, 2010). In turn, the complexity of mine waste (i.e., tailings, waste rock) management increases, and remains the most significant environmental challenge facing the mining industry (Harries, 1997).

In order to prevent sulphide oxidation and AMD generation in tailings storage facilities, appropriate control strategies are needed. Widely used strategies aim to exclude one or more of the ingredients required for oxidation; e.g., water, iron, oxygen, bacteria and sulphide minerals. Lottermoser (2010) suggested that the most effective control on oxidation rate is specifically reducing oxygen availability. Generally, this is achieved by using wet or dry covers, with a summary given in the GARD Guide (2014). More technologically advanced and innovative strategies have recently been developed and involve induced hardpan formation, grouting or mineral surface treatments (e.g., Ahn *et al.* 2011; Quispe *et al.* 2013). Lottermoser (2010) concluded that no single technology is appropriate for all mine sites and in many cases a combination of technologies offer the best chance of success.

When dealing with historic/legacy tailings sites, a cost-effective management strategy is favoured as the funds available to the lease holder (typically the mine regulator; i.e., government) is likely limited. In such cases, the use of a water cover should be considered. Recent studies by Yanful *et al.* (2004), Bjelkevik (2005) and Kachhwal *et al.* (2010) demonstrate the use of shallow water covers in North America and Sweden. Such covers are effective as the maximum concentration of dissolved oxygen in water is greater than three orders of magnitude lower than that of the atmosphere, so AMD formation is significantly retarded (Lottermoser, 2010). However, a minimum water cover depth must first be established. Yanful *et al.* (2004) proposed two criteria to determine this: (i) hydrological forecasting of the probability of occurrence of a drought event; and (ii) the minimum depth necessary to prevent re-suspension of tailings. Generally, deep water covers are not favoured due to concerns regarding the engineering stability of the containment walls, with high associated capital expenditure. Published studies documenting the use of water covers in Tasmania are scarce. However, as this state experiences a cool temperate climate (~600 mm rainfall/year) it would be well-suited to this type of rehabilitation strategy (c.f. GARD guide, 2014).

At the Savage River Mine AMD is emanating from the OTD, where 38 million tonnes of pyritic tailings were deposited from 1967 to 1982. Consequently, the OTD accounts for 50% of Savage River Mine's AMD load (Williams *et al.* 2014). To manage this, the Tasmanian State Government established the Savage River Rehabilitation Project (SRRP) in co-operation with the mine operator (currently, Grange Resources). This study focussed on: (i) confirming the necessity for a water cover at the OTD, and (ii) establishing an appropriate minimum water depth, should this type of cover be used.

METHODOLOGY

Site description

The Savage River Mine is located on the Savage River 420 km from Hobart on the northwest coast of Tasmania (Figure 1). It consists of five open-cut workings exploiting a group of magnetite-rich lenses irregularly distributed within a series of highly metamorphosed rocks of marble, schist and metabasic rocks. Open-pit mining and processing has resulted in the formation of several large excavations, waste rock piles, and tailings dams (Hutchison and Brett, 2006; Kent, 2013). The concentrated magnetite is slurred by pipeline to Port Latta on Tasmania's northwest coast, before shipping to market. The presence of pyrite in the waste materials (i.e., tailings and waste rock) has

caused AMD to emanate from the mine operations, which is of primary concern to the SRRP (Kent, 2013).

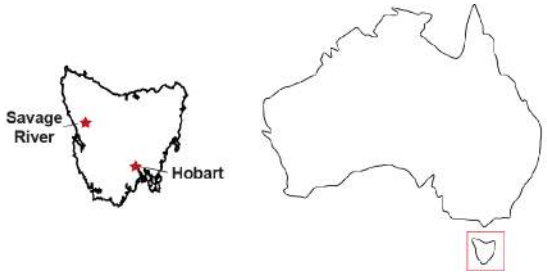

Figure 1 Location of the Savage River Iron Mine, Tasmania, Australia

Operations over the first 30 years of mine life caused environmental degradation to approximately 30 km of the Savage River, and downstream of the confluence with Main Creek exhibits the most severe degradation. This section was found in 1995 to have lost 90% of its invertebrate biodiversity and 99% of its invertebrate abundance. The OTD is located approximately 3 km from the township and 1.3 km from the processing plant. Pyritic tailings from Centre Pit South (CPS) and Centre Pit North (CPN) were deposited in the OTD (Kent, 2013). These were initially deposited behind the starter dam by end-of-pipe spilling into the southwest corner of the dam (Hassell, 2005). Subsequently, tailings were sprayed as slurry from the dam wall to allow it to be raised in lifts (Thompson and Brett, 1996). This deposition method has concentrated coarser, heavier and more permeable material against the dam wall (Kent, 2013). Consequently, the water table in the tailings has decreased proximal to the wall, resulting in extensive oxidation of the tailings in this area and AMD generation.

Sampling and sample preparation

In May 2014, an excavator was used to dig 12 trenches up to 1.5 m depth in the southern end of the OTD (Figure 2). At the northern end the tailings were saturated, so materials from locations 12, 13 and 24 were obtained by hand-dug trenches (c. 60 cm depth). From locations 14 to 23, a weighted piston corer was used, allowing the collection of samples below the northern pond under a varying water depth of 0.3 to 10 m. Samples to a maximum depth of 1.5 m were collected by the piston corer. All tailings samples were cooled and transported to the University of Tasmania (UTas). Cores were frozen to enable logging, and then oven-dried. Each sample (n= *144*) was split in two, with one portion milled to <63 μm for geochemical testwork, and the other used to prepare polished thin sections and grain mounts for mineralogical evaluations.

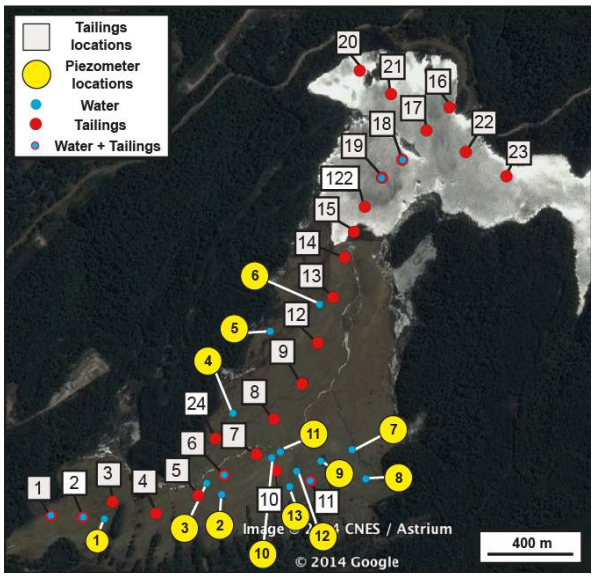

Figure 2 Plan view map of the Old Tailings Dam showing tailings sample locations (red; n=24), and water collection locations (blue). Established piezometer locations are shown in yellow circles (image from Google).

Geochemical testwork

Paste pH testing represents the most efficient manner by which to assess a sample's immediate acid forming characteristics, and was performed on all samples at UTas, according to ASTM D4972-01(2007) following the recommendations given in Noble *et al.* (2012). In addition, rapid and accurate measurement of total sulphur (wt. %) for calculation of maximum potential acidity (MPA) was performed on all samples using an Eltra C-S 2000 instrument at UTas. A sub-set of samples (*n=55*) was chosen for multi-addition NAG pH (UTas) and acid neutralising capacity (ANC) testing (Australian Laboratory Services, Brisbane, Australia). Pore water chemistry was assessed on 20 samples collected from established piezometers (Figure 2), the base of trenches, and the frozen waters in cores. These were analysed by solution ICPMS methods at UTas. Six samples were selected from across the OTD for laser-ablation ICPMS (LA-ICPMS) testwork to provide an indication of the pyrite chemistry. Appropriate sample blanks and standards and certified reference materials were used throughout all analyses, with the standard deviation for each data set calculated as <0.5.

Mineralogical evaluations

To determine their mineralogy, tailings samples were subjected to XRD analysis (*n=55*). A benchtop Bruker D2 Phaser X-ray diffractometer (XRD) instrument with a Co X-ray source was used to perform these analyses at UTas. Each sample was ground in an agate mortar and pestle, loaded into the sample holder and placed into the machine chamber. XRD analysis was performed for 1 hour at an operating voltage of 30 kV and 10 mA using a cobalt X-ray tube. A 0.6 mm (0.3°) fixed divergence slit, 2.5° soller slit and an iron-filter were also used. Each scan ranged from 5 to 120° (2θ) with a 0.02° step size and a measurement time of 0.6 seconds per step. Mineral phases were identified using the Bruker DIFFRAC.EVA software package with the PDF-2 (2012 release) powder diffraction file mineral database. Mineral abundances were semi-quantified by Rietveld analysis using TOPAS pattern analysis software. In general, bulk mineralogy is considered unable to confidently identify the presence of trace sulphide oxidation products (i.e., < 1 wt. %), so a modified sulphide alteration index (SAI) following Blowes and Jambor (1990) was established. Criteria for this SAI (Table 1) were established following the examination of select grain-mounted samples (*n=10*) using a Hitachi SU-70 field emission scanning electron microscope (UTas, Central Science Laboratory). Thin sections (*n= 55*) prepared from tailings samples were evaluated by reflected light

microscopy, with 20 pyrite grains ranked by this criteria and the values averaged to give a final SAI value.

Table 1 Modified sulphide alteration index (SAI) defined and used in this study.

Score (/10)	Features
0-1	Only a few grains of pyrite are weakly altered along edges and fracturing is minor; >95% of the grains have sharp, fresh margins.
2-4	Pyrite grains have rims emerging and fracturing is minor.
5-6	Pyrite grains have >narrow alteration rims with fracturing becoming predominant.
7-8	Appearance of secondary minerals, increase in abundance of fracturing and subsequent altering.
9	Pyrite <30% pyrite remaining, dominated by alteration around rims and fractures.
10	Only traces of pyrite remain.

RESULTS AND DISCUSSION

Tailings facies

Tailings within the OTD demonstrate a high degree of heterogeneity with ten facies identified, and four distinct zones defined: A - unsaturated coarse-grained (locations 1 to 3); B - unsaturated fine-grained (locations 4 to 6); C - intermediate (saturated/unsaturated; locations 7 to 14, 24); and D - saturated (locations 15 to 23). Oxidation of sulphide minerals in the tailings was indicated by a change in colour from grey to yellow, orange or red. The vertical extent of oxidation into the tailings varied throughout the OTD. For example, in Zone A, (proximal to the discharge) water percolation occurs due to the coarse nature of these tailings, therefore this zone is extensively oxidised (Figure 3a). In general, the oxidised hardpan layer thickness decreases towards the northern pond. Thin oxidised layers observed at depth (e.g., c. 10- 50 cm; Figure 3b) in trenches represent former hardpan surfaces, which have subsequently been covered with tailings. Some subsurface layers, particularly coarse sulphide sand layers, appeared to be undergoing some degree of oxidation (Figure 3c). This is likely caused by vertical fissures (occasionally observed) allowing water and oxygen ingress through the buried tailings. Re-sedimentation of hardpan material in the shallow pond area (e.g., Figure 3d) added complexity in determining the minimum depth of water cover required, as there may be a combined protective effect of both hardpan and water.

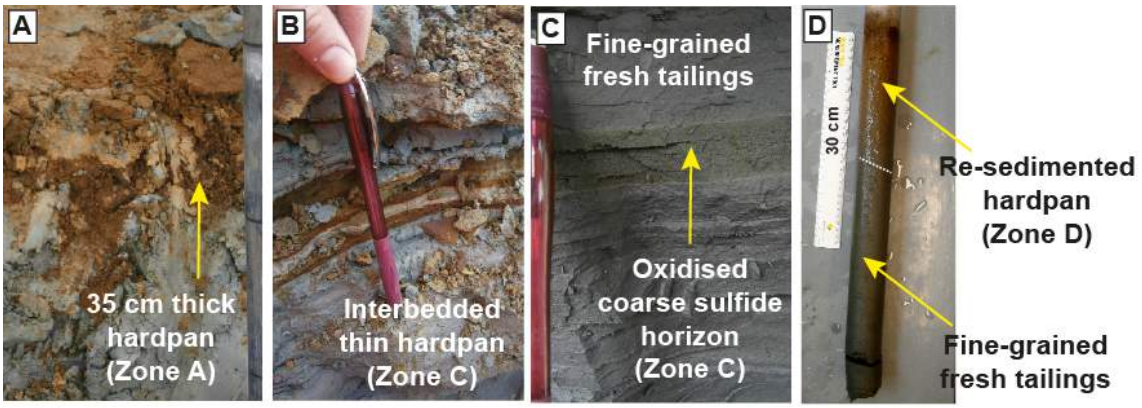

Figure 3 Examples of tailings oxidation observed in the OTD. A: Thick oxidised hardpan (30 to 35 cm depth) prevalent in Zone A; B: Thin hardpan layers interbedded within fresh tailings packages at depth (c.1 m; Zones B and C); C: Coarse oxidised sulphide horizon observed in Zones B and C; D: Re-sedimented hardpan seen in Zone D.

Tailings geochemistry

The assessment of lag-time to AMD and therefore risk (from high to low) was determined using the net acid generation (NAG) pH vs. paste pH classification scheme (Figure 4; Weber *et al.* 2006). The majority of samples from Zones A (unsaturated, coarse-grained), B (unsaturated, fine-grained) and C (intermediate zone) were classified as intermediate-high risk with acid formation rate predicted as rapid to immediate. This is new evidence that these tailings are severely acid forming at depth and require rehabilitation, as previously this has only been inferred from water chemistry and assessments of samples taken from the upper 30 cm (c.f. Hassell, 2005). The majority of Zone D samples fall into potentially acid forming (PAF)-low risk, inferring a potential relationship between permanent saturation and higher paste pH values. A net acid producing potential (NAPP) vs. NAG pH classification plot showed that the majority of OTD samples are PAF, with a NAPP range from -2.5 to 797 kg H_2SO_4/t (average: 187 kg H_2SO_4/t; median; 160 Kg H_2SO_4/t). Acid neutralising capacity (ANC) values were in the range from 0 to 41 kg H_2SO_4/t, with an average value of 15 kg H_2SO_4/t. Despite the presence of magnesite in the primary ore-mineral assemblage at Savage River, it was not reported by XRD (i.e., only trace amounts below the detection limit of 1% present). Therefore, ANC is likely sourced directly from chlorite, an effective silicate neutraliser (c.f. Craw, 2000; Jambor *et al.* 2002; 2007). Additionally, Hutchison and Brett (2006) and Gerson *et al.* (2014) have documented the use of the chlorite-calcite schist/amphibolite for AMD control at Savage River, from which both calcite and chlorite are thought to contribute to the net-neutralising potential.

Chemical analyses of pyrite (LA-ICPMS; *n= 180*) in six samples collected across the OTD indicated that generally the pyrite is enriched in Co and Ni (Figures 5a and 5c). Copper, which is elevated in the waters draining the site (c.f. Hassell, 2005), is also relatively high in these samples (average 620 ppm), with the highest concentrations measured in Zone A (Figure 5b). Zinc was generally low (average 10 ppm): however, its concentration steadily increased towards Zone D (Figure 5d), indicating that it has leached from Zone A; i.e., susceptible to meteoric water influx and under low pH conditions (average pore water pH: 2.7).

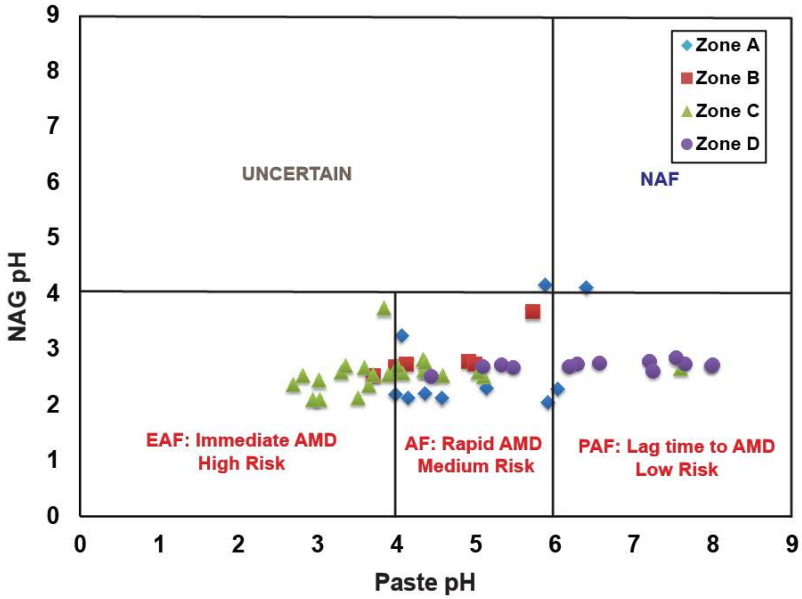

Figure 4 NAG pH vs. paste pH risk classification plot (after Weber et al. 2006) for tailings samples collected across the OTD (samples grouped by zones: A- unsaturated and coarse-grained; B- unsaturated, C- intermediate saturation and D- saturated). Abbreviations: EAF, extremely acid forming; AF, acid forming; PAF, potentially acid forming; NAF, non-acid forming.

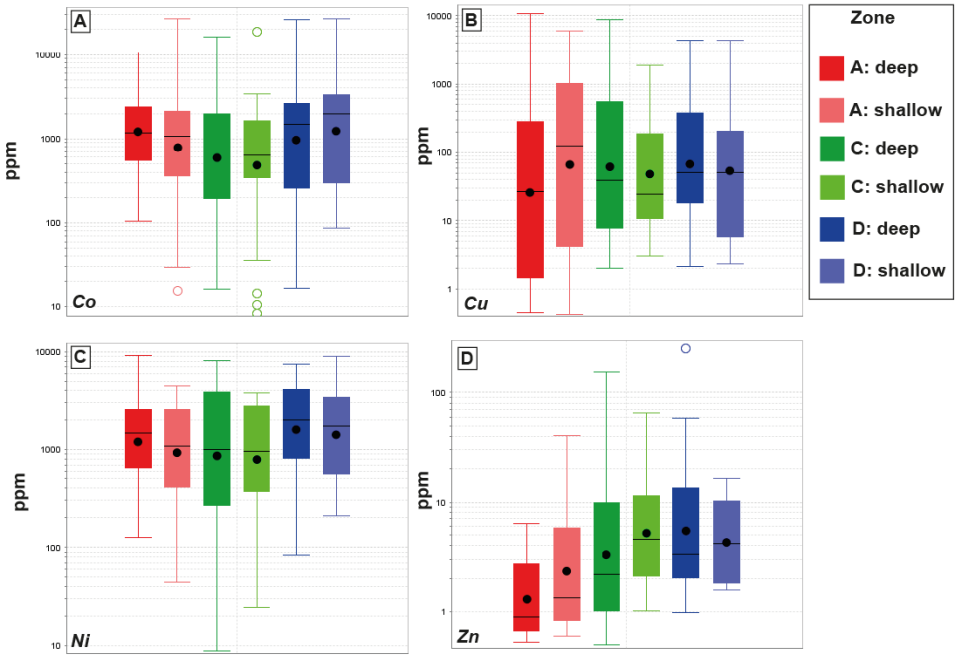

Figure 5 Tukey geochemical plots of select potentially deleterious elements (ppm) contained in pyrite (n=6) from the OTD: Co (A), Cu (B), Ni (C) and Zn (D). (NB/ black dots indicate average, solid black line the median, solid colour box ends indicate the interquartile range, whiskers include outliers (indicated by open circles and triangles) in the recalculated interquartile range).

Chemical analyses of tailings pore water showed high sulphate concentrations (max. 12,900 mg/L; Zone C) in the unsaturated and intermediate saturated zones, indicating active AMD formation. In Zone D concentrations below ANZECC (2000) drinking water guideline (DWG) values (500 mg/L) were measured (average 157 mg/L), confirming that the established natural water cover is effective at retarding AMD formation. Furthermore, average pH values of 4.5 were measured in this Zone. Across the OTD As, Cd, Ni, Sb, Pb and U were below ANZECC (2000) DWG values. Occasional exceedances of Al (max. 180 mg/L), Cu (max. 35 mg/L), Se (max. 0.1 mg/L) and Zn (max. 4.6 mg/L) relative to ANZECC (2000) DWG values were identified, predominantly in Zones B and C, but not in Zone D. In general, Fe was high across the OTD, with six locations reporting concentrations >1000 mg/L; however, no ANZECC (2000) DWG value is available for comparison. This is also the case for Co, with average concentrations of 5 mg/L measured.

Tailings mineralogy

The bulk mineralogy of the tailings across the OTD was dominated by albite, actinolite, antigorite, quartz, tremolite, talc and chlorite, as shown in Figure 6. In all zones the content of pyrite increased with depth, confirming the presence of fresh tailings at depth. In the upper most samples from Zone A and B trenches (0 to 30 cm), secondary minerals goethite, ferrihydrite, hematite and jarosite were observed, which are common hardpan minerals. The presence of goethite and jarosite indicated the latest stages of sulphide oxidation (c.f. Jambor, 2003). The highest jarosite concentrations were observed in Zone C (intermediate saturation), which concurs with the environment of its formation (c.f. Dutrizac and Jambor, 2000). In Zone D there was a notable decrease in the quantity of these secondary minerals, confirming that these materials are relatively fresh. Additionally, there is also a lower pyrite content, likely related to the distance from the discharge; although on average the grain size was finer. The bulk mineralogy confirms that the established water cover is effective in retarding oxidation, with very minor (< 2 wt. %) secondary minerals developed. Where these were observed (i.e., locations 15 and 18; Figure 2) it indicated re-sedimentation of hardpan materials from Zone C.

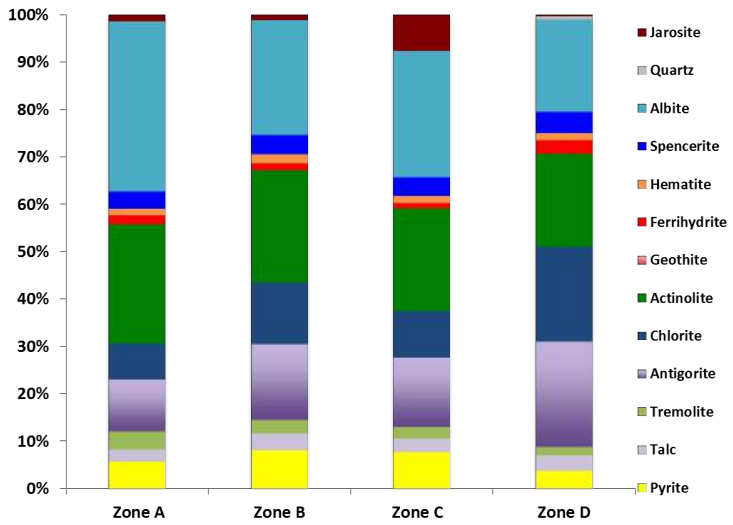

Figure 6 Summary of bulk mineralogy (measured by XRD semi-quantitative, modal abundance as a % shown) for Zones (A to D).

Sulphide alteration index (SAI) values calculated across the OTD are shown in Figure 7. The highest SAI values were measured in Zone A (6/10) in the upper horizons (c. 30 cm; Figure 8a). The lowest readings (1/10) were recorded in Zone D at depth (150 cm, under 430 cm water cover; Figure 8b). These results concur with the tailings geochemistry. From these values, the minimum depth of an effective water cover for retarding AMD formation is identified as 1 to 1.5 m.

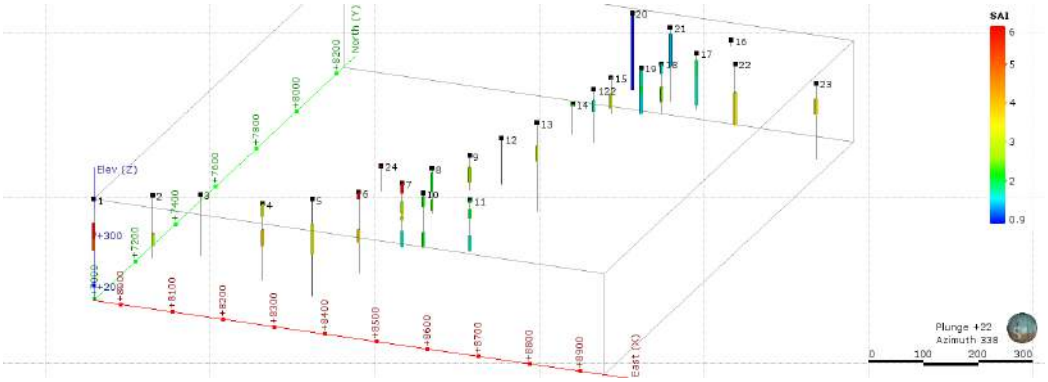

Figure 7 3D schematic diagram of the OTD showing sample locations and sulphide alteration index (SAI) values. Zones A to D are indicated (by thick black lines) and the northern pond is shown in Zone D.

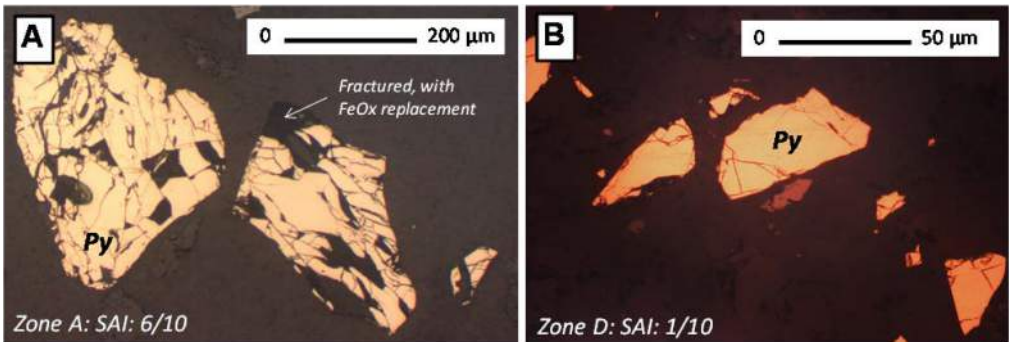

Figure 8 Photomicrographs (reflected light) of pyrite. A: Grains from Zone A (30 cm depth) showing extensive oxidation with a sulphide alteration index (SAI) score of 6/10 given; B: Grains from Zone D (45 to 75 cm depth, under; 100 cm of water) are comparatively smaller, and much less altered with a SAI score of 1/10 given, indicating this is an appropriate water cover depth.

CONCLUSION

The presence of a natural water cover in the northern portion of the OTD at the Savage River Mine provided the unique opportunity to evaluate the application of a total water cover as a cost-effective rehabilitation strategy. The OTD currently contributes 50% to the total AMD load from the Savage River Mine. As the OTD tailings are historic (managed by the SRRP), knowledge of the tailings geochemical and mineralogical characteristics at depth were limited, and therefore the nature of potentially reactive pyritic tailings remaining in the OTD unknown. This study has penetrated the OTD to depths of 1 to 1.7 m, revealing complex sediment architecture, with ten facies identified and four zones (A to D) defined based on grain size and degree of saturation. Geochemical results indicated that these tailings remain acid forming, with Zones A to C (unsaturated coarse-grained, unsaturated fine-grained, and intermediate, respectively) classified as high risk. Tailings in Zone D (saturated) were less reactive, and classified as low-risk. The sulphide alteration index (SAI) mineralogical assessment allowed for the oxidation front to be better approximated, and confirmed the natural water cover as effective for retarding oxidation. Furthermore, the results indicate that a minimum water cover depth of 1 to 1.5 m is required across the entire OTD. Predictions of re-suspension by wind or wave action have yet to be performed; however, observations of re-sedimented hardpan in the surface of core samples from Zone D show that at 1.5 m such sediments are not seen. Potentially, this more conservative depth of 1.5 m should be used.

Ultimately, a phased tailings rehabilitation management strategy which utilises a water cover will prove the best solution at the OTD. Phase one should focus on the removal of the upper most > 0.5

m of tailings (i.e., oxidised portion) in Zone A, followed by clay capping. This will leave this zone with characteristics similar to the remainder of the unsaturated portion of the dam (i.e., Zones B and C), allowing them to be managed together. Phase two involves the extension of the northern pond area to saturate tailings in Zones A (after clay-capping), B and C to 1.5 m depth in order to reduce sulphide oxidation rate. However, this should only be undertaken after geotechnical work to raise the dam walls has been completed. Phase three requires installation of flow-through reactors to neutralise any AMD emanating from the OTD. At least two alkaline flow through reactors should be installed, one at the north slot monitoring station where seepage is occurring, and the other at the former southwest spigot point in case the water in the OTD back flows as it is being filled. Phase four involves establishing a long-term monitoring programme, which focuses on identifying any additional seepage points, measuring water quality to test how effective the water cover is, measure water level fluctuations, and identifying if there has been any re-suspension of tailings. In several years, a follow up mineralogical study should be performed to evaluate the performance of the water cover by measuring the degree of oxidation using the SAI.

ACKNOWLEDGEMENTS

Financial support for this BSc. honours project was provided by the SRRP for which they are acknowledged. The authors would like to thank staff at the University of Tasmania (Dr. Nathan Fox, John Aalders, Sean Johnson, Dr. Paul Olin, Dr. Karsten Goemann, Dr. Sandrin Feig) for their analytical assistance. In addition, site personnel at Grange Resources past and present (Bruce Hutchison, Dr. Victoria Braniff) are acknowledged for initiating the project and providing additional information on the site.

ABSTRACT

Initial characterization at Geita Gold Mine (GGM) identified that ~38% of waste rock materials are potentially acid forming (PAF) and tailings are sulfidic (~4% pyrite). GGM has historical acid and metalliferous drainage from naturally-exposed sulfidic rocks and artisanal mining. Pre-mine groundwater studies indicated elevated concentrations of lead and iron, with bores in areas of known mineralization indicating elevated sulfate, arsenic, chromium and nitrate. During mine operation waste rock has contributed limited sulfate and metals. The mine's closure plan for the waste rock is to encapsulate the PAF waste rock within a buffer zone of non-acid forming (NAF) waste rock. The waste placement plan was developed prior to and in the early stages of mining based on geochemical characterization, mapping, and pit block modelling and is reconciled against the updated waste block model as mining progresses. The mine actively minimizes the infiltration of water into the waste rock materials using truck compaction of each dump lift and progressive reclamation.

This paper outlines the approach to designing cover systems and landforms suitable for final closure of the waste storage facilities. A detailed geochemical and geotechnical material characterization program of the current waste storage landforms, consisting of material sampling and field and laboratory testing was undertaken. The results of groundwater and surface water analyses indicated that the waste rock dumps are most likely constructed and behaving as designed with respect to PAF encapsulation. Thus, the conceptual model developed was that a cover system that resulted in moderate net percolation rate, coupled with a stable (geotechnical and geomorphologic) landform that properly managed surface water, was sufficient for reducing contaminants in downstream receptors to below discharge standards. The conceptual model was confirmed using soil-plant-atmosphere, groundwater flow, and contaminant transport numerical modelling to evaluate the predicted long-term water quality.

Keywords: PAF encapsulation, cover design, geochemical characterization, landform design, contaminant transport

INTRODUCTION

The modern Geita Gold Mine (GGM) owned by AngloGold Ashanti Ltd. and operated by Geita Gold Mining Ltd. is an open-pit mine situated in the Mwanza Region of north-western Tanzania, approximately 90 km from the regional capital of Mwanza and 20 kilometres south of Lake Victoria, in an area known as the Lake Victoria Goldfields.

GGM's broad reclamation objective is to leave the site in a condition that is safe, stable, and minimizes long-term environmental impacts as well as providing opportunities for alternative forms of business development. The project described in this paper was initiated to develop mitigation methods for the waste rock and tailings storage facilities that would result in GGM meeting or exceeding their stated reclamation objectives. GGM's closure criteria to meet these objectives for the waste storage facilities were the creation of stable landforms and the reduction of solute loading from the waste storage facilities to meet discharge standards at the downstream compliance points.

Prior to the onset of mining, GGM developed a waste placement plan for the waste rock storage facilities to proactively mitigate against AMD production. This involved detailed characterization of the future waste rock material into non-acid forming (NAF) and potentially acid-forming (PAF) categories (which are continuously updated during mining). The waste rock storage facilities were then designed to encapsulate the PAF materials.

It was hypothesized that a cover system and landform design using the locally-available borrow materials would reduce net percolation to a moderate level (10-15% of mean annual rainfall) in the waste rock and tailings materials and that this would be sufficient to reduce the solute loading at the downstream receptors to below discharge standards. This paper describes the support studies used to verify this hypothesis.

BACKGROUND

The modern Geita Gold Mine began to process ore mid-2000. The GGM operation comprises three mining areas: one centred on the old Geita Hill area (Geita Block) comprising several pits: Nyankanga, Geita Hill, Lone Cone and their associated waste rock dumps: WD1, WD5, WD6, WD14, WD15, the Nyamulilima Block is west of Geita Hill and comprises Star & Comet, Robert and Ridge 8 and waste rock dump WD16, and the third – Kukuluma Block, located ~20km away comprising the Kukuluma and Matandani pits and waste rock dumps WD7, WD8 and WD9. Tailings have been deposited in an historic TSF constructed prior to the current mining operation and referred herein as the Old TSF and a modern storage referred to as the New TSF (NTSF). The materials' composition in these landforms has the potential to generate acidic drainage from natural oxidation of contained sulfidic minerals and result in metal leaching. Previous characterization has shown up to 38% of waste rock materials as potentially acid forming (PAF), based on initial assessment in 2001 (Scott et al, 2014). Currently gold is mined from Nyankanga, Geita Hill and Star & Comet Pits. Kukuluma and Matandani pits and the Lone Cone pits are not operational. The current life of mine is planned until 2030.

Geology

GGM is located in the Geita Greenstones that form the northern arm of the regional Sukumaland Greenstone Belt of the Archaean Tanzanian Craton. Stratigraphically the Sukumaland Greenstone Belt belongs to the Neoarchaean Nyanzian Supergroup (Barth, 1990; Borg and Shackleton, 1997). The Geita deposits are hosted in Archaean-age rock Upper Nyanzian formations characterized by banded iron formation (BIF), felsic volcanics and andesite/diorite lithologies (Sibilski and Stephen, 2006). The BIF outcrops in all of the high ground in the area, while felsic volcanics occur in the lower flanks of the ridges and are either inter-bedded within the BIF or occur either side of it. The other main lithology in the Geita area is a trachyandesite, encompassing a suite of volcanic rock types, ranging from basalt to diorite in composition. The trachyandesite units are commonly interbedded and folded with the BIF. The volcanics, which host the gold mineralization, have been metamorphosed to lower greenschist facies. At Nyankanga the principal waste rocks are microdiorite and BIF. The Kukuluma host waste rock sequence is more variable and includes mafic to felsic volcanics, BIF and metasediments. The western section of the belt, in the GGM area, is cut by regional scale Proterozoic quartz-gabbro dykes with a strong north-east trend. The area is dominated by both NW and NE structural trends, with a weaker NNW trend occupied by Karoo dolerite dykes. The greenstone belts of the Tanzanian Craton are characterized by more localized and discontinuous structures.

Mineralogy

Gold mineralization is typically associated with quartz veins (inner belts) and disseminated sulfides (outer belt) in quartz-carbonate-chlorite shear zones replacing and crosscutting magnetite-rich BIF. Gold mineralization can also be associated with massive and disseminated sulfide bodies on contacts between felsic tuffs and BIF. The principal sulfide present in the shear and vein-hosted deposits is pyrite, with minor pyrrhotite and trace arsenopyrite, chalcopyrite, galena and sphalerite. Gold occurs as free native gold in quartz veins and as inclusions or surface adherents to iron sulfides. Carbonate minerals that are present in the mine sequence are dominated by calcite with accessory dolomite, ankerite and siderite. The carbonates occur as fine-grained pervasive mineralization in the altered BIF matrix and as coarser-grained calcite in veins. The supergene mineral assemblage is dominated by oxyhydrates of iron and aluminium.

Climate and Hydrology

The Geita District has a highland equatorial wet-dry weather pattern with a bimodal wet season (generally October to December and February to May) with a mean annual rainfall of ~980 mm. A distinct dry season extends from June to August/September with an average annual pan evaporation of ~1,300 mm. The areas annual minimum and maximum temperatures are between 14°C and 32°C. The average altitude is 1,180-1,350 m ASL for Nyankanga and Geita Hill-Lone Cone site, 1,550-1,620 m for Kukuluma-Matandani mine site and 1,450-1,500m ASL for Nyamulilima Star & Comet site to the west.

The main GGM operations (Geita Block) are located within the Mtakuja River catchment that drains to Lake Victoria 25 km to the northwest. Surface water enters the main Nyankanga and Geita Hill-Lone Cone site from the southeast via a dam diversion of the Nyankanga River, which diverts water and outlets to the Mtakuja River. The Mtakuja River runs through the main mine site between the NTSF and WD1 and continues northwest towards Lake Victoria. Surface water runoff from the upland ridges and ferricrete areas can be high, and under heavy rainfall conditions can produce fast response flows within surface water channels.

Two hydrogeological units have been identified in the main GGM site area that act to transmit the majority of groundwater seepage: transported ferricrete and saprock. The transported ferricrete acts as a shallow, unconfined aquifer, while a deep aquifer exists within the basement rock profile (saprock and fractured bedrock). The saprolite unit generally acts as an aquitard between the shallow and deep aquifers.

Waste Management Plan

The presence of sulfides in the host rocks to the GGM gold mineralization necessitated a set of waste management procedures be developed prior to commencement of mining to ensure effective waste rock storage facility (WRSF) design and correct placement of reactive (PAF and metal leaching) waste to minimize and manage AMD as outlined in Scott et al, 2014. These procedures included:

- Waste rock and tailings characterization using acid base accounting (ABA), metals analysis, and kinetic testing of representative waste rock and ore;
- Construction of the geological model of the waste;
- Block modelling of waste rock and merging with the ore resource model;
- Validating the waste model using in-pit geological mapping;
- Selective handling and placement of waste in designated areas of the WRSF and the NTSF embankments;
- Validating placement of waste within the WRSF and tailings dam embankment;
- Monitoring for success of placement using piezometers within the WRSF, tailings embankment and downstream of these facilities;
- Regular technical reviews monthly (internal), three to six monthly (external);
- Implementing these procedures for LOM.

The WRD design facilitates PAF encapsulation, with a NAF base layer 10-20 m thick, PAF placed in the middle of each dump lift, and an outer NAF layer between 80 and 100 m on each dump lift to complete the encapsulation. The basal layer is constructed by paddock dumping and then worked with a dozer to form the flattened base layer. Tipping of PAF material within the internal part of the dump is commonly undertaken by paddock dumping and worked continually by dozer to form the dump lift. Tipping of NAF material to form the outer layer is usually done at 35-37° batter angle depending on type of material (oxides to fresh), interspersed with 36 m wide berms at 20 m vertical increment lifts and the final batter angle is <20°.

METHODOLOGY

To verify the hypothesis, that a cover system and landform design that resulted in an average net percolation rate of 10-15% and a reduction in erosion would meet GGM's closure objectives, a number of studies were undertaken, including:

- Site visit and material characterization (geotechnical and geochemical);
- Surface and groundwater quality data assessment; and
- Soil-plant-atmosphere modelling, seepage and solute transport modelling, erosion modelling, and landform evolution modelling.

Site Visit and Material Characterization

A site visit and material sampling program was conducted at GGM in the fall of 2012. Samples of waste rock, tailings, topsoil, and laterite borrow material were sampled both for geochemical and geotechnical characterization. Material samples were sent to laboratories in both Australia and Canada for further detailed testing. The material characteristics were used refine the conceptual model and were used to develop input parameters for the numerical modelling. The geotechnical parameters measured were particle size distribution, gravimetric water content, Atterburg limits, specific gravity, saturated hydraulic conductivity, and the water retention curve. The geochemical testing included acid base accounting, metals geochemistry, and short-term leach testing.

Surface and Groundwater Quality Data Assessment

A review and compilation of the water quality monitoring data collected by GGM for the three distinct mining areas within the GGM licence area was undertaken to provide background in regards to water quality, hydrology, hydrogeology, the effects of AMD, and hence the information for a holistic approach to AMD management at the GGM.

Two mine pits (Matandani and Kukuluma) that have ceased operation and are filling with groundwater are impacted by AMD and contain significant acidity and metals. Downstream of WD7 and WD9 (Kukuluma/Matandani) the chemical signature is Ca, Mg, and HCO_3 dominated. This is typical of the background chemistry in the area indicating WD7 and WD9 are not significantly acid forming.

Another significant source of AMD is the toe seep derived from WD1 (SW37/SW37a). Treatment of the seep was implemented in 2010 and monitoring results suggest that water quality in the area has improved in recent years, which is represented by a drop in sulfate and TDS concurrent with an increase in pH.

The NTSF that was commenced in 2000 shows that a change in water quality has occurred with time for key indicators Ca, Na, sulfate, alkalinity, and TDS. While the concentrations for these analytes is above the concentrations recorded for upstream surface water monitoring sites they remain below the GGM discharge standards. Further, the concentrations vary over the year with higher concentrations occurring in the drier months of May to August and lower concentrations occurring in wetter months of October to April, a pattern that has remained consistent since 2005. The chemical signature of groundwater upstream and downstream of the NTSF is dominated by Na, K, Ca, Mg, SO_4 and HCO_3. Below the NTSF increases in sulfate concentration in groundwater occurs locally. Concentrations are below GGM discharge standards.

There are no surface water data for upstream of the WD1 facility, but it is expected to be similar to surface water quality upstream of the NTSF. Below WD1 surface water is low in major cations, chloride, sulfate and metals; above concentrations in waters upstream of the TSF; but below GGM discharge standards. Monitoring data for groundwater upstream of WD1 are not available; however, the chemical signature upstream of WD1 is expected to be similar to that upstream of the NTSF i.e. dominated by Na, K, Ca, Mg and HCO_3. Downstream of WD1 the groundwater is dominated by Ca and HCO_3, which suggests WD1 has minimal influence on groundwater.

Further down gradient, the groundwater compliance monitoring point has a similar chemical signature to the upstream NTSF suggesting WD1 has a minimal effect on groundwater chemical composition. Although it should be noted that the meq/L concentration at the groundwater compliance site is double the upstream NTSF concentration. Further down gradient, the surface water compliance monitoring point chemical signature is dominated by Na, K, Ca, and SO_4. This is consistent with influence from both the NTSF surface and groundwater.

From the data set available, the Star and Comet area appears to have been affected by artisanal workings, although the water quality appears to be improving. The Star and Comet groundwater has a chemical signature dominated by Ca and HCO_3. The surface water chemical signature is similarly dominated by Ca, Na, K, and HCO_3. This suggests mining at Star and Comet has a relatively minor effect on chemical signature.

Overall there is relatively little exceedance of discharge limits in groundwater across the GGM site. Sites that have generated AMD (including the Kukuluma Pit and Matandani Pit; and the toe of WD1 (SW37) up to 2011) have historically exceeded compliance limits for a number of trace metals, however ongoing data may show these metals are now compliant. Most other sites show evidence of sulfide oxidation in either elevated sulfate concentration and/or elevated Fe, Al, or trace metal concentrations. However typically these sites are circum neutral pH with relatively low acidities possibly driven by Fe^{2+} or residual Al.

Source-Term Development

Source terms were developed for sulfate (SO_4), chloride (Cl), and fluoride (F) as conservative analytes for modeling purposes. They were derived from results from short term leach tests on samples collected from WD1 and the new tailings storage facility as part of this study as well as from comparison with surface and groundwater monitoring data from 2000-2012. The waste materials were divided into three types for the development of source terms: WD1 NAF waste rock, WD1 PAF waste rock, and new tailings. Source terms for the waste materials, as well as discharge limits defined by the Tanzania Bureau of Standards (2006), ANZECC (2000, 2011), and GGM, are shown in Table 1.

Numerical Modeling Assessments

Numerical modeling tools were used to verify the conceptual model of the site and to evaluate various cover system and landform designs for the waste storage facilities. The evaluations included soil-plant-atmosphere modeling, seepage and solute transport modeling, and erosion and landform evolution modeling.

Table 1 Summary of source terms and water quality guideline values used in modeling.

Source	Sulfate (mg/L)	Chloride (mg/L)	Fluoride (mg/L)
WD1 – NAF Waste Rock	276	59	0.65
WD1 - PAF Waste Rock	960	59	0.65
Tailings - Base Case	588	41	0.65
Tailings - Elevated Sulfate	1590	41	0.65

Source	Sulfate (mg/L)	Chloride (mg/L)	Fluoride (mg/L)
Guideline Values			
ANZECC – Livestock	1000	n/a	2
ANZECC – Drinking water (health)	500	n/a	1.5
GGM discharge standards (Tanzania)	500	200	8

Cover Design Conceptual Model

A spectrum of achievable net percolation (NP) rates using a cover system was developed for GGM based on available materials and quantities, the vegetation potential, the local climate, and the landform. Four levels of NP rates were developed for the conceptual categories of "very low", "low", "moderate", and "high" NP. Table 2 summarizes these four levels, as well as the conceptual cover system designs that are anticipated to achieve each NP level at GGM.

The locally-available borrow materials at GGM are a laterite material (which is highly variable). Based on laboratory measurements, an appropriately-compacted layer, utilizing the laterite materials that contain a higher clay percentage, could achieve a saturated hydraulic conductivity (k_{sat}) of ~5 x 10^{-6} cm/s. A non-compacted layer of laterite material could achieve a k_{sat} in the range of 5 x 10^{-3} to 1 x 10^{-5} cm/s and act as a growth medium and to achieve store-and-release of infiltrating water.

Using a cover consisting of 0.3 m of compacted laterite overlain with a 0.5 m thick layer of non-compacted laterite, a low net percolation rate of 10% of mean annual rainfall could likely be achieved. Alternatively, using a cover consisting of a layer of non-compacted laterite between 0.5 m and 1.0 m thick, a moderate net percolation rate of 15% of mean annual rainfall could likely be achieved. The conceptual model assumes that water will be managed on the plateaus and slopes to prevent erosion and that there will be upland diversion to prevent upland water running onto the landform.

The production conceptual model assumed for AMD generation from the waste materials was a direct linear relationship between solute loading at the base and net percolation rate at the surface (i.e. a constant concentration model). The source terms developed based on the surface and groundwater quality assessment (Table 1) were used to complete the conceptual model for GGM.

Table 2 Spectrum of achievable net percolation (NP) rates for conceptual cover system design options for the GGM waste storage facilities.

NP Level	NP (%)	Conceptual Cover System Design	
		Plateau Areas	**Batter Slope Areas**
Very Low	< 5%	Geosynthetic product or 0.3 m compacted clay (10^{-7} cm/s) and 0.5 m non-compacted growth medium	0.3 m compacted clay (10^{-7} cm/s) and 0.5 m non-compacted growth medium

Low	5 to 10%	0.3 m compacted laterite (≤ $5x10^{-6}$ cm/s) and 0.5 m non-compacted laterite	0.3 poorly-compacted laterite and 0.5 m non-compacted laterite
Moderate	15 to 20%	0.5 non-compacted laterite	0.5 non-compacted laterite
	10 to 15%	1.0 m non-compacted laterite	1.0 m non-compacted laterite
High	>20%	<0.5 m non-compacted laterite	<0.5 m non-compacted laterite
	25 to 35%	Uncovered waste rock or tailings	Uncovered waste rock or tailings

Soil-Plant-Atmosphere Modeling

Soil-plant-atmosphere modeling using VADOSE/W was completed to confirm the conceptual model; in particular, this assessment was used to predict performance (in terms of net percolation) of various cover system designs for the waste materials. A 100-year climate database and estimates of key vegetation characteristics were developed for the modeling program. Material characteristics were developed from the results of the geotechnical characterization program.

The results of the soil-plant-atmosphere modeling confirmed the conceptual spectrum of cover performance shown in Table 2. The modeling indicated an improvement in performance when the non-compacted laterite thickness was increased from 0.5 m to 1.0 m but showed performance levelling off for thicknesses greater than 1.0 m. This result was due to the higher available water holding capacity in the thicker cover layer and greater volumes available for evapotranspiration (but this benefit tapers off in thicker layers when the water gets too deep for roots). The modeling also showed an increase in performance on the slopes for all cover types due to increased runoff rates. Thus a coarser-textured material could be used on the slopes, if required for erosion control, and performance of 10% net percolation could still be expected.

Seepage and Solute Transport Modeling

Both 3-D and 2-D seepage and solute transport modeling programs were completed to confirm the hypothesis that a cover system resulting in a net percolation rate of 10%, together with the assumed source terms and constant concentration production model, would reduce solute loading at the downstream receptors to below discharge limits.

A risk assessment conducted for GGM in 2012 highlighted an area of the main Geita Mine site including WD1, the NTSF, the OTSF, and the Mtakuja River as an area of highest risk owing to the potential for AMD from the waste storage facilities and their close proximity to surface water. This area is known as the Geita Triangle and was a particular focus for the 3-D seepage and solute transport investigation. The 3-D modelling of the Geita Triangle area was developed using the model Hydrogeosphere (HGS) (Brunner and Simmons, 2012).

The key outcomes from the seepage and solute transport analysis were to understand the long-term concentrations of solutes at the compliance points under various rehabilitation scenarios. An analysis of the dilution of solutes in the Mtakuja River was also completed to help inform on future diversion of water between the Nyankanga Pit and the river.

Six different solute transport scenarios were simulated with the 3-D model using the source terms shown in Table 1. Only the results of one scenario are presented in this paper: Scenario #1 used a

weighted average sulfate concentration of 500 mg/L (40% PAF (960 mg/L) and 60% NAF (276 mg/L)) applied to the entire WD1 and a sulfate concentration of 588 mg/L applied to the NTSF tailings, which was considered the base case. Source terms were applied to the waste materials as constant concentration values for the full 2000-year simulation as a conservative assumption. Each solute was evaluated to determine if water quality guidelines or discharge standards were exceeded at Mtakuja River, GW29 or GW56 (groundwater compliance locations). Figure 1 shows the predicted sulfate concentration plume 100 years post-closure for (a) uncovered and (b) covered (10% NP) (b).

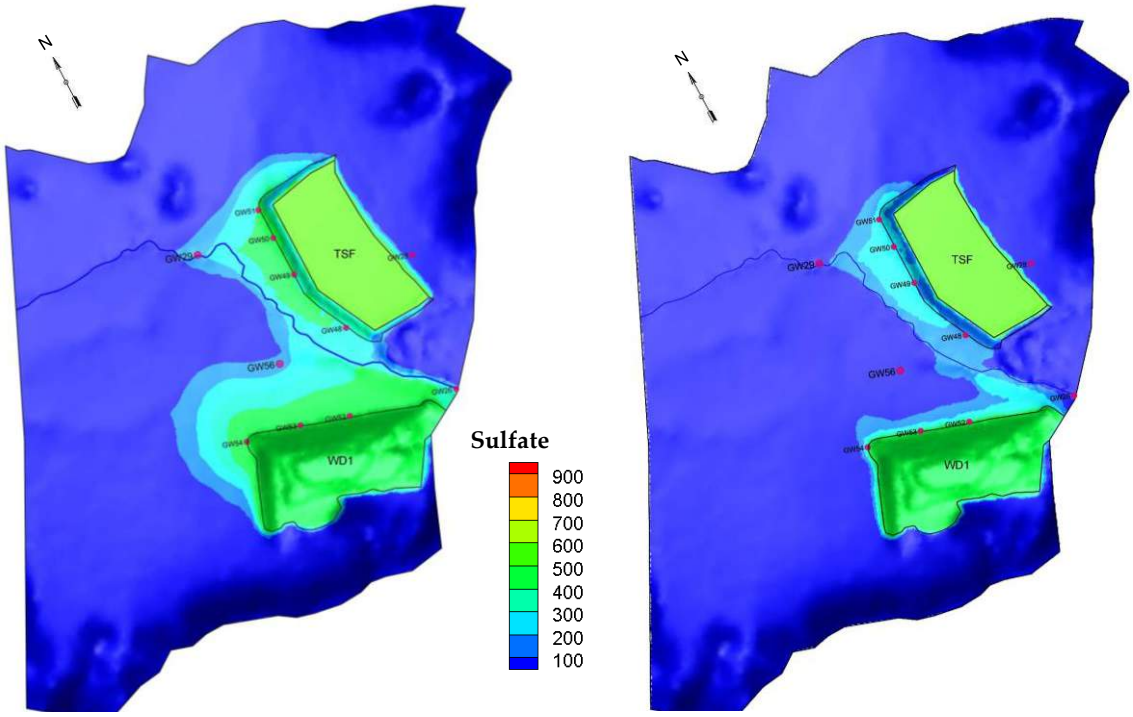

Figure 1 Predicted sulfate plume within Geita Triangle 100 years post-closure for (a) uncovered and (b) covered with net percolation of 10%. Groundwater compliance points GW29 and GW56 shown as well as Mtakuja River (surface water compliance).

Applying a cover system with an average NP rate of 10% is shown to significantly decrease the extent of the contaminant plume that develops from WD1 and the NTSF. Concentrations were predicted for the Mtakuja River based on the above model results. The mass loading predicted to report at the river included the predicted steady-state mass loading to the river from groundwater, WD1 and NTSF toe seepage, and upstream loading from the river. The Mtakuja river flow rate required to dilute loading to the river below the sulfate discharge standard (500 mg/L) for various NP rates was estimated. River concentrations were estimated for high and low river flow rates of 670 L/s and 50 L/s (based on both measured and estimated river flow rates). With high river flows (670 L/s), predicted sulfate concentrations in the river are diluted well below GGM discharge standards for all cover system scenarios. There is potential for river concentration to exceed GGM discharge standards if river flows are low (50 L/s) and cover system NP rates are 15% or higher,

indicating that the cover system and landform for WD1 and NTSF should reduce net percolation to 10% or less.

Erosion and Landform Evolution Modeling

Landforms at GGM are (generally) prone to erosion, owing to the local climate, the abundance of erodible lateritic soils, the presence of relatively steep landforms and the absence of water management structures in some locations. Erosion modeling and landform evolution modeling were conducted on various slope configurations for GGM's waste facilities to evaluate if the proposed mitigation measures would result in landforms that were safe, stable, and would meet expectations for business development opportunities. The main tools and information used in these analyses included LiDAR survey of the landforms, aerial imagery (Google Earth), the SIBERIA landform evolution model, the Water Erosion Prediction Project (WEPP) model, and material laboratory analysis results. A detailed discussion of these analyses can be found in Dobchuk et al. (2013) and Kemp et al. (2014).

Based on the results of the analysis conducted for this project, recommendations were made for a cover and landform design for each of the waste rock and tailings landforms at Geita Gold Mine (GGM) using a combination of specific strategies including:

- Re-vegetation strategies (seeding etc);
- Modification of soils to include a higher proportion of coarse NAF waste rock materials;
- Provision of drainage and bunding, especially to prevent plateau overtopping;
- Resloping the tops of each bench, during dump construction, towards a hard landform (natural hillslope) to direct surface water away from the crest areas of each lift; and
- Re-shaping landforms to profiles that resist erosion (final benched landforms on the outer slope of the waste rock dump are not recommended, linear or concave landforms are preferable).

DISCUSSION AND CONCLUSIONS

The project described in this paper was initiated to develop mitigation methods for the waste rock and tailings storage facilities at Geita Gold Mine (GGM) that would result in GGM meeting or exceeding their stated reclamation objectives including the creation of stable landforms and the reduction of solute loading from the waste storage facilities to meet discharge standards at the downstream compliance points. The conceptual model was that a cover system and landform design using the locally-available laterite material would reduce net percolation to a moderate level (10-15% of mean annual rainfall) and that this would be sufficient to reduce the solute loading at the downstream receptors to below discharge standards. This design was verified based on the results of the material characterization, the surface and groundwater quality assessment, and various numerical modeling analyses.

Based on the site visit and the results of the surface and groundwater quality assessment, it was determined that the PAF waste encapsulation as part of the GGM waste management plan was acting to reduce exposure of the PAF waste to oxygen and water and was leading to a reduced contaminant load to downstream receptors (versus non-encapsulated waste). The placement methodology, with trafficked layers of laterite material on top of each lift and the paddock-dumped base and PAF layers was likely acting to reduce the vertical infiltration of water and the advective movement of oxygen through the waste rock via preferential flow paths. Thus, with a lower

potential contaminant load within the waste facility, a cover system with only low to moderate reduction in net percolation (NP of 10-15%) was shown to be sufficient in reducing the solute concentrations at downstream receptors to below discharge limits. The cover system and landform design that met these requirements was also shown to be feasible using the locally-available laterite materials with only slight improvements to the landform design to increase stability—leading to rehabilitation options that were cost effective.

ABSTRACT

Mining in permafrost regions of Canada has increased due to the rich natural resources, the offer of increased employment and revenue for the local people. However, Acid Rock Drainage (ARD) is also a major concern for the environment in the permafrost regions that are also being impacted by climate change and other industrial activities. In continuous permafrost regions, cold temperature provides an exceptional means to limit ARD using permafrost encapsulation of reactive waste rock. Oxidation of sulfide minerals in reactive waste rock decreases significantly in a sub-zero temperature environment, in addition, water in a frozen state limits transport of reactants and contaminants.

In this paper, thermal simulations of a full-size waste rock pile constructed in a continuous permafrost region with a Mean Annual Air Temperature (MAAT) of -9.1 °C are examined. Different cover thickness and climatic effects such as wind speed and warming air temperature are evaluated to determine their influences on the internal temperatures of the reactive waste rock stockpile. Under a warming of 5.6 °C/100 year, without a cover, the active layer in the waste rock is around 6 m, 5 m and 4.2 m at 10 %, 20 % and 30 % volumetric moisture content, respectively, after 100 years. However, with the pile covered by layers of 1.5 till and 3 m of a non-reactive rock, the active layer penetrates 3.3 m into cover layers after 100 years under this warming condition. At a permeability of the pile of 10^{-8} m^2, an average wind speed of 20 km/h has insignificant effects on thermal transport near the centre of the pile.

INTRODUCTION

Mining involves the removal of significant quantities of waste rock to reach ore bodies and this waste is usually placed in engineered stockpiles. The stockpiles are often well above the water table; therefore they are generally unsaturated. In addition, waste rock usually contains some amount of sulfide minerals and the oxidation of sulfide minerals has the potential to produce acid rock drainage (ARD). Acidic drainage (low pH), high dissolved metal contaminants and other harmful components in leaching water from waste rock are a major concern for the receiving environments at and nearby the mine (Olson et al., 1979; Nordstrom and Alpers, 1999; Lefebvre et al., 2001). Based on the closure objectives of waste rock piles at a mine, engineered soil covers can be designed for different types of waste rock and they can be grouped into (MEND1.61.5b, 2010): "isolation covers", "barriers covers", "store and release covers", "water covers", and "insulation covers". However, in cold regions, cold temperatures are known to slow chemical and biological processes that are responsible for the oxidation of sulfide minerals and thus limit the generation of ARD (Jaynes et al., 1984; Langman et al., 2014). Therefore, to promote permafrost aggradation into reactive waste rock placed in a continuous permafrost region, insulation covers are a candidate as they transmit significant amounts of heat during the winter months and they serve as an insulation layer during the short summer (Arenson and Sego, 2007).

However, if climate change and warming occur, increasing air temperatures, changes of snow cover thickness and distribution, precipitation and other processes will significantly alter the subsurface thermal regime. The equilibrium between air temperatures and ground temperatures will change and cause a gradual increase in ground temperatures. The effects of warming in continuous permafrost regions would be a thickening of the active layer (the layer undergoing freeze and thaw near the surface) as a result of increases in temperatures. The impacts of warming would be more severe in discontinuous permafrost regions: such as thawing permafrost causing slope instability and loss of bearing capacity of infrastructure in these regions (Esch and Osterkamp, 1990). If a waste-rock pile is placed in a discontinuous permafrost area, the increase in ground temperatures due to warming could trigger the oxidation of sulfide minerals causing ARD. Various methods have been used to protect the underlying permafrost and to overcome the potential global warming in buildings and infrastructure,. These methods can also be used in waste-rock piles. Methods such as: ventilation pipes or ducts, thermosyphons and thermal piles, natural air convection embankments, foam insulation and other artificial ground freezing techniques (Goering and Kumar, 1996; Andersland and Ladanyi, 2004; Arenson and Sego, 2007).

SITE DESCRIPTION

The Diavik Diamond Mine is located on East Island, a 17 km^2 island in Lac de Gras, approximately 300 km northeast of Yellowknife, Northwest Territories in the Canadian Arctic (64°31′ N, 110°20′ W, el. 440 m). The site is located within the continuous permafrost region with an average precipitation of 283 mm including 60 % from snow (Neuner et al., 2013). Based on ground temperature measurements, the permafrost may extend to a depth of around 400 m and the active layer varies from 1.0 m in high moisture content soils to around 5.0 m in bedrock (Hu et al., 2003). Due to the cold and long winter season and relatively high evaporation at the site, water movement is limited to the active layer during the relatively short summer. Therefore, for the purpose of thermal modeling of the subsurface, convection associated with water flow is usually small and neglected; however, convective transport due to air is sometimes significant because of the high permeability of the waste rock.

Depending on the sulfur content, waste rock at Diavik is sorted into: Type I rock (< 0:04 wt % S), Type II rock (0.04 to 0.08 wt % S) or Type III rock (> 0:08 wt % S). Sorting the waste rock was used to classify between acid and non-acid generating waste rock. As a result, Type I rock is non-acid generating, Type II rock is low acid generating and Type III rock is potentially acid generating. At the end of the mine life, about 184 Mt of waste rock will be stockpiled in 60 to 80 m high piles covering about 3.5 km^2. Placement of an insulation cover is a closure concept for the Type II and Type III waste rock, including re-sloping the Type II and III areas to 18.4° (3H:1V) and covering the

stockpile with a 1.5 m low permeability layer of till, and a 3 m layer of Type I waste rock to act as an active freeze-thaw layer (Smith et al., 2013).

In this paper, ground temperatures were obtained using drill holes FD4 (39.8 m depth) and FD5 (77.4 m depth) from the top of full scale Type III waste-rock (Figure 1). Thermistor cables were installed into the drill holes at 5 m vertical spacing and ground temperatures are recorded on a 12 h interval. Ambient air temperature is measured hourly at the Diavik meteorological station, which is approximately 1 km from the waste rock dump. Numerical simulations of thermal transfer within the pile were also run under a predicted temperature warming over the next 100 years

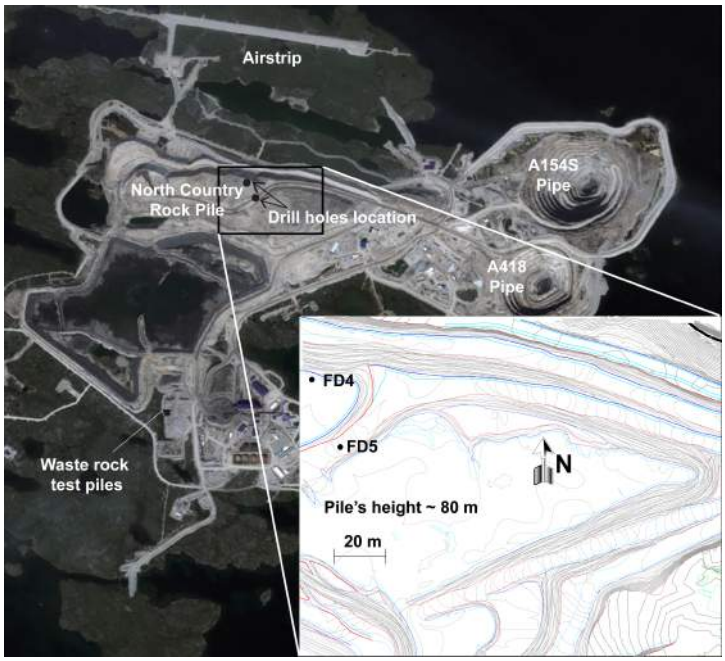

Figure 1 Drill holes location at Diavik diamond mine

Field data in 2013

Figure 2a indicates ground temperatures at depths between 45 m and 77.4 m (both holes) were constant throughout the year between -1.2 °C and -3.5 °C. Based on a thermistor near the ground surface the coldest and warmest temperatures were -28.5 °C and 13.5 °C, respectively. At a depth of 40 m, ground temperatures fluctuated and were much colder than nearby locations, which varied between -9 °C and -14 °C. This response occurs because the pile was built with 40m lifts and therefore permeability of the pile at locations near 40 m depth is higher, due to material segregation during tipping. Figure 2b shows that the thaw depth was at 4.8 m in August and September.

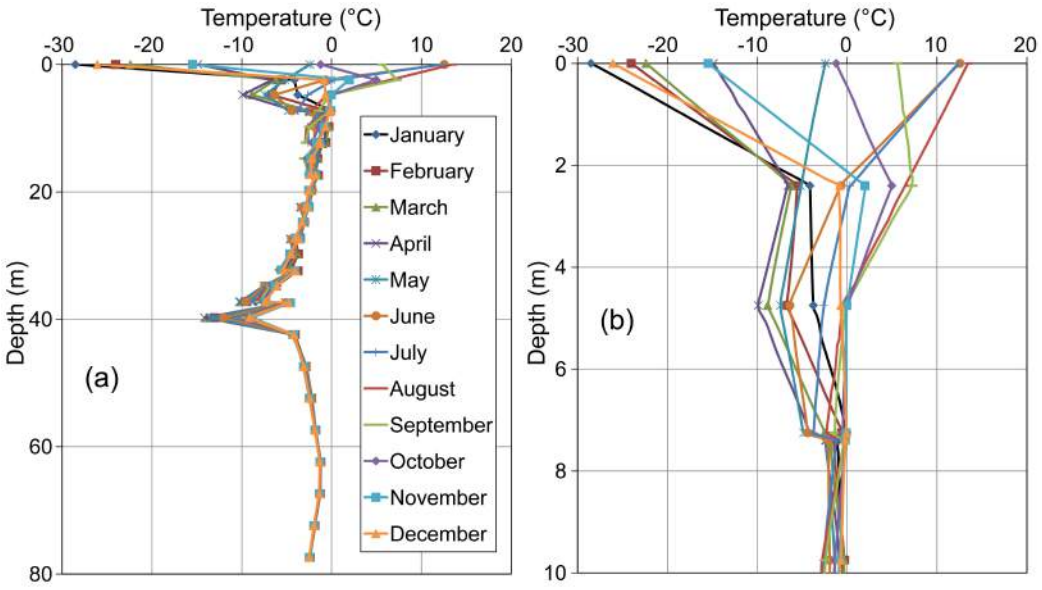

Figure 2 Measured ground temperatures in 2013, entire profile (a) and zoom-in the active layer (b)

NUMERICAL SIMULATIONS

In this section, the governing equations of heat conduction and convection due to moving air associated with density driven and wind effects were solved for temperature within the pile. The commercial Comsol Multiphysics software, which uses the finite element method, was used to solve the governing equations (Comsol, 2008). The mesh of the domain was refined near the surface to capture thaw depth due to the annual variation of air temperature.

Inputs to simulations

One cross section of the pile was chosen for the simulations because it is closely aligned with the dominant wind direction. The cross section is 2.5 km long and 80 m in height and the sides are at 3H : 1V (Figure 3). Furthermore, the bedrock foundation beneath the pile was placed at 100 m depth to complete the domain being analyzed. Air temperature measured at the site varies significantly throughout a year with the warmest and coldest temperatures in July with an average of 11.5 °C, and January with an average of -29.3 °C, respectively (Figure 4). Over the ten year period between 2000 and 2010, the MAAT is -9.1 °C, with 2004 air temperature being the coldest with MAAT of -12.1 °C and in 2010 the warmest with MAAT of -6.7 °C. The values of waste rock properties used in the simulations are listed in the Table 1 (Pham et al., 2013 and Neuner et al., 2013).

The initial in situ temperature profile was obtained using two thermistor cables installed from the top of the pile (FD4 and FD5) (Figure 5). Initial temperatures in bedrock between -15 m and -100 m were set to the same value as at -15 m. Surface temperatures of the pile were determined using measured temperature data from one thermistor near the surface which can be simulated using a sinusoidal function as:

$$T_s = A_s \sin\left(\frac{2\pi t}{365} - 4.34\right) - MAST + \frac{0.056t}{365} = 20.2\sin\left(\frac{2\pi t}{365} - 4.34\right) - 6.2 + \frac{0.056t}{365} \quad (1)$$

where t is time in days with the initial simulation time is January 1st, 2013, $A_s = 20.2$ is the amplitude, MAST (Mean Annual Surface Temperature) = -6.2 °C, which is different than MAAT

due to soil's surface conditions and local climate and the last term represents the predicted potential global warming of 0.056 °C/year (or 5.6 °C/100 years) for the site (Diavik, 2008).

Three scenarios were analyzed to evaluate the thermal behavior of the pile: Scenario 1: the pile was covered with 1.5 m till and 3 m Type I waste rock and no extrenal wind effect is assumed; Scenario 2: wind effects on temperature within the pile without a cover as air advection due to wind may change the thaw depth or active layer within the pile; Scenario 3: the pile without the covered layers and wind effects. All simulation scenarios include the effects of natural air convection, which will occur during winters as cold air sinks into the pile. All simulations were run for 100 years with the volumetric moisture contents of waste rock varying from 10 %, 20 % and 30 %.

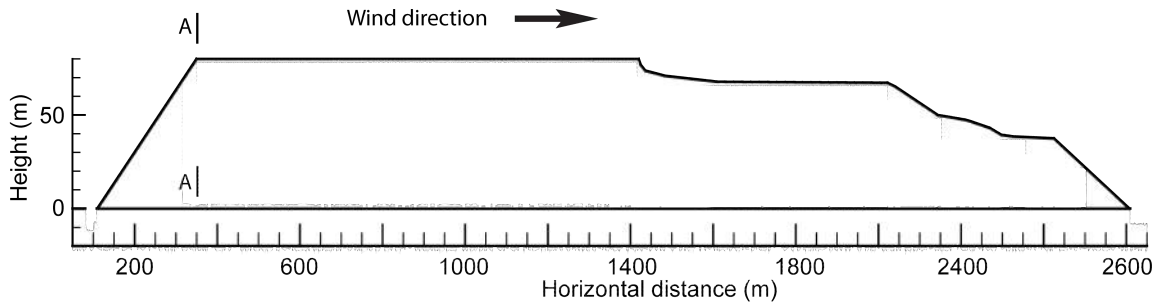

Figure 3 Geometry of the cross-section, the cut A-A is used to show temperature profiles in Figure 9.

Simulation results

Covered with 1.5 m till and 3 m Type I waste rock (scenario 1)

Figure 6 shows that the trumpet curves of ground temperatures at the center of the cross section indicate the waste rock beneath the till layer stays frozen year round. The till layer thaws down about 0.3 m between September and November each year and during the other months the till and Type III waste rock stay frozen (Figure 6). Depths below elevation 65 m are not shown because the temperature profiles remain constant between the elevation 65 m and 0 m. Due to the effects of latent heat in the till cover, ground temperatures in the Type III waste rock beneath the till after 100 years for various moisture contents are similar. Due to the till cover, the results indicate that conduction is dominant within the pile. The calculated pore air velocity beneath the till is on the order of 10^{-9} m/s, which is insufficient to effect heat transfer.

Pile with wind effects and no cover (scenario 2)

In this scenario, wind was assumed to be blowing at steady state at a velocity of 20 km/h, which is a little higher than an average wind speed at the site around 17 km/h (Chi et al., 2013) assuming that future wind speed will increase. Wind direction is from left to right as indicated in Figure 7. Air velocity within the pile was obtained by applying surface pressures around edges and top surface of the pile as boundary conditions. The surface pressures were obtained by solving the simplified 2-D representation of wind flow around the pile (Amos et al., 2009). Figure 7 shows that when using a permeability of waste rock of 10^{-8} m^2 the wind only affects the regions near the leading outer edge of the stockpile. Air velocities within the pile due to wind are also small with an average of about $2 \acute{} 10^{-4}$ m/s in the affected region around the edges.

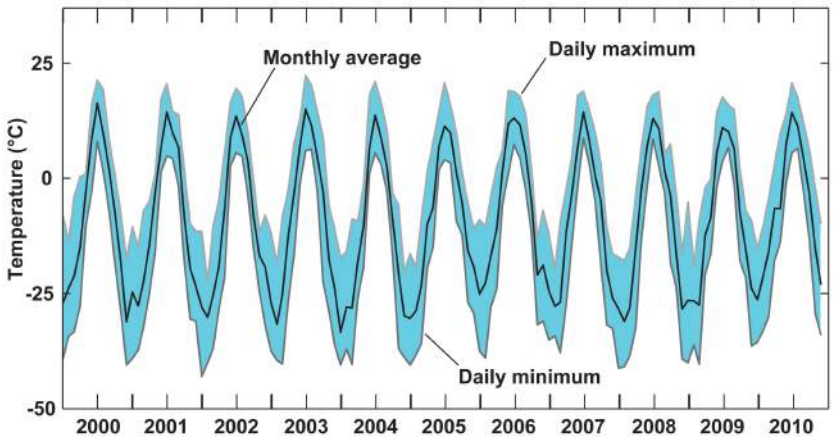

Figure 4 Monthly averaged air temperatures plotted with daily maximum and minimum air temperatures

Table 1 Material properties (data from Pham et al., 2013 and Neuner et al., 2013)

Property	Type I waste rock	Type III waste rock	Till	Bedrock
Porosity	0.25	0.25	0.2	0.003
Thermal conductivity (Frozen / thawed) (W/(m K))	1.7	1.8	3.2 / 2.9	3.0
Frozen bulk heat capacity (MJ/(m^3 K))	2.3	2.1	2.1	2.2
Thawed bulk heat capacity (MJ/(m^3 K))	2.4	2.3	2.5	2.2
Volumetric water content	0.1, 0.2, 0.3*	0.1, 02, 0.3*	0.18	0.0
Permeability (m^2)	10^{-8}	10^{-8}	$5 \cdot 10^{-16}$	0.0

* These values were assumed to examine the effects of moisture on ground temperatures within the pile

At this velocity, the effects of air convection on heat transfer within the pile would be insigficant due to the small specific heat of air. Therefore, the effects of wind on thermal regimes in the pile away from the edges will be negligible. Trumpet curves (Figure 8) show that the active layers are 6 m, 5 m and 4.2 m into the pile for 10 %, 20 % and 30 % volumetric moisture contents, respectively. The shallower active layer at higher moisture content is due to the effects of higher latent heat associated with the additional water. However, at 15 m below the surface, ground temperatures are constant of -2 °C regardless of moisture content.

Figure 9 shows the trumpet curves at 10 % volumetric moisture contents at the edge, 40 m offset and 80 m offset from the edge. The active layers are around 6.1 m and 6.3 m at the edge and 40 m

offset (Figure 9a and b) which are larger than at the centre of the pile (6 m). However, at 80 m offset from the edge at active layer is 6 m and the trumpet curve is similar to that of the centre location (Figure 8a and 9c).

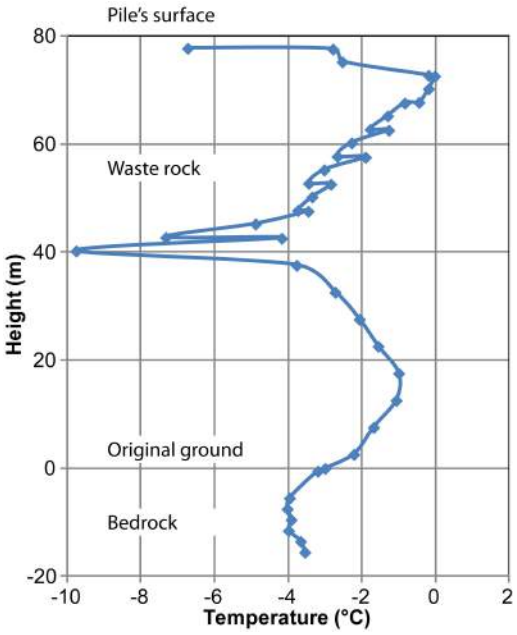

Figure 5 Initial temperature profile used in simulations, which is measured in January 1st, 2013.

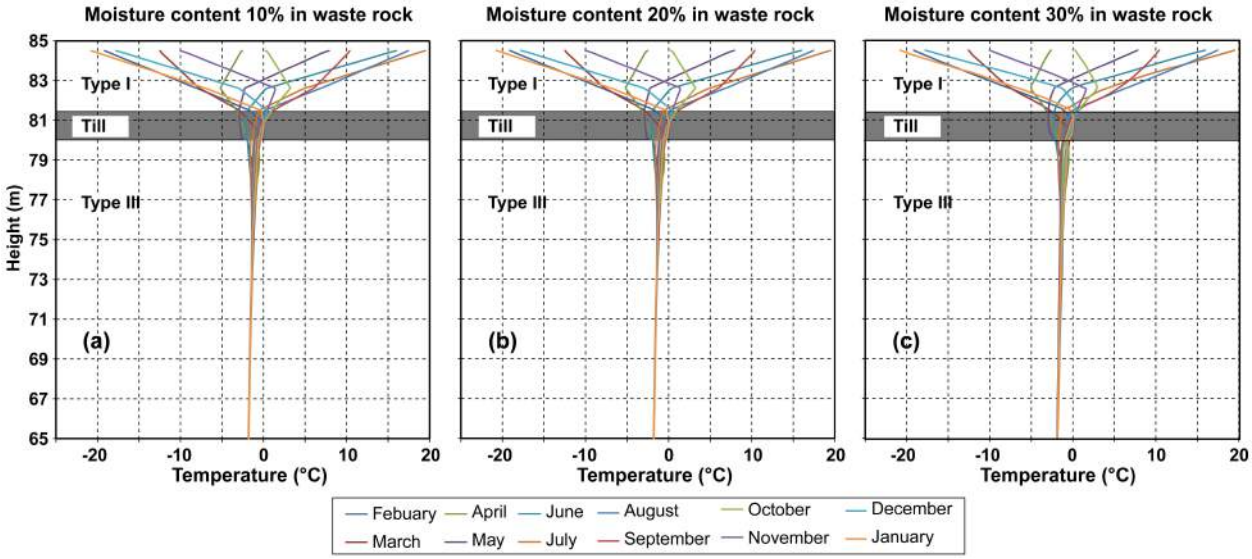

Figure 6 Trumpet curve of temperature profile in the pile for Scenario 1, with cover with 10 % (a), 20 % (b) and 30 % (c) volumetric moisture content in waste rock and no advective wind flow in year 100

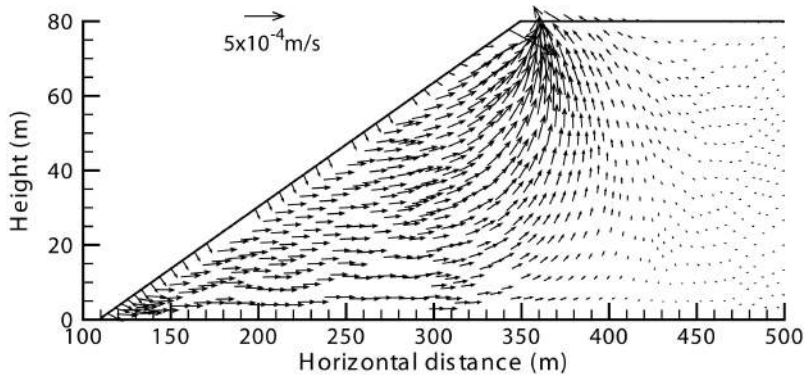

Figure 7 Air velocity within the pile due to wind

Pile without cover and wind effects (scenario 3)

As mentioned earlier, wind affects heat transfer only at the edges of the wind-facing side. Therefore, trumpet curves within the centre of the pile without and with wind effects are similar. The active layers are 6 m, 5 m and 4.2 m for the pile having 10 %, 20 % and 30 % volumetric moisture content, respectively (Figure 10). Figure 11 shows the isotherms during a winter after 100 years with warming and the thermal core with ground temperatures between -2 °C and -4 °C is the greatest in scenario 1 (Figure 11a) and smallest in scenario 3 (Figure 11c). Away from the edge, the thermal regimes between scenarios 1 and 2 are similar (Figure 11a and 11b).

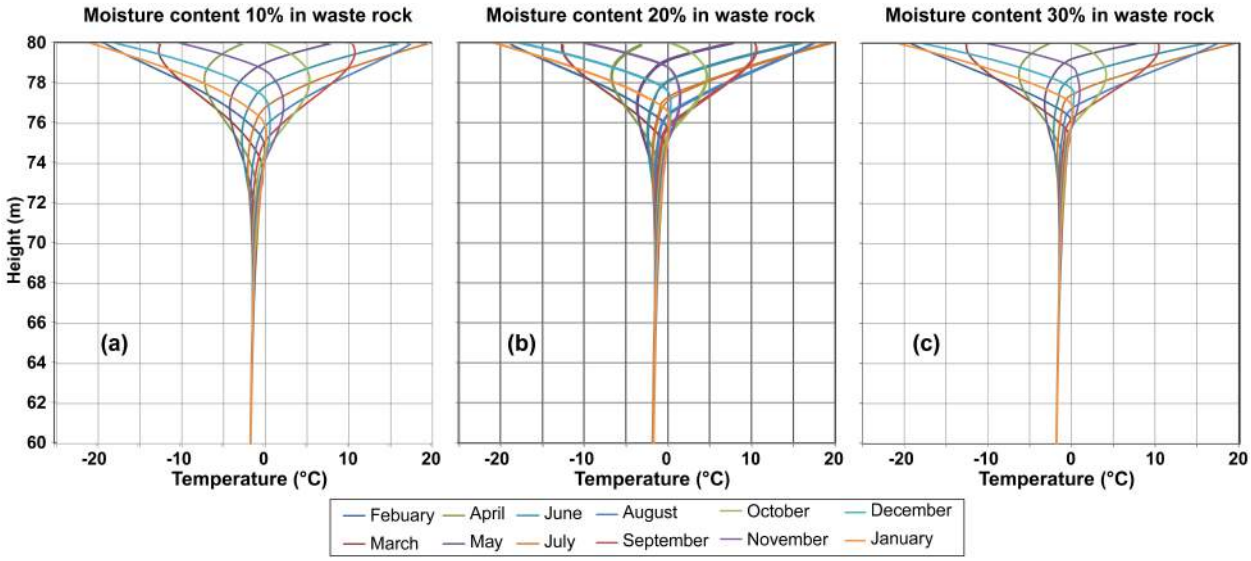

Figure 8 Trumpet curve of temperature profile in the pile for Scenario 2 with no cover, but with wind effects with 10 % (a), 20 % (b) and 30 % (c) volumetric moisture content in waste rock in year 100

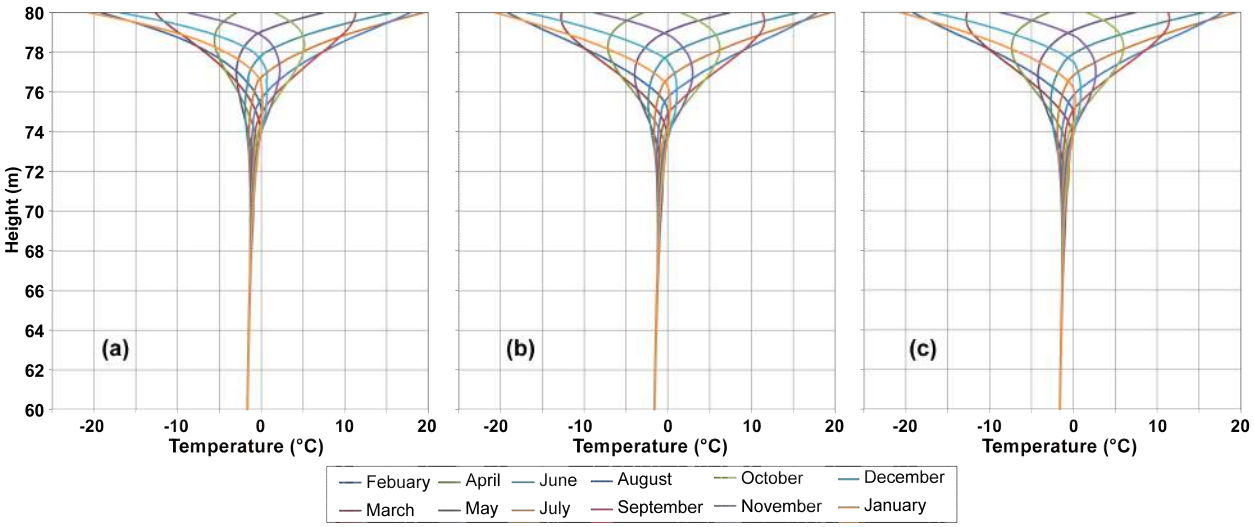

Figure 9 Trumpet curve of temperature profile in the pile with wind effects with 10 % volumetric moisture content in waste rock in year 100 at the edge, section A-A in Figure 3 (a), 40 m offset (b) and 80 m offset (c) from the edge

CONCLUSION

Field temperatures from drill holes on top of waste rock pile indicate that the thaw depth was 5 m in 2013. However, under a warming of 5.6 °C/100 years and with the pile covered by layers of 1.5 till and 3 m of Type I rock, the active layer penetrates 3.3 m into cover layers after 100 years. Without a cover, the active layers will be 6 m, 5 m and 4.2 m at 10 %, 20 % and 30 % volumetric moisture content, respectively. The effects of wind on thermal regimes are insignificant near the centre of the pile. The region near the edge of the pile is affected by the wind with a permeability of the pile is 10^{-8} m^2 and a wind speed of 20 km/h. Therefore, under the predicted warming scenario, oxidation in waste rock may occur within a thin layer of active layer, of up to 6 m in the central portion of the waste rock pile.

ABSTRACT

The prediction of how waste materials will evolve geochemically within waste rock storage facilities (WRSF) has been the subject of many hundreds of thousands of hour's research by geoscientists globally. Despite the quantity of research there are two significant areas of uncertainty that remain as partially resolved issues: (a) the majority of the research carried out has been at the laboratory not site scale (b) many predictions made using computer modelling have not, or are not normally able to be validated from site data.

OKC has had the opportunity to lead two large scale WRSF drilling programs at different sites in Western Australia where 12 historical waste dumps of around 10-30 years in age have been subject to detailed intrusive investigation. This has included approximately 2,000 m of sonic drilling, the recovery and detailed analysis of over 2000 samples of core material and the installation of over 150 sensors at depths between 5-140 m within the waste which have provided over 5 million points of monitoring data.

The extensive data gathered as part of the assessment has allowed OKC to determine the geochemical, hydrological and geophysical evolution of the waste rock facilities as a result of 10-30 years of exposure. This valuable site data has been used to both back test the results of predictive models made for the waste facilities, and to optimise predictive models for future scenarios. In addition the data has allowed the development of scaled up site specific kinetic leach columns.

Keywords: Kinetic testing, geochemical evolution, scale parameters, intrinsic oxidation rate

INTRODUCTION

The prediction of how waste materials will evolve geochemically within WRSFs has been the subject of many hundreds of thousands of hours of research by geoscientists globally. Despite the quantity of research there are two significant areas of uncertainty that remain as partially resolved issues: (a) the majority of the research carried out has been at the laboratory not site scale (b) many predictions made using computer modelling have not, or are not normally able to be validated from site date.

As part of a large scale investigation to improve the understanding of waste rock geochemistry at macro scale OKC has had the opportunity to lead two large scale WRSF drilling programs at different sites in Western Australia. 12 historical WRSFs of around 10-30 years in age have been subject to detailed intrusive investigation. This has included approximately 2,000 m of sonic drilling, the recovery and detailed analysis of over 2,000 samples of core material and the installation of over 150 sensors at depths between 5-140 m within the waste which have provided over 5 million points of monitoring data.

This paper focuses specifically on research carried out on sites within a semi arid climate and waste rock containing sulfidic black shale material taken from mines within the Pilbara in Western Australia.

LABORATORY TESTING AND THE ISSUE OF SCALABILITY

Laboratory testing methods have been developed and refined over many years for geochemistry assessment and AMD prediction which has resulted in a broad set of standardised testing methods being generally accepted internationally by the mine-geochemistry industry. This has been possible by and large because laboratory experiments are completed in a controlled environment with high degree of precision and accuracy. However a common factor and limitation to all laboratory assessments is that the scale at which these experiments are carried out.

Kinetic testing methods offer a good example of the issue of trying to determine how laboratory data should be used to extrapolate from the laboratory (micro) to site (macro) scale. Common kinetic tests such as humidity cells and leach columns utilise a few kilograms of material that has been crushed to a few millimetres in size that are then exposed to wetting and drying cycles with very high leaching rates. The concept of these kinetic tests is that by using small grain sizes and high leaching ratios the weathering processes (sulfide oxidation rates and carbonate dissolution) can be accelerated allowing the assessment of sulfide oxidation rates, acidity generation, neutralisation reactions, and leachate geochemistry to be assessed within a reasonable timeframe. It has been proven that these tests achieve the aim of simulating accelerated weathering. However, the precise method (and value) of how to utilise these results in a scaled up situation, for example in the extrapolation of data to predictions of field conditions such as oxidation rates or seepage quality has not yet been conclusively determined.

Table 1 outlines some scale factors that require consideration when using kinetic test data for "predictions" of field conditions, which will have a significant influence on the ability to predict field geochemical conditions and processes from laboratory data.

Table 1 Scale variables for laboratory kinetic tests compared to field conditions for medium to large size waste rock storage facility (>1 million tonnes)

Scale parameter	Laboratory test conditions	Typical Australian field conditions	Challenges extrapolating from lab to field
Grain size	PSD = 100% <6mm	PSD = 40% <6mm	Oxidation rates faster and dissolution of silicates/carbonates higher for smaller grain sizes. Lab tests may over estimate both sulfide oxidation rates and acidity buffering processes
Geochemical system	Open	Variable from open to closed	Open systems discharge acidity closed systems store acidity, lab tests are not reflective of field drainage geochemistry
Oxygen consumption measurement	Estimate from sulfate release	Estimate from in situ measurement	Using sulfate produced from leaching tests may not provide accurate prediction of oxygen consumption
Mass of material	1-2 kg	>1 Mt	Heterogeneity effects not accounted for in lab tests, bulk geochemistry of material in the field may not be well represented by material tested in the lab
Air flow (Oxygen supply)	Diffusion dominated unrestricted	Advection dominated potentially restricted	Lab tests assumed unlimited oxygen supply, field conditions may vary, generally significantly lower than lab conditions
Temperature	20-30 degrees	0-100+ degrees	Due to effect of thermal properties by total mass of material, field temperatures may be significantly higher than lab, this can effect geochemical reaction rates
Liquid : solid ratio	8:1 per year	0.001: 1 per year	Lab leachate is more dilute then field conditions due to high L:S ratio. No restriction on sulfide oxidation rates based on H_2O supply in lab, field reaction rates may be H_2O supply limited.

REACTION KINETICS IN CLOSED AND OPEN SYSTEMS: THE SUPPLY OF O_2 AND H_2O AS CRITICAL FACTORS

At the most basic level sulfide oxidation reaction kinetics are controlled by the relative supply of O_2 and H_2O. The commonly stated (simplified) reaction for iron sulfide oxidation in this case pyrite, to form sulphuric acid H_2SO_4 and ferrihydrite $Fe(OH)_3$ is (from Lottermoser, 2010):

$$FeS_2 + {}^{15}/_4\, O_2 + {}^{7}/_2\, H_2O \Rightarrow Fe(OH)_3 + 2\, H_2SO_4 \quad (1)$$

It is important to note that this reaction represents the interaction of O_2 with FeS_2 (pyrite) with H_2O thought to be acting as a catalyst. It is clear then that if either water or oxygen are not present then the reaction will not proceed, the kinetics of the reaction will therefore be determined by the relative supply of both. Lottermoser (2010) states that *"there is little consensus in the literature on the precise reaction mechanisms describing the oxidation of pyrite"*. Therefore it is not clear how the varying

supply of O_2 and H_2O will impact the pyrite oxidation reaction kinetics. It is however widely accepted that *"the transport of oxygen to the oxidation sites is considered the rate limiting process in dumps"* Lottermoser (2010). For example from equation (1) 7/2 moles H_2O are required for oxidation of 1 mole of FeS_2. However, in field conditions reactions take place in pore spaces of unsaturated waste rock where the pyrite mass is disseminated (at grades of a few percent) through the host rock. As a result this molar ratio of H_2O to Pyrite on a per kg rock mass basis will not be sufficient because at such low water contents the pore waters may not physically be in contact with sulfide mineral surfaces. The supply of O_2 and H_2O is in turn determined by the nature of the geochemical system as open or closed. In an open system there is a potentially unlimited supply of O_2 and H_2O into the system and a means for reaction products to exit the system. These systems are represented by laboratory free draining leach columns. A closed system in contrast is represented by either a restriction of supply of oxygen or water or a restriction on the means for reaction products to exit the system. With respect to field conditions the internal zones of WRSFs can vary between open and closed system conditions, and can often fluctuate between conditions on a seasonal basis.

Supply of H_2O, O_2 and the intrinsic oxidation rate (IOR)

The liquid to solid ratio (L:S) is a convenient way to express the relative supply of H_2O into the system, this simply reflects the weight for weight balance of water against the mass of the porous solid through which the liquid is passing. Free draining leach columns have very high L:S ratios in general, an AMIRA (IWRI and EGi, 2002) column has an annual L:S ratio of approximately 8:1 for example. In contrast WRSFs typically have low L:S ratios and annual ratios in the Pilbara are estimated to be around 0.001:1 (assuming a 40 m high WRSF has 400 mm of net percolation per annum).

Oxygen supply is dominated by the degree of saturation of the pore space within the material, and the process of air movement which can be driven by advective or diffusive processes. Within free draining leach columns the supply of oxygen is driven by diffusion as no advective forcing is applied. In WRSFs the supply of oxygen can be driven by advection or diffusion depending on site conditions. The work of Brown *et al*. (2014) indicates that convection of oxygen accounts for 90% of the oxygen transport into a WRSF and diffusion accounts for 10%. This is close to an order of magnitude difference between the two oxygen ingress processes.

The IOR is the oxidation rate where oxygen is freely available (Bennett *et al*., 1995). It has been reported that based on free draining leach column tests thast the IOR ranged from 1.6×10^{-8} to 3.3×10^{-6} kg $O_2/m^3/sec$ (EGI, 2001) for samples of pyritic shale materials (Mt. McRae shale) sourced form the Pilbara, Western Australia. Levay and Co (2013) report an acidity generation rate of ~1.5 kg H_2SO_4/t/week for a Mt. McRae shale sample having 3.2 wt.% S, which is equivalent to an IOR of 2.5×10^{-6} kg $O_2/m^3/sec$ and comparable to the EGi (2001) work.

Because an IOR of 2.5×10^{-6} kg $O_2/m^3/sec$ has been calcualted form a free draining leach column then it is assumed that given an unresticted oxygen supply that this is the minium oxygen requirement for the pyrite oxidation reaction not to be rate limited. On the same basis the amout of H_2O required for the reaction to not be rate limited can also be calculated. Based on reaction (1) and the produciton of 1.5 kg H_2SO_4/t/week requires a minmium of approximately 0.5 kg t/week of H_2O, which can be converted into an L/S ratio of 0.026 per year. Clearly given the L:S ratio is 8:1 in

column tests then there is a significant excess of H_20 for pyrite oxidation not to be rate limited, in fact there is approximately 300 times excess H_2O. It should be noted that the use of such excess H_2O in these tests will inevitably result in significant dilution of leachates, that is to say leachate strengths are unlikely to be representative of field conditions. For materials with low sulfide contents this is likely to be of particular concern as these tests will tend to significantly underestimate the concentration of contaminants of AMD leachates in the field

It is widely accepted in the industry that laboratory column leach tests and similar field based lysimeter trials provide elevated reaction rates compared to the field (Miller *et al*., 2003; Andrina *et al*., 2012). For example the calculated IOR for waste rock was an order of magnitude lower in trial dump experiments compared to a 500 tonne trial and lab columns in the work of Andrina *et al*., 2012. Most importantly, Andrina *et al*. (2012) notes that the trial dump was often well oxygenated with oxygen content often at 20%, which is comparable to atmospheric concentrations. Based on these studies when oxygen is generally freely available it may be proposed that the laboratory based IOR can be reduced by an order of magnitude due to scaling effects, which, for the purpose of this report is referred to as Laboratory to Field Conversion Factor (LFCF). However, as demonstrated by Table 1 there are many scaling effects that may impact the determination of field IOR rates, in addition the method of estimating IOR from sulfate production in these tests is subject to a degree of error that may be significant depending on the geochemistry of the situation.

WEATHERING PRODUCTS OF PYRITE OXIDATION: GEOCHEMICAL CONSIDERATIONS

Although a simple summary equation to represent the oxidation of pyrite (Equation 1), the weathering of metal sulfides in the environment do not often progress as shown in the direct production of H_2SO_4 and $Fe(OH)_3$. This is because interaction of the H_2SO_4, Fe^{x+}, H^+ or SO_4^{2-} with H_2O and O_2 results in the formation of many different compounds which are often meta-stable in the surface environment. Further interaction with H_2O and O_2 can occur depending on the pH/Eh of the geochemical environment. This simplified model of pyrite oxidation does not tell the whole story. Sulfide weathering has the potential to release all the acid 'potential' by the precipitation of hydroxides and oxides such as goethite or ferrihydrite:

$$Fe^{3+} + 3H_2O = Fe(OH)_3 + 3H^+ \quad (2)$$

This process does not store H^+ as stored metal acidity and releases maximum acidity. Hudson and Edwards *et al.* (1999) point out that even low concentrations of SO_4^{2-} in solution can suppress the formation of Fe hydroxides, and instead favours the formation of oxyhydroxysulfates. This alternative is the storage of acidity in secondary salts, which are only stable in oxidising acidic pH conditions. For example in the formation of jarosite:

$$3Fe^{3+} + K^- + 2SO_4^{2-} + 6H_2O = KFe_3(SO_4)_2(OH)_6 + 6H^+ \quad (3)$$

Often there is incomplete oxidation of the ferrous (Fe^{2+}) iron to ferric (Fe^{3+}) iron and ferrous salts such as melanterite, $FeSO_4$ (Equation 4) can form, which following any subsequent wetting can release the stored ferrous acidity (Equation 5). These acid salts are highly soluble.

$$FeS_2 + 7/2O_2 + H_2O \circledcirc FeSO_4 + SO_4^{2-} + 2H^+ \quad (4)$$

$$FeSO_4 + 1/2O_2 + 5/2H_2O \circledcirc Fe(OH)^3 + 2H^+ + SO_4^{2-} \quad (5)$$

However, if oxidation to ferric iron is complete yet the hydrolysis is incomplete, jarosite type secondary minerals can form. Jarosite type minerals form at pH values below 3.5 and release only $2H^+$ per Fe^{3+} incorporated into jarosite, not the associated $3H^+$ ions associated with complete Fe hydrolysis. Thus jarosite type minerals store acidity that can be released once pH increases (Equation 6). Jarosite is stable at pH values < 4 and above pH 4.7 it is soluble, dissolving slowly (Li et al., 2007), which has long term implications for the rebound of pH to circum-neutral conditions after sulphide exhaustion and/or for the treatment of AMD impacted waters.

$$KFe3(SO_4)2(OH)^6 + 3H_2O \circledcirc 3Fe(OH)^3 + 3H^+ + 2SO_4^{2-} + K^+ \quad (6)$$

The acid load associated with the dissolution of ferrous salts such as melanterite will occur immediately upon wetting. The precipitation and dissolution of these sulfate bearing minerals will exert a significant control on the sulfate produced in leachates and therefore the ability to accurately predict IOR rates from laboratory leaching experiments.

In semi-arid environments the precipitation of these secondary sulfate minerals as a result of low L:S ratios may therefore be a significant factor in determining how much acidity is released from the WRSF.

OPEN AND CLOSED GEOCHEMICAL SYSTEMS

Table 2 outlines the importance of consideration of the geochemical system being studied as open or closed. Laboratory methods are open systems and will generally have unlimited oxygen supply and very high L:S ratios so oxidation reaction rates are not rate limited. In addition these conditions will limit the potential storage of acidity as secondary sulfate minerals, which will also result in high output of dissolved phase oxidation reaction products. Field conditions in comparison represent a variable state system which may have a seasonal aspect as the system ranges from open to a closed state. It should be noted that contrary to widespread belief oxygen supply can still represent an unlimited condition in WRSFs as a result of advective air movements in coarser zones of waste. Whereas in semi-arid environments the supply of H_2O is likely to be the limiting factor with respect to formation of an open system due to low L:S ratios.

Table 2: Open and closed systems

Scenario	System	Oxygen supply	H_2O supply	Storage of acidity as meta stable minerals	Output of Fe^{2+}, Fe^{3+}, H^+ and SO_4^{2-} in leachate
AMIRA Leach column	Open	Diffusion controlled potentially unrestricted	Unrestricted. Annual LS ratio 8:1	Low	High due to high flushing rates (L:S ration 8:1)
Waste rock prior to "wetting up"	Closed	Advection controlled potentially unrestricted	Restricted: depth variable dependence,	Very high	Low due to very low flushing rates
Waste rock "wetted up"	Open	Advection controlled potentially unrestricted	Limited to net percolation rate, Annual LS ratio of 0.001:1 common	Variable	Variable due to seasonality of flushing rates. Annual L:S ratio of 0.001:1 common

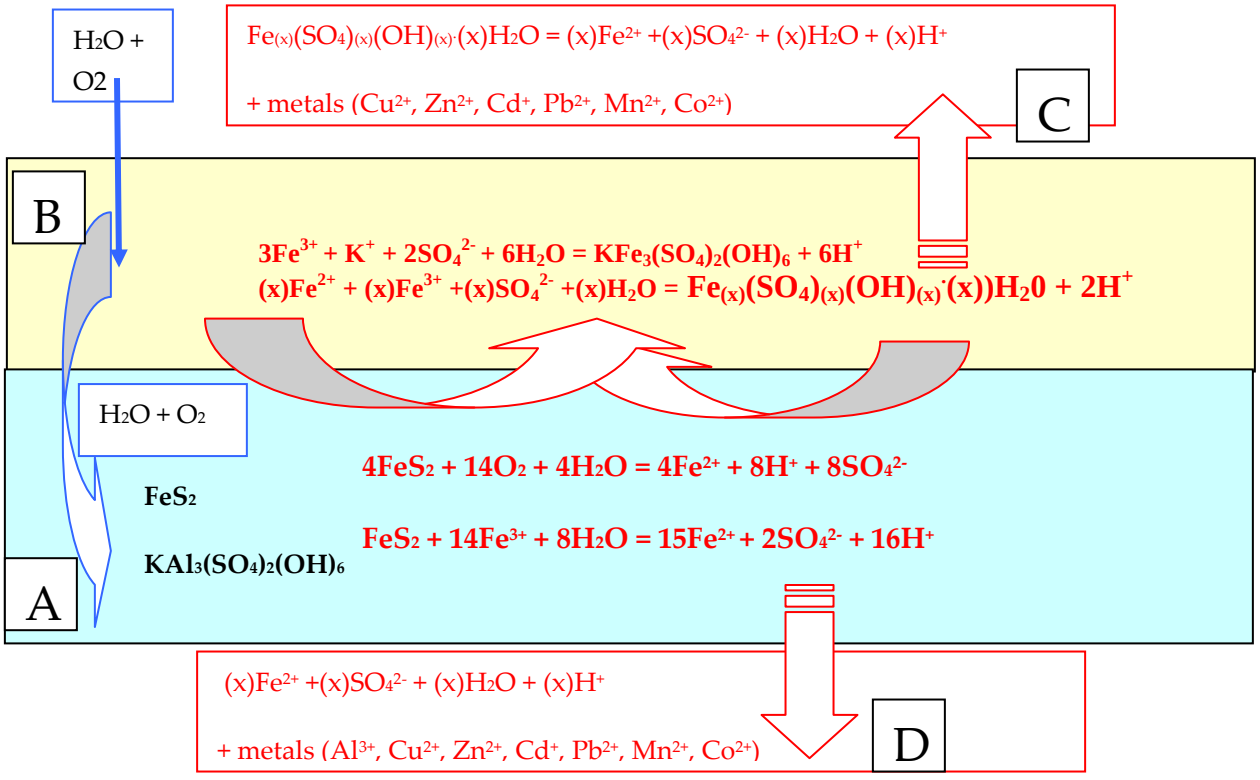

Figure 1 Simplified geochemical model of sulfide oxidation showing open and closed system pathways

Figure 1 shows the simplified geochemical model for initial stages of sulfide oxidation in an open system

- Box A indicates sulfide minerals that are undergoing oxidation in the presence of aluminium and potassium bearing silicate minerals and in contact with an unrestricted supply of oxygen and water resulting in production of Fe^{2+}, Fe^{3+}, H^{+} and SO_4^{2-}

- Box B indicates production of secondary oxyhydroxysulfates on mineral surfaces within pore spaces from dissolved phase species released from Box A. This process is likely to dominate in a closed system where L:S ratios are low and precipitation of these minerals exceeds losses from leachate discharges

- Box C indicates a situation where the precipitated oxyhydroxysulfates dissolve to form Fe^{2+}, Fe^{3+}, H^{+} and SO_4^{2-} and H_2O. This situation is representative of an open system where L:S ratios are high enough to dissolve any secondary minerals present that are soluble.

- Box D indicates the situation where the soluble products from Box A are directly discharged from the system. This is an open situation common to free draining laboratory kinetic tests where L:S ratios (flushing rates) are high. In this scenario secondary minerals (Box B) do not have much chance to form due to high dissolution rates caused by high L:S ratios.

CASE STUDY: INTRUSIVE WRSF INVESTIGATION

The presented study includes 12 WRSFs at various mine sites in the Pilbara, Western Australia. The mine sites are made up of multiple WRSFs which have been constructed by various techniques including end dumping. A proportion of the dumps contain pyritic black shale with some incorporating encapsulation techniques. OKC completed a drilling programme that resulted in 2,000 m of sonic drilling, the recovery and detailed analysis of over 2000 samples of core material the installation of over 150 instruments within 12 WRSFs up to a depth of 100 m. The WRSF monitoring systems were equipped with instrumentation to measure *in situ* moisture, oxygen pore-gas concentrations, pore-water pressure and *in situ* temperature within the WRSFs.

The Pilbara region consists of a climate classified as arid-tropical. Summers last from October to April and mild winters occur from May to September. Sporadic and intense thunderstorms are typical for the region from January to March, and tropical cyclones can result in daily rainfall amounts of up to 200mm over a 24hr period.

Presentation and analysis of the data collected from the instrumentation to date is beyond the scope of this paper and is reported in a separate paper published in Pearce and Barteaux 2014. A summary of the results is provided below which is important for understanding of field conditions within the WRSFs that are driving geochemical conditions:

- Wetting up of the WRSF's is not occurring uniformly throughout the waste. Generally the coarse cobble zones did not match the wetted-up model as moisture contents were lower than expected, whereas the finer textured materials had moisture contents closer to the wetted up model scenario.

- Based on responses of installed instrumentation the internal movement of water is considered to be governed by preferential flow paths predominantly within zones of coarser waste rock particle sizes. Fast responses to rainfall events are noted in these zones through the middle of the WRSFs, which can be tracked to basal zones of the WRSFs.

- The results of moisture content analysis indicates that water content varied between the borehole locations with the majority of results ranging from 3-15% by volume. If the moisture content is assumed to be on the upper end of the estimate at 10% on a mass basis this represents a current static L:S ratio of 0.1.

- Oxygen sensors installed indicate the WRSF's have high internal air flow rates and connectivity which is providing ample supply of oxygen to the whole waste rock profile with oxygen levels of between 16-20% being recorded through the whole profile of the waste in many WRSFs. In general oxygen concentrations increase with depth indicating convective supply source.

- Elevated internal dump temperatures (30-40 ^{o}C), high (and connected) internal air flows and supply of H_2O within preferential zones are postulated to be driving evaporative drying of pore waters which results in the transport and re distribution of water in the gaseous phase within the waste mass throughout much of the profile. This mechanism is considered to comprise a significant means of transfer of H_2O within the WRDs from zones of preferential flow to zones that do not receive much direct net percolation

Given the above observations it may be inferred that oxidation reactions within the WRDs studied may not be O_2 limited, but are more likely to be limited by the supply and movement of H_2O.

Geochemical analysis of drill core supports this conjecture as there is a significant presence of secondary sulfate minerals which are indicative of precipitation of sulfate bearing minerals as a result of stationary pore fluids (and therefore a very low L:S ratios). The geochemical system can therefore be best thought of as semi closed in that oxygen and H_2O (possibly supplied from internal evaporation rather than matrix pore water flow) can enter the waste but very limited leachate leaves the system. This results in a buildup of secondary sulfate minerals. Sulfur speciation results from analysis of black shale samples suggest a high degree of oxidation of sulfides for a large proportion of samples tested. From older WRSFs (30 yrs+) approximately 1500 samples were analysed from 49 boreholes, the average and median percentages of total sulfur that was in the form of sulfate was 80% and 72% respectively. The average proportion of total sulfur present as sulfate was 80%. At higher grades of >1% sulfur the sulfate ratio is slightly lower, around 60% average. It is assumed based on understanding of the mineralogy of the black shale that the material when deposited comprised sulfide as pyrite and little sulfate minerals. It is assumed therefore that the majority of sulfate present as measured represents secondary sulfate minerals that are the result of oxidation of the pyrite.

If it is assumed that the oxidation reactions have been occurring for approximately 30 years and no loss of sulfate from the system has occurred then IOR rates are determined as followed:

- IOR field = 3%S @ 60% oxidation over 30yrs = 0.04 kg H_2SO_4/t/week = 7.5^{-8} kg O_2/m^3/sec
- IOR field = 9%S @ 60% oxidation over 30yrs = 0.1 kg H_2SO_4/t/week = 1.9^{-7} kg O_2/m^3/sec

The field IOR rate calculated is considered a lower bound estimate as reaction rates may have declined with time as a result of fresh sulfide surfaces being smothered by secondary minerals. Laboratory calculated values lie in the range 4.9E-7 to 2.9E-6 kg O_2/m^3/sec. İn general the results of the case study assessment broadly agree with Andrina *et al*. (2012) where an order of magnitude difference in IOR was observed between field and lab IOR rates. It is interesting to note that even with the very low L:S ratios observed in the WRSFs that oxidation reactions have proceeded to 60% or greater completion. If it is assumed based on field monitoring data that oxygen is not the limiting factor, the main causes of the lower obsered field rates are likely to be:

- The impact of restricted water supply and time taken for "wetting up" to occur
- Formation of secondary sulfate mineral coatings around sulfide grains as a result of low matrix pore water flow and leachate "flushing"
- Larger particle sizes than laboratory tests

CONCLUSIONS

The use of laboratory leach column data for field estimates of IOR and seepage quality requires careful consideration as scaling factors will considerably impact the validity of the results. For WRDs in semi arid climates such as the Pilbara the low rainfall environment creates conditions of very low L:S ratios and geochemical systems within WRDs may remain in a quasi closed state for many years. High levels of oxygen ingress are indicated to occur as a result of high internal WRSF air temperatures and low waste rock saturation levels which means that sulfide oxidation reactions may become limited to a greater extent by net percolation rates than oxygen supply. It is noted that even with very low WRSF L:S ratios (0.1 or less), oxidation reactions have proceeded to 60% or greater completion. Storage ratios of acidity as secondary sulfate minerals are high during the period that the WRD remains as a quasi closed system. As a result future predictions of seepage quality must therfore consider the impact that future dissolution of these minerals will have if the WRD approches a "wetted up" state. Laboratory leach columns in comparrison to field conditions are charaterised by high L:S ratios and low levels of stored acidity. When extrapolating laboratory results to field conditions in semi arid envonrnments therefore it must be considered that leach columns data may overestimate IOR (by an order of magnitude), but likely significalty underestimate potential seepage quality compared to field conditions.

Scaling Laboratory Sulfate Release Rates to Operational Waste Rock Piles

Kim Lapakko and Mike Olson
Minnesota Department of Natural Resources, USA

ABSTRACT

There is little agreement on scaling factors to be used for extrapolating laboratory dissolution test results for predicting solute release rates from proposed waste rock piles in the field. The scaling factor for a given solute is the ratio of its release rate in the field to that observed in the laboratory, and its magnitude is dependent on both the solute and site-specific variables. Scaling factors for sulfate release rates from Duluth Complex rock of moderate sulfur content were determined empirically by comparison of laboratory rates to field rates. The laboratory rates were calculated based on sulfate release during weeks 6 to 71 observed for 17 blast hole samples with sulfur contents of 0.18 to 1.64 percent. The samples were collected from the mine site from which comparative field data were generated. Annual field rates were determined over a period of 3 to 13 years for five waste rock piles, ranging in mass from 2,000,000 to 15,000,000 tons, with estimated sulfur contents of 0.24 to 0.97 percent. Laboratory and field rates were expressed per unit mass sulfur. Comparison of 17 laboratory rates and 42 annual field rates yielded in 714 distinct calculated scaling factors. These values were fit to a beta distribution for which the mean and standard deviation were 0.127 and 0.083, respectively.

Keywords: mine waste rock, mine drainage, environmental review, mine waste drainage quality prediction, laboratory scaling

INTRODUCTION

Environmental review for proposed operations requires predicting solute release from mine waste storage facilities. Such predictions can be informed by operational phase data from mine wastes of similar composition, disposed in similarly constructed facilities, and weathering under similar climatic conditions. Such information from "analog" sites is often not available. Consequently predictions are based on the scaling of laboratory data to field conditions. The magnitude of such scaling will depend on the solute being scaled, drainage pH, rock type, rock composition, method of laboratory rate generation (e.g. humidity cells vs. column tests), method of field rate generation (e.g. test plots vs. full scale storage facilities), and reaction environment variables in both the laboratory and field (e.g. temperature, leachate to rock ratio, oxygen availability). Consequently, it cannot be assumed that scaling factors quantified will be universal.

Previous Studies

Two approaches have been used for scaling laboratory rates to the field, the first of which applies scaling factors for individual mechanistic factors to account for differences such as rock composition, reaction environment, and solute transport. Considerable data and analysis for this approach was generated by studies focused on waste rock piles containing two varieties of both gneiss and schist in northern Sweden (Strömberg & Banwart, 1994; Strömberg et al., 1994; Strömberg & Banwart 1999a; Strömberg & Banwart 1999b). Apparent rates of pyrite, chalcopyrite, biotite, and plagioclase weathering in the field were found to be roughly 0.01 to 0.2 times those derived from laboratory batch tests on six different particle size fractions (Malmström et al., 2000). A "scale-dependence model" accounted for the differences between field and laboratory rates using quantitative contributions of particle size, temperature, pH, and hydrologic variables affecting solute transport.

Kempton (2012) included these factors as well as moisture content and pore gas oxygen concentration in a literature review of scaling factors for solute release from waste rock. This is less detailed consideration than that of scaling mineral dissolution rates but is adequate for application to predicting solute release from waste rock. He concluded that prediction of solute release rates based on reported ranges of scaling factors would have a high degree of uncertainty. For example, he stated that waste rock particle size distribution and its relationship to hydrologic factors affecting solute transport produced a scaling range covering a factor of 7.5.

A second approach is that of empirically determining scaling factor based on comparison of laboratory and field rates for the rock in question. Wagner et al. (2006) compared sulfate release rates from mafic and feldspathic gneiss in a northern Saskatchewan test pile (8 x 8 x 5 m high) to those derived from laboratory dissolution tests on five different size fractions of the rock (Hollins et al., 2001). Sulfate release rates (normalized for surface area) in the field were 0.3 times those observed in the laboratory, suggesting that factors such as temperature and solute transport limited sulfate release in the field. There were no humidity cell data for the typical -0.25-inch fraction used in humidity cell tests to calculate a scaling factor directly from this test to the test pile.

Shaw & Samuels (2012) conducted paired humidity cell and 30-gallon barrel tests on three porphyritic intrusive rocks and one metasedimentary rock. The particle size was similar in both tests and the average temperature and precipitation in the field were approximately 16 °C and 100 mm, respectively. Drainage pH from two of the field tests were 3.5 and 1 unit lower than the corresponding laboratory test, and values from the remaining two pairs were in fairly close agreement. Direct extrapolation of laboratory data yielded predicted sulfate concentrations that

were roughly 0.07 to 0.3 those observed in the field tests. The comparatively low laboratory rates were attributed to higher pH conditions resulting from the higher flushing rate in the laboratory. It was speculated that the higher flushing enhanced dissolution of neutralizing minerals and prevented development of acidic micro-environments in the laboratory tests.

Robertson, Barazzuol & Day (2012) compared sulfate release rates from 13 humidity cell tests on fresh drill core to field rates observed for 7.6 million tonnes of rock that had been weathering for 27 years in the field, roughly 200 km northeast of Timmons, Ontario. The rock was predominantly massive and pillowed basaltic rocks, some hydrothermally altered, and felsic and mafic intrusives. Comparison of the sulfate release rate for the median sulfur content rock (0.5 percent S) in the laboratory with that observed in the field yielded a scaling factor of 0.1. The corresponding factor assuming a 95 percentile sulfur content (1.46 percent) to be controlling release in the field yielded a scaling factor of 0.05.

Hanna & Lapakko (2012) determined scaling factors for sulfate release using data generated by 26-week humidity cell tests on seven drill core samples of finely laminated, fine-grained rock, referred to by miners locally as the lower slaty member of the Biwabik Iron Formation (Severson et al., 2010). Sulfate release rates, normalized for pyrite mass, calculated for roughly 50 million tonnes of this rock in northeastern Minnesota were generally equal to or greater than the corresponding rates in the laboratory.

Lapakko (1994) compared results from laboratory dissolution tests on fine noritic and gabbroic Duluth Complex rock (0.053 < diameter ≤ 0.149 mm) from the South Kawishiwi Intrusion to those generated by roughly 1000-tonne test piles of similar Duluth Complex rock from the Partridge River Intrusion in northeastern Minnesota. Rates in the field were compared to laboratory rates for rock of similar sulfur content and yielded scaling factors of roughly 0.1 to 0.3.

OBJECTIVE AND APPROACH

The objective of this report is to present scaling factors for sulfate release from operation scale stockpiles of Duluth Complex rock in the field relative to those that would be generated in humidity cell tests. The approach employed data that was generated in studies previously conducted by the Minnesota Department of Natural Resources (MN DNR) (Kellogg et al., 2014, MN DNR, 1996). Specifically, field data are from monitoring at the Dunka Mine and laboratory data are from dissolution tests on rock from that site. Those tests were conducted on rock with diameters in the range of 0.053 – 0.149 mm. Corresponding humidity cell rates were projected using data comparing results from the two methods.

METHODS

Field

Beginning in the 1960's, Duluth Complex rock was excavated at the Dunka taconite mine (Figure 1) and stockpiled at the site in order to access the underlying iron formation. In the mid-1970's it was discovered that sulfate and trace metal concentrations were elevated in Unnamed Creek, which drains the mining watershed, and the Duluth Complex rock was determined to be the source of these solutes. Due partly to concerns regarding water quality impacts from potential copper-nickel mining in the area, a program was

Figure 1 Location of Dunka Mine, Iron Formation and Duluth Complex in northeastern Minnesota

initiated to monitor the Duluth Complex rock seepage at the Dunka Mine. The following information was taken from a summary of waste rock composition, flow, and drainage quality data from the site (MN DNR, 1996).

The Duluth Complex rock mass within the individual seepage watersheds ranged from roughly 2 to 15 million tons, with average sulfur contents of approximately 0.2 to 1 percent (Table 1). Sulfur contents were determined based on analyses conducted on blast hole samples from 1980 to 1988. These analyses accounted for most of the rock in stockpiles 8018 and 8031, which drain to sites W1D and W4, respectively. Therefore, there is a relatively high degree of confidence in the sulfur contents and calculations based on these contents. In contrast, sulfur contents of stockpiles 8011, 8013, and 8014 were estimated based on analyses of roughly 19, 35, and 44 percent of the rock present. No sulfur analyses were submitted by the company for rock stockpiled after 1988.

Sulfate and metals are transported from the stockpiles in several well-defined seeps, as well as in diffuse flows. The seeps (and the associated stockpiles) discussed in the present report are designated EM8 (stockpiles 8011, 8014), Seep X (8013), Seep I (8013), W4 (8027, 8031), and WID (8018, 8031). Duluth Complex drainage quantity and quality data presented in this report were collected for periods of 3 to 13 years during the time span from 1979 to 1992. Since 1976, data have been collected on the drainage quality, quantity, and chemical mass release associated with stockpile drainages at the site. The Regional Copper-Nickel Study began the data collection and after 1980 monitoring was conducted by Erie Mining Company and LTV Steel Mining Company. The seasonal flow period typically extended from the middle of April to the end of November. Weirs and flow recording equipment were installed at all sites and flow was recorded automatically from roughly mid-May to mid-November. Beyond this time period flow measurements were conducted manually. Grab samples were typically collected 15 to 20 times per year for determination of pH, sulfate concentrations, and concentrations of other solutes that are not discussed in this paper.

Table 1 Duluth Complex stockpile and seep watershed characteristics

Seep	Stockpile	Deposition (start-end)	Mass in watershed,	%S	Area of pile in watershed, $ft^2 \times 10^6$	Watershed area,	Monitoring (start-end)
Seep X[1]	8013	1967-1991	8.44	0.24	1.3	1.7	1990-1992
Seep 1[2]	8013	1967-1991	1.86	0.24	0.50	0.65	1986-1992
EM8[3]	8011	1965-1986	12.92	0.23	3.6	7.7	1979-1991
W4[4]	8027[6]	1979-1979	0.14	0.12	0.12	7.5	1980-1991
W1D[5]	8018	1979-1985	2.18	0.98	0.75	1.9	1986-1992

Laboratory

Seventeen samples were collected from blast holes at the Dunka mine (Figure 2a). These samples were characterized (chemistry, mineral content, mineral chemistry) and subjected to dissolution testing (Kellogg et al., 2014). For 15 of the 17 samples, particle size was reduced using a bucking maul, or mechanically, with a pulverizer. These samples were subjected to dissolution tests in duplicate. The remaining two samples (0.67, 0.82 %S) were stage crushed with a jaw crusher and were not replicated in dissolution testing. Particles with diameters from 0.053 to 0.149 mm (-100/+270 mesh) were retained for experimental use. For the crushed samples, sulfur content was determined by LECO furnace, metal concentrations were determined using ICP-AES, and mineral content and mineral chemistry were determined by microprobe analysis of 100 to 125 mineral grains for each sample.

Seventy-five grams of crushed rock were placed into the upper segment of a two-stage filter unit (Figure 2b). The solids were placed on a glass fiber filter that rested on a perforated plastic plate near the bottom of the reactor. At the inception of the experiment, each reactor was rinsed three times to remove any oxidation products that accumulated between sample crushing and onset of the experiment. Each week thereafter, two hundred milliliters of distilled-deionized water was added, and remained in contact with the solids for four to seven minutes, and then vacuum-pumped from the upper stage through a 0.45- micron filter on top of the lower stage of the filter unit. This procedure changed slightly beginning in July 2002. During weeks where no sample was collected, the reactors were filled with water as before, but were then gravity drained. The procedure remained the same as before for weeks during which samples were collected. Sample pH was determined weekly using either a Radiometer 29 or an Orion SA720 meter. Sulfate concentrations were determined biweekly (R1-R20) or monthly (R29-R43) at the MN DNR lab in Hibbing, MN using an HF Scientific DRT-100 nephelometer for the barium sulfate turbidimetric method (APHA et al., 1992). The sample volume was determined by weighing the sample collection flask containing the sample and subtracting the flask mass.

Figures 2a,b,c The first photo (a) depicts the weir at a site used for monitoring flow and water quality at the Dunka taconite mine in northeastern Minnesota, the second photo (b) depicts an MN reactor apparatus, and the third photo (c) depicts a typical humidity cell apparatus.

Between rinses, the solids remained within the reactors, allowing evaporation of retained rinse water and continuous oxidation. The reactors were stored in individual cubicles that formed a rectangular matrix within a topless housing with a perforated base; the housing was stored in a temperature and humidity controlled room (8.5 x 10.5 x 9.5 ft). Reactor experiments were initiated at three different times. For weeks 6-71 average temperatures for the three sets of samples ranged from 25.2-26.3 °C with standard deviations of 0.5-1.3 °C. Corresponding values for average relative humidity were 55.3-59.7% and 3.4-6.8%.

Calculations

For waste rock piles in the field, sulfate mass release was calculated for each day sulfate concentrations were measured. Flow data from the previous and subsequent measurements were used to determine the flow volume associated with the sulfate concentration (equation 1).

$$SO_4 \text{ mass release, } M(SO_4) = [SO_4]_i \left(\frac{Q_i+Q_{i-1}}{2}\right)\left(\frac{t_i+t_{i-1}}{2}\right) + [SO_4]_i \left(\frac{Q_i+Q_{i+1}}{2}\right)\left(\frac{t_i+t_{i+1}}{2}\right), \text{ where} \quad (1)$$

M (SO_4) = mass of sulfate associated with sample i, mg.

[SO_4] = sulfate concentration (mg/L),

Q = flow (liters/sec), and

t = time (seconds).

Cumulative sulfate mass release for the year was then divided by the product of the molecular weight of sulfate, annual mass of sulfur in the watershed and the time over which release occurred to determine annual average sulfate release rates (mol SO_4 (g S)$^{-1}$ s^{-1}) for each seep (Appendix 1, Table A1.1).

Annual rate of sulfate release was calculated as follows:

$(dSO4/dt)_A = \Sigma MSO4/(96.1*M(S)_{ws} * t)$, where (2)

$(dSO4/dt)_A$ = Average annual rate of sulfate release (mg/(gS*s)),

ΣMSO_4 = sum of mass sulfate release for individual sampling periods (mg), and

$M(S)_{ws}$ = mass of sulfur in the watershed (g).

The period over which flow and sulfate concentrations were determined typically extended from mid-April to the end of November. The calculation assumed that the sulfur content in each stockpile did not change over time (the final weighted average sulfur content was used), where in reality the sulfur content added to each pile varied each year.

For the 17 laboratory tests, the average sulfate release rate and associated standard deviation were determined for weeks 6 through 71 (Appendix 1, Table A1.2). The initial five weeks were omitted to eliminate contributions of sulfate generated during sample storage. Drainage pH values for most samples were circumneutral during this period, although minimum values as low as about 4.5 were observed for some of the higher sulfur sample. The mass sulfate release for each point at which sulfate concentration was determined was calculated as the product of that concentration and sample volume. For sulfate concentrations below detection (2 mg/L) a value of 1.0 mg/L was assumed. A total of 887 sulfate measurements were made for the 17 reactors (including the replicates), out of those 93 were below the detection limit. These typically occurred in the samples with S ≤ 0.41%. To determine the rate of release, normalized for sulfur content, the mass release was divided by the product of 604,800 seconds/week and the mass of sulfur present in the sample. Normalizing relative to the sulfur content allowed for direct comparison among laboratory and field rates.

Scaling factors were calculated to express the ratio of field rates to a laboratory rate from a humidity cell test (Figure 2c). This required scaling rates from the MN DNR reactors to humidity cells. This was done using data generated by subjecting Duluth Complex rock samples to testing in both reactors and humidity cells (seven and ten samples, respectively) (Lapakko, Olson, & Antonson, 2013). During weeks 6 through 71 (and throughout the first three years of testing) sulfate release rates as a function of sulfur content from the humidity cells were approximately one-third those from the reactors. Thus, the observed sulfate release rates for the reactors were divided by three to represent humidity cell rates.

A set of scaling factors was then calculated using the ratio of each of 42 annual field rates to each of the adjusted 17 laboratory rates. This generated a set of 714 distinct scaling factors (42 x 17 = 714) (Figure 3a). This data set was fit to normal, beta, and log normal distributions, and the associated mean and standard deviations were determined.

RESULTS AND DISCUSSION

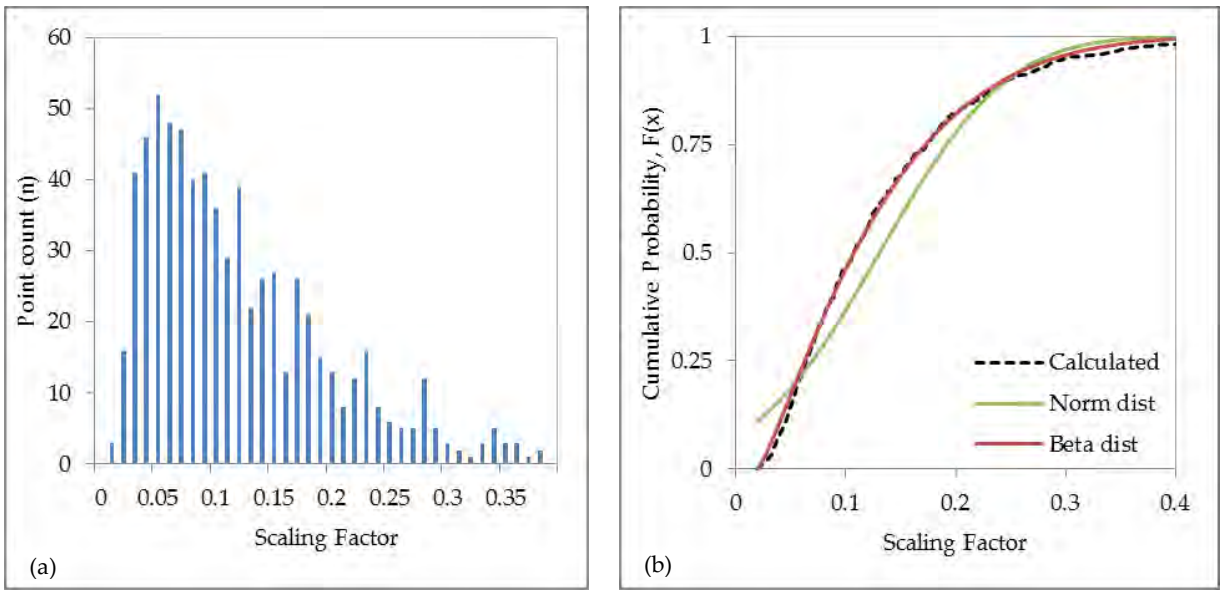
The Duluth Complex rock mass within the individual seepage watersheds ranged from roughly 2 to 15 million tons, with average sulfur contents of approximately 0.2 to 1 percent (Table 1). Because lab samples were collected from blast holes at the site, it is assumed that the mineralogy is similar to those in the lab (see below). Sulfate concentrations in the field generally ranged from 600 to 1600 mg/L and geochem equilibrium modeling of 269 seepage samples indicated that the drainages were undersaturated with respect to gypsum in all cases except one.

Sulfate release rates in the field typically ranged from 0.8 x 10^{-12} to 4 x 10^{-12} mol (g S)$^{-1}$ s^{-1}, with a median value of 1.7 x 10^{-12} mol (g S)$^{-1}$ s^{-1} (Appendix 1, Table A1.1). These values were in good agreement with calculations by a slightly different method (MN DNR, 1996). Rates calculated for Seep 1 tended to be on the lower of the range and those from W4 on the higher end. Their respective mean rates were 1.2 x 10^{-12} and 3.3 x 10^{-12} mol (g S)$^{-1}$ s^{-1}. Rates for individual seeps showed no consistent temporal trend and values for each seep fell within a fairly consistent range over the period of record. The percent standard deviation of the mean value ranged from about 35 to 55 percent (Appendix 1, Table A1.1). Rates for Seep X, Seep 1 and EM8 were in reasonable agreement with those for W4 and W1D (Appendix 1, Table A1.1). Sulfur content of the rock in the watersheds of the last two sites was determined throughout the period of stockpiling (see Methods). The agreement among sulfate release rates suggests that estimations of sulfur content made for rock in the first three watersheds were not unreasonable. Minimum annual pH values for four of the five seeps reflected circumneutral pH conditions, typically ranging from 6.2 to 6.6. Values for Seep 1 were markedly lower, generally in the range of 4.6 to 4.8 (Appendix 1, Table A1.1).

Sulfur content of samples subjected to dissolution testing ranged from 0.18 to 1.64%. Pyrrhotite was the dominate sulfide mineral, followed by chalcopyrite, cubanite, and pentlandite. Cu and Zn sulfides were also observed in trace amounts. Plagioclase (36-65%), augite (3-17%), hypersthene (5-28%), and olivine (3-21%) contributed 65-97% of mineral content in Duluth Complex samples. Eleven samples contained the plagioclase species labradorite, while six samples contain the more sodium-rich species andesine (0.18 to 1.64%S). Unleached Duluth Complex silicate minerals had the following range of stoichiometric coefficients: plagioclase $(Ca_{0.40-0.63}Na_{0.32-0.55})Al_{1.44-1.66}Si_{2.35-2.57}O_8$, augite $((Ca_{0.76-0.95}Na_{0.01-0.03})(Mg_{0.36-0.79}Fe_{0.27-0.63}Ti_{0.01-0.02})(Si_{1.95-2.00}Al_{0.03-0.1})O_6)$, hypersthene $((Mg_{0.91-1.16}Fe_{0.78-1.66})2Si_{1.97-2.00}O_6)$, and olivine $((Mg_{0.72-1.00}Fe_{0.96-1.25})Si_{0.99-1.01}O_4)$ (Kellogg et al., 2014).

Laboratory rates typically ranged from 1.1 x 10^{-11} to 2.3 x 10^{-11} mol (g S)$^{-1}$ s^{-1} with three values in the range of 2.5 x 10^{-11} to 3.9 x 10^{-11} mol (g S)$^{-1}$ s^{-1} (Appendix 1, Table A1.2). Rates for six of the samples included estimations of sulfate concentrations for values reported as less than detection (Appendix 1, Table A1.2). For three samples with seven or fewer below detection values this introduced a maximum error not exceeding two percent. The maximum error increased to eight percent for 15 below detection values and 19 percent for 35 sulfate concentrations reported below detection. Median pH values for the period of record ranged from 4.3 to 6.6, and minimum pH values were generally 0.6 to 1.3 units lower. There was little dependence of these rates on pH, as indicated by a correlation coefficient of 0.062 for the regression of sulfate release rate against the median pH values.

The overall range of scaling factors was 0.019 to 0.687 with about two thirds of the values falling between 0.053 and 0.21 (Figure 3a). Fitting the set of scaling factors to a normal distribution yielded respective values for the mean, standard deviation, and skewness of 0.13, 0.09, and 1.69, respectively. Given the asymmetry of the data relative to a normal distribution (Figure 3a), a beta distribution was applied for dynamic systems modeling for scaling at a proposed mining operation in Minnesota. Scaling factors for probabilities of 5, 25, 50, 75, and 95 percent were 0.034, 0.064, 0.11, 0.17, and 0.30, respectively (Figure 3b). The respective mean and standard deviation for this distribution were 0.127 and 0.083; minimum, maximum, alpha, and beta values were 0.019, 0.687, 1.25, and 6.50, respectively. A log-normal distribution also fit the data well with mean and standard deviation for ln(x) of -2.25 and 0.675, respectively.



Figures 3a,b a) Calculated scaling factor histogram showing point counts and b) cumulative probability of composite scaling factors compared to normal and beta distribution fits. Omitted scaling factors > 0.40 to improve resolution.

The modeling used the distribution of scaling factors to generate a corresponding distribution of sulfate release rates for the field. Such distributions are recommended by the National Academy of Sciences (National Research Council, 2007) as opposed to a single value. They are deemed more appropriate for assessment of risk by regulatory agencies, an assessment that is essential to environmental review of proposed mining operations.

It should be noted that the scaling factors presented were calculated based on field rates determined during periods of open flow (roughly April through November) and ignored winter periods when ice covered seepage areas (roughly December through March). There were few data available to compare sulfate release rates during the winter to those during the remainder of the year. The best data available were from the outflow of the watershed, site EM1, roughly 1 to 3 km downstream of the seeps. From 1975 to 1998 average sulfate concentrations during the winter were 0.71 times the average during the summer (99 and 389 measurements, respectively). From 2000 to 2014, National Pollution Discharge Elimination System (NPDES) data indicated the monthly average flow during the winter was 0.46 times that during the open flow season (52 and 116 measurements, respectively). Using these ratios allowed estimation of yearly field rate (open flow and ice cover) as 84 percent of that during open flow alone. This would in turn yield scaling factors that were 84 percent of those calculated. For example, the mean value for the beta distribution would be reduced from 0.13 to 0.11. The lower scaling factor does not, however, imply a lesser potential for environmental impact. The lower field sulfate release rates estimated for the winter months actually yielded higher sulfate concentrations in the receiving stream due to lower input flows of unimpacted water.

Beyond the statistical description of uncertainty, specific variables in the calculation were considered. First, field rates were calculated based on sulfur contents of rock within seep watersheds. As discussed above, sulfate release rates for watersheds in which sulfur content was determined throughout stockpiling were in reasonable agreement with those for watersheds with less frequent rock analyses. Thus, it appears that such estimation did not introduce substantial error.

Second, the potential role of pH was investigated. As discussed above, the laboratory rates exhibited little dependence on pH for the period of record considered. Although most of the field seeps exhibited circumneutral pH, it is possible that acidic "hot spots" with elevated sulfate release rates could develop in isolated areas of piles. However, there were no indications suggesting such areas existed. That is, there were no sudden drops in pH and release rates of sulfate remained with constant ranges (Appendix 1, Table A1.1).

Indicators of acidification were observed at Seep 3 at the Dunka mine, a seep not included in the present calculation of scaling factors. From 1975 through1988 drainage pH at the seep was near 7.0, but declined to a minimum of 4.8 in 1989 (MN DNR, 1996). Despite pH values in the typical circumneutral range, the annual release rates for nickel, copper, cobalt, and zinc increased by factors of roughly 20 to 80 from 1986 to 1988, and the sulfate release rate increased by about a factor of nine during this period. Such increases are often associated with isolated acidic zones in waste rock piles generating circumneutral pH. In contrast, sulfate release rates from each of the seeps used for scaling calculations fell within a fairly constant range (Appendix 1, Table A1.1), as discussed above. Similarly, heavy metal concentrations from these seeps did not exhibit the radical changes observed at Seep 3. Thus, it seems unlikely that acidic zones within these piles influenced rates of solute release.

Acidic drainage pH was observed at Seep 1, where minimum values were between 4.6 and 5.2 (Appendix 1, Table A1.1), but the sulfate release rate for this site was the lowest of the five sites examined. This, in conjunction with the laboratory data, suggests there is not a strong dependence of sulfate release on pH in the range of roughly 4.5 to 7.

Third, the reliability of flow measurements was considered. Flow measurements were automated from roughly the middle of May to the middle of November and measurements were made manually beyond this period. To assess the reasonability of the annual flow volumes, these values were divided by total precipitation onto the seep watershed to quantify the annual fractional yields. The average annual yield coefficients for the periods of record for EM8, Seep 1, W1D and W4 were 0.28, 0.33, 0.36, and 0.37, respectively. These values do not suggest any substantial error in flow measurement.

The average annual yield coefficient for Seep X was notably higher at 0.74. At this site the yield coefficient decreased steadily from 1.03 to 0.56 over the three-year period of record and declined to 0.34 the following year. Visual observation of flow at the site was consistent with the high values reported. It is believed that release of stored water was responsible for the initial elevated flows, although the precise mechanism is unknown. The ultimate value of 0.34 is consistent with the annual averages from the other sites and is believed to reflect "typical flow" from the pile.

Finally, the scaling factors determined are in general agreement with values previously determined empirical scaling factors for Duluth Complex and Biwabik Iron Formation rock in northeastern Minnesota. Lapakko (1994) compared sulfate release rates from South Kawishiwi Intrusion rock tested in MN DNR reactors to rates observed for 1000 tonne test piles of Partridge River Intrusion rock. The approximate range of scaling factors reported was 0.1 to 0.3. The rates for the South

Kawishiwi rock in MN DNR reactors reported in the study can be converted to Partridge River rock in humidity cells. Subsequent research indicated that transforming these rates for influences of dissolution test type (MN DNR reactor rate/humidity cell rate ~ 3) and specific intrusion (South Kawishiwi rate/Partridge River rate ~ 0.5) (Lapakko, Olson, & Antonson, 2013). The resultant range of 0.15 to 0.45 represents that for scaling sulfate release rates from humidity cells to test piles, which is higher than the 0.127 mean for scaling humidity cell rates to operational scale piles. This seems reasonable considering, for example, that reaction product transport would likely be higher in the smaller test piles.

Hanna & Lapakko (2012) determined empirical scaling factors for waste rock piles from the lower slaty unit of the Biwabik Iron Formation waste rock piles in northeastern Minnesota. The more reliable of two methods reported yielded a range of 1.0 to 1.3, that is, field rates of sulfate release per gram pyrite were higher than those observed for drill core in the laboratory. This was largely attributed to laboratory rates determined for weeks 15 to 26 of humidity cell testing. Additional testing of weathered rock yielded rates that were roughly an order of magnitude higher than those for drill core. Using these rates for determination of scaling factors would have produced values near 0.1, which is in general agreement with the values determined in the present work. The values determined in the present work generally agree with those presented for operational scale piles by Robertson, Barazzuol, & Day (2012) and not extremely deviant from other literature values presented. However, as discussed previously, comparisons of scaling factors among different sites must be done with caution due to differences in site specific environmental conditions, rock characteristics, and test methods.

SUMMARY AND CONCLUSIONS

Sulfate release rates from Duluth Complex rock were determined for 17 laboratory tests and five operational waste rock seepages in northeastern Minnesota. The 714 scaling factors, representing the ratio of field rates to those in the laboratory, were fit to a beta distribution that yielded a mean of 0.127 and a standard deviation of 0.083. This empirically-based distribution forms a foundation on which laboratory rates can be scaled to develop a probability distribution of predicted operational rates for the purpose of environmental review, consistent with recommendations by the National Academy of Sciences (National Research Council, 2007). It should be noted that the results were generated based on dissolution of a specific rock type in the laboratory and under specific conditions of climate and waste rock stockpile design in the field. Consequently, care must be taken when applying these results to other conditions. It does provide an example for development of empirically based scaling factors. Further application of this approach to other rock types and field conditions will reduce uncertainty in the presently tenuous extrapolation of laboratory test results to the field conditions for proposed mining operations. Consequently, it is recommended that operations and regulatory agencies generate, compile and analyze data to develop additional distributions for empirical scaling factors.

Scaling Geochemical Loads in Mine Drainage Chemistry Modeling: An Empirical Derivation of Bulk Scaling Factors

Timo Kirchner and Bruce Mattson
Lorax Environmental Services Ltd., Canada

ABSTRACT

The development of water quality predictions for seepage from mine waste facilities is an integral component of the environmental assessment of minesites. Direct scaling of geochemical loads measured by laboratory kinetic tests such as humidity cells relative to the mass of a full-scale mine waste facility will lead to concentration predictions for mine drainage that are unrealistically high for many dissolved constituents. As a result, "scaling factors" are applied to account for discrepancies in parameters such as grain size, temperature and water/rock ratio between the laboratory experiments and the field scale waste rock facilities.

In this study, waste dump seepage chemistry data from two minesites are compared to upscaled, representative laboratory test cell leachate data in an attempt to better constrain bulk scaling factors. Additionally, larger scale field experimental data (field bins) were considered as an intermediate scaling step.

It was observed that geochemical loads for major ions from the sites are commonly more than two orders of magnitude lower than those predicted by direct scaling of laboratory kinetic test loads, yielding bulk scaling factors of <1%. In these models, many dissolved trace ions that may be of concern in mine drainage (*e.g.*, As, Cu, Cd, Se, *etc*.) may still be significantly overpredicted if the model is calibrated to major ions, likely as a result of solubility limits and other attenuation mechanisms. Unlike loading rates, concentrations in field bin and waste dump drainage were commonly found to be on the same order of magnitude for both neutral and acidic sites suggesting that geochemical equilibrium may be attained at relatively small scales in waste piles, highlighting the importance of intermediate-scale field experiments.

INTRODUCTION

One of the biggest environmental concerns related to modern mining is the release of acidity and metals into the surrounding environment in response to water-rock interaction occurring in sulfidic waste rock storage facilities. Drainage quality predictions conducted as part of geochemical studies incorporate small- to intermediate-scale kinetic experiments that are carried out on mine rock and tailings. These tests provide insight into the reaction mechanisms, lag time for onset of acid rock drainage (ARD), and metal leaching (ML) behavior. A major challenge associated with the application of kinetic test results is the extrapolation of leachate chemistry to predict full-scale minesite drainage chemistry even when waste rock compositions, tonnages and site water balance are constrained. A common approach is to convert laboratory kinetic test leachate concentrations into a geochemical loading rate (*e.g.*, mg/kgrock/week) which is then upscaled to the tonnage of the waste dump to predict drainage quality:

$$Predicted\ Concentration = \frac{HC\ Load\ x\ Time\ x\ Mass\ of\ Rock\ in\ Dump}{Volume\ of\ Infiltrating\ Water} \quad (1)$$

It has long been recognized that the resulting loads commonly strongly overestimate actual geochemical loads seen in drainage from waste dumps (Morin & Hutt, 1994; Malmström *et al.*, 2000). This is largely attributed to discrepancies in geochemical and physical conditions between laboratory kinetic reactors and full-scale waste dumps, including but not limited to:

- water-rock interaction (contact);
- gas transport and oxygen content;
- reactive grain size distribution (and associated occlusion of reactive minerals);
- temperature (both sulfide and carbonate dissolution reactions are temperature-dependent).

In an attempt to account for the variable geochemical regimes, many authors have begun introducing scaling factors based on theoretical assumptions and field observations (Malmström *et al.*, 2000; Neuner *et al.*, 2009; Kempton, 2012). In theory, a scaling factor (generally <100%) is assigned to each of the lab-to-field discrepancies identified and multiplied by the upscaled load. Understandably, depending on the type of waste material and the climatic conditions at a minesite, the sometimes inter-related individual scaling factors vary widely in practice (Kempton, 2012). A so-called bulk scaling factor, defined as the product of all individual scaling factors can be calculated empirically where laboratory kinetic and waste drainage chemistry data are available, however a comprehensive database for different deposit types and climate conditions is missing. Nevertheless, several studies have addressed this topic and bulk scaling factors on the order of 5 to 60% have been reported (*e.g.*, Andrina *et al.*, 2012; Hanna & Lapakko, 2012; Morin & Hutt, 1994).

This paper presents waste rock leachate and drainage chemistry results from reactors of various scales. The waste rock is associated with two minesites located in semi-arid regions, one with neutral and the other one with acidic drainage. The focus of this study is the dependence of geochemical loading rates on the scale as well as the variability of geochemical behavior between different species.

METHODOLOGY

Humidity cell experiments for materials from both sites were conducted according to the standardized method outlined in ASTM D5744 (2010) applying three days of dry air and three days of moist air flow to each 1 kg of waste rock followed by flooding with deionized water (500 mL) and leachate sampling on day seven. Column experiments on waste rock from Site B are made up of 5 kg of material with variable irrigation volumes (300-500 mL) applied as a trickle leach at 1 mL/min every two weeks. Between sampling cycles the cells were exposed to dry air allowing for a better representation of the mine-specific climate.

Field kinetic experimental procedures are consistent between the two minesites with field bins containing 150-200 kg of waste rock which are either flushed naturally by rain water or, in case of longer dry periods, are manually irrigated with deionized water. As the leachate sample is taken, the outflow volume is recorded to allow the calculation of geochemical loads.

RESULTS AND DISCUSSION

Static test results of the various waste rock materials and WRSA dimensions for Sites A and B are given in Table 1.

Table 1 Selected static test results and WRSA dimensions for the studied minesites

		Site A		**Site B**
		Oxide	*Sulfide*	*Diorite*
Total S	%	0.82	2.9	0.22
Sulfide S	%	0.020	2.5	0.030
NP	*kg CaCO3/t*	-1.0	-1.1	88
NPR		<0	<0	40
WRSA tonnage	*Mt*	57	38	2.7
WRSA footprint	*ha*	91		9.9

Notes: chemical results are median values; NP = bulk neutralization potential; NPR = net potential ratio.

Site A (acidic drainage)

Site A is a porphyry-gold deposit located in a semi-arid environment with an average annual precipitation of 550 mm. The waste rock storage area (WRSA) contains rock from volcanic intrusions and volcaniclastic sediments of intermediate to felsic composition. Sulfide S content and associated drainage chemistry is predominantly associated with the degree of natural weathering which led to the subdivision of waste rock into two main categories, namely Oxide and Sulfide materials. The former is generally devoid of sulfide minerals, but contains considerable amounts of acid-producing sulfate salts such as jarosite and alunite. Sulfide waste rock contains up to 7.6% of sulfide S with a median value of 2.5% (Table 1), mainly in the form of pyrite. Both material classes show little to no carbonate mineralization, and therefore have little capacity for acid-neutralization. All waste rock is stored within the same facility with Oxide rock used as cover material for the highly reactive Sulfide waste. Figure 1 shows a tertiary diagram of major elemental ratios in Site A WRSA drainage compared to Sulfide and Oxide humidity cell leachates. This plot illustrates the

mixed nature of the waste dump with the influence of Sulfide waste material becoming progressively more important over time. Due to the mixed nature of the WRSA, certain assumptions and data adjustments were made with respect to the calculation of geochemical loads:

- At the time of WRSA drainage collection the ratio of Oxide to Sulfide rock was set to 60% to 40%, consistent with the waste production schedule provided by the client;
- All flows contacting the WRSA are captured by the flow measurements at the seepage collection pond.

WRSA geochemical loading rates were calculated for a 64 week duration extending from September 2011 to December 2012 (construction of the WRSA began in 2010). Selected major ion and minor/trace ion loads are compared to the loading rates derived from kinetic experiments in Figure 2. In this plot, both field bin and humidity cell loads are normalized to the loads derived for the WRSA seepage to calculate an "exceedance factor":

Exceedance factor = Kinetic test load / WRSA load

The humidity cell exceedance factors range from 578 (Na) to ~52,000 (As), corresponding to bulk scaling factors of 0.17% to 0.002% (calculated as the inverse of the exceedance factor). These exceedance factors are greater than the field bin exceedance factors which range from 29 to ~24,000, for all parameters except arsenic. The latter is the only species showing a higher load in field bin versus humidity cell leachates. Greater exceedance factors for the humidity cells are consistent with

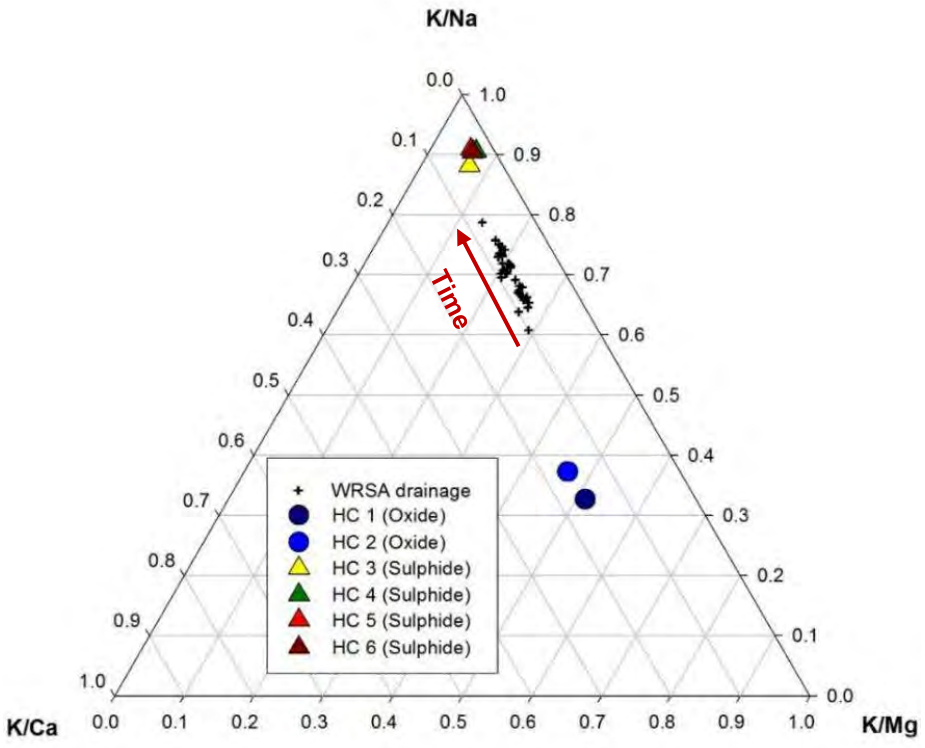

Figure 1 Ternary diagram showing the major elemental ratios in humidity cell leachates versus WRSA drainage for Site A

the greater scale differential between humidity cells and the WRSA compared to field bins versus WRSA.

Humidity cell exceedance factors for the major ions are typically lower than trace ion loads ranging from ~600 to ~1,000 (median bulk scaling factor of 0.15%) not including Fe and K (Figure 2). The latter species display higher exceedance factors around or greater than 5,000 indicating that they are being attenuated in WRSA drainage relative to humidity cell leachates. Under the pH conditions measured in the WRSA drainage, geochemical modeling using PHREEQC (Parkhurst & Appelo, 1999) suggests that the most likely solubility control for Fe and K is the mineral jarosite, which was also commonly identified in Oxide waste rock. The median humidity cell based bulk scaling factor for the shown minor and trace ions is 0.02%, almost an order of magnitude lower than that calculated for other major ions.

As a sensitivity analysis and to account for a conservative case in which the WRSA constantly produces a pH in the range of that seen in the latter stages of the Sulfide humidity cell experiments, the worst geochemistry (pH 3.2) recorded at the seepage collection pond was applied to the same drainage volume over the entire modeling period (64 weeks). In this scenario the median bulk scaling factor for major ions (SO_4, Na, K, Ca, Mg) increases to 0.41%, while the bulk scaling factor for minor and trace ions is 0.13%, still well below bulk scaling factors reported by other workers.

Several species in waste rock seepage can be expected to become saturated when a certain scale (or water/rock ratio) is reached. Therefore, in addition to assessing geochemical loads, it is crucial to also compare concentrations measured in leachate versus seepage waters. In Table 2, the range of field bin leachate concentrations is listed along with the median Site A WRSA drainage concentration for episodes of comparable pH (pH = 3.0 – 3.3). Of the presented parameters, only Al, Cd, and Cu exceed the maximum concentrations observed in field bin leachates but fall within a factor of three of the latter. The remaining species are within the range observed in field bin leachates suggesting that solubility limits control their concentrations.

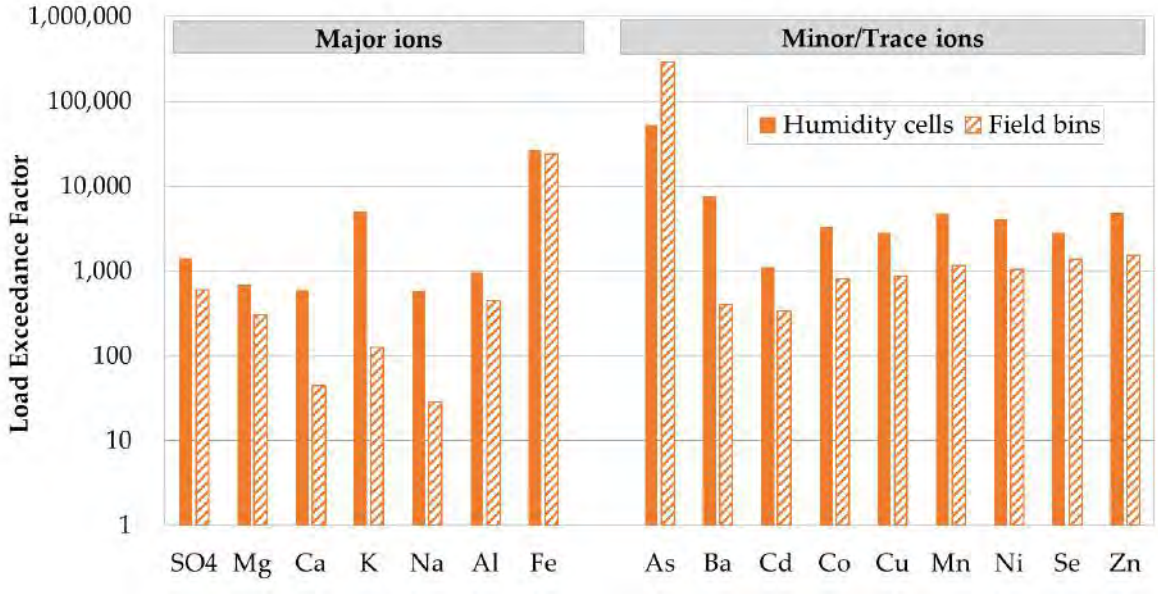

Figure 2 Exceedance factors (relative to WRSA drainage) in humidity cell and field bin leachates for acidic Site A

Notes: FB = field bin; WRSA drainage concentrations indicated in bold exceed the maximum field bin leachate concentration.

Site B (neutral drainage)

Site B represents a porphyry-copper deposit located in a semi-arid environment and hosted in a complex igneous system of mafic to intermediate plutonic and volcanic rocks. Several hybrid units comprising the major intrusions and volcanic rocks were identified near contacts. Compared to Site A, the sulfur contents at Site B are low with median sulfide sulfur concentrations of 0.22% (Table 1). Carbonate neutralization potential is abundant (median = 29 kg $CaCO_3$/t) and additionally it was identified that reactive silicate NP is present (median bulk NP = 88 kg $CaCO_3$/t; Table 1). Overall, waste rock from this site is not expected to generate net acidity, however species that form oxyanions under neutral conditions (*e.g.*, As, Se) may still be mobile in waste rock drainage. Geochemical loads released by humidity cells and their duplicate columns were compared against field bin leachate data (same lithology; no duplicates) and site pore-water from waste rock that is primarily made up of the same dioritic waste rock.

Seepage analyses from the WRSA were obtained through two monitoring wells that were installed at two different depths within a backfilled pit. Sampling depths are both below the water level, however geochemical analyses suggest that the water is sufficiently oxic to be representative of oxidizing pore-water chemistry. Geochemical loading from Site B WRSA was calculated based on the following assumptions:

- Tonnage: only the non-saturated rock (the upper 12 m) stored in the backfilled pit will contribute to sulfide oxidation, yielding a tonnage of 2.7 Mt;
- Flows: all infiltration into the waste pile (27 mm/yr) will be available for reaction.

Figure 3 shows the exceedance factors of geochemical loading rates calculated for humidity cells (1 kg), duplicate unsaturated columns (5 kg), and field bins (~150-200 kg) relative to the inferred loads from the WRSA at pH-neutral Site B. Loading rates from humidity cells are higher than or similar to those in column leachates. The discrepancy is highest for Al and Fe, suggesting that the attenuation of these two species under neutral conditions is already effective at small scales. The fact that geochemical loads calculated for several species in field bin leachates are similar to or even higher (exceedance factor < 1) than those in the WRSA pore-water suggests that assumptions made for WRSA loading calculations are conservative. This is likely a result of the poorly constrained water balance at this site and/or the fact that field bins were manually irrigated several times, likely increasing the overall load in this climatic setting. Consequently, exceedance and bulk scaling factors presented for Site B in the following should be considered semi-quantitative.

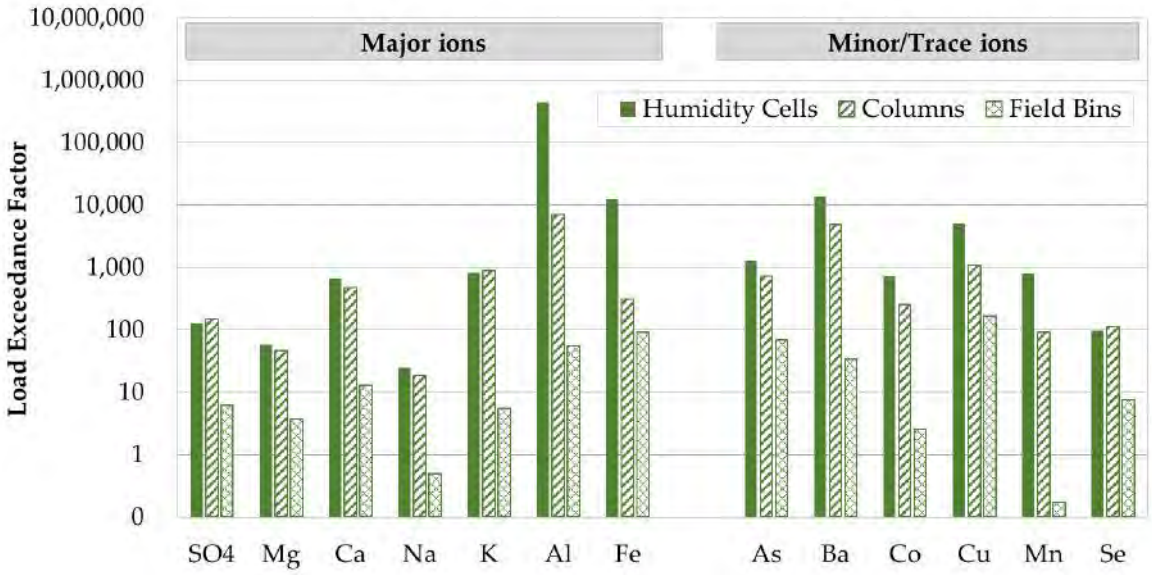

Figure 3 Exceedance factors (relative to WRSA drainage) in humidity cell, column and field bin leachates for neutral Site B

The discrepancy between major ions and trace ions is not as apparent as for Site A, which is likely a result of the different attenuation mechanisms occurring at neutral pH. For example, exceedance factors for laboratory kinetic experiments vary by more than three orders of magnitude for major ions ranging from 25 (Na) to ~444,000 (Al) (Figure 3). Excluding Fe and Al, which are known to be highly immobile under circum-neutral pH, a median bulk scaling factor of 0.8% was calculated. It should be noted that due to the high gypsum content observed in Site B waste rock, Ca and SO_4 are unlikely to behave conservatively. For the shown minor and trace ions, the calculated bulk scaling factor is 0.1% suggesting that, with few exceptions (*e.g.,* Se), scaling to major ions would generally overestimate predicted concentrations for these species in site drainage.

As for Site A, in addition to the geochemical load analysis, selected dissolved concentrations measured in field bin leachates are compared to the WRSA drainage chemistry in order to shed light on possible solubility controls occurring at different scales (Table 3). Na and Mn from the WRSA exceed five times the maximum concentrations in field bin leachates, while sulfate, Mg, K, and Co only slightly exceed the range of field bin leachate concentrations. The very high Na and Mn values may be explained by the impact of blasting residues and the development of suboxic conditions in the backfilled pit, respectively. The fact that many dissolved species fall within the range of field bin leachate concentrations suggest that attenuation mechanisms are active and equilibrium conditions are partly reached at relatively small scales.

Table 3 Comparison of the range of field bin leachate concentrations with WRSA drainage chemistry at Site B

Notes: FB = field bin; WRSA concentrations shaded indicated in bold and with a border exceed the maximum and five times the maximum field bin leachate concentrations, respectively.

CONCLUSIONS

Leachates from laboratory and field kinetic tests were compared to WRSA seepage at two different sites, one producing acidic and the other one with neutral drainage. The main findings from this study are summarized below:

- In order to predict WRSA seepage concentrations at Site A (acidic drainage) bulk scaling factors are <1% (based on humidity cell loads) would have to be applied. These scaling factors are significantly lower than those reported previously, commonly using major ion concentrations for model calibration purposes. Overall, bulk scaling factors for major ions tend to be higher than those calculated for minor/trace parameters, unless major ions are solubility-controlled under acidic conditions (*e.g.*, K and Fe by jarosite). This highlights the importance of differentiated water quality modeling for specific ions;
- Bulk scaling factors calculated for the neutral Site B, excluding Fe and Al, vary between 0.01% and 4% where major ion scaling factors are generally higher (median = 0.8%) than those calculated for minor/trace ions (median = 0.1%). Field bin loading rates that are on the same order of magnitude or even lower than calculated WRSA pore-water loads suggest that assumptions made for the calculation of WRSA loads are conservative and bulk scaling factors for this site are likely lower;
- For both sites, many species appear to be solubility-limited at a scale of field bin experiments (150-200 kg), which is a factor that should be accounted for in water quality prediction modeling.

ABSTRACT

Column leach tests in the laboratory have been conducted for overburden samples from Lati coal mine in East Kalimantan, Indonesia. The samples consist of three different rock types, namely, potentially acid forming mudstone, non-acid forming mudstone and sandstone. Six columns were prepared for simulation of different layering scenarios between the rock types with one control column. This experiment was aimed to study the performance in controlling the acid mine drainage generation with different rock layer configuration and was conducted over 26 weeks.

The same simulation scenario was also implemented at the mine site with larger columns and sample grain size. The columns were placed in the open air area and exposed to the local climatic condition. An automatic rain gauge was also installed to continuously record the rainfall events.

The analysis was conducted by comparing the leachate collected from both the laboratory and field experiments of the different columns. Similar trends behaviour on the water quality, especially on pH parameter, have been observed in most of the columns except the column containing 100% PAF mudstone and 25% sandstone over PAF materials. Due to its water holding capacity as well as buffering capacity, NAF mudstone shows the potential for capping material.

Keywords: acid mine drainage, column leach test, laboratory experiment, on site experiment.

INTRODUCTION

Geochemical characterization that aims to classify a material as potentially acid forming (PAF) or non-acid forming (NAF) is an important step in the management of acid mine drainage (AMD). Static tests, which include acid base accounting and net acid generation tests, are the most common initial tools used to classify the geochemical conditions. However, static tests are uncertain in some cases and do not give the oxidation rate of sulfide minerals or the neutralization potential of the rock, which are very useful for the prediction of long-term water quality. Therefore, kinetic tests are often conducted to confirm the results of the static test and to get a picture of the quality of water that will leach from sulfide containing rocks that undergo oxidation.

Kinetic tests can be carried out both in the laboratory and in the field with various advantages and disadvantages. In laboratory tests, each input parameter (i.e. interval and volume of flushing water and temperature) and output (e.g. pH and metal content in the leachate water) that will affect each other, will tend to be more controlled when compared with the field test. The field test tends to be highly dependent on local weather conditions during the test. However, kinetic tests conducted in the field are believed to give a better picture of conditions on the ground, although this certainly requires a longer observation time and costs are relatively larger (Frostad et al., 2005).

Laboratory and field scale kinetic tests have been conducted with different layering scenarios between the rock types with one blank or empty column. The rock types include potentially acid forming (PAF) mudstone and non-acid forming (NAF) mudstone, and sandstone taken from Lati coal mine in Berau, East Kalimantan, Indonesia. The climate on Lati mine site is characterized as tropical, with rainfall in the range of 70.7 – 292.2 mm/month, temperature in the range of 21.2 – 35.8°C (average 26.68°C) and relative humidity in the range of 42 - 100% (average 87%).

The objectives of the current study were to compare the results obtained from the field kinetic tests with the laboratory kinetic tests based on the data of 6 columns (and 1 blank column) with similar configurations. They were conducted to provide more confidence in the use of laboratory data for the prediction of acid mine drainage generation of different rock layer configuration.

MATERIALS AND METHODS

Materials

Fresh rock samples consisting of two lithological types, namely mudstone and sandstone were taken from an active coal mine pit in Lati which lies in the late Eosen-middle Meosen Berau sub-basin, part of the Tarakan Basin. By considering the dominant existence of mudstone in Lati mine site, two samples were taken to represent the geochemical characteristics of PAF and NAF mudstone rock. While the sandstone, which exists as lenses between mudstone, is generally dominated by NAF rock type. Geochemical characteristics of the sample based on the static test results, which consist of acid base accounting (ABA) tests and the net acid generating (NAG) tests, are shown in Table 1. The MS-1 sample consists of 0.88% of total sulfur with no neutralizing capacity and produced low NAG pH (3.55), hence categorized as PAF material. On the other hand the NAF categorized MS-2 and SS samples consist of quite low total sulfur content (0.17% and 0.20%), with a small capacity to neutralize acid (5.74 and 1.51 Kg H_2SO_4/ton) and produce high NAG pH (8.72 and 6.63). Comparing with the geochemical characteristic databases of material in Lati Mine, these value were represent the general geochemical condition of this mine.

Table 1 Samples' Geochemical Characteristics

Rock Type	Tot. Sulfur*)	MPA**)	ANC**)	NAPP**)	Paste pH	NAG pH	NAG**)		ANC/MPA
							pH 4.5	pH 7

*) = in % ; **) = in Kg H_2SO_4/ton

Methods

Kinetic tests were conducted using free draining column leach test methods on transparent acrylic columns. Both laboratory tests and field kinetic tests used similar methods of sample placement in the column, with proportional consideration on column diameter and the initial grain size of samples. The C01 and C06 columns consisted of 100% PAF and NAF Mudstone, respectively. The C02 and C03 columns consisted of 75% and 50% PAF mudstone capped by 25% and 50% NAF mudstone, whereas C04 and C05 columns consisted of 75% and 50% PAF mudstone capped by 25% and 50% NAF sandstone, respectively (see Figure 1).

In the laboratory tests, columns with a diameter of 15 cm and a total height of 30 cm were used (Figure 2). The sample volume in the column was around 0.018 m^3, and the sample height in the columns was 25 cm. The sample grain size was in the range of 3 - 5 mm in diameter, which was obtained from crushing and sieving the bulk sample. A 60 watt light bulb was used to simulate solar radiation for 12 hours a day for 6 days in order to maintain the temperature in the range of 30-35 °C. Flushing was conducted with approximately 1,000 ml of de-ionized water in weekly cycles to simulate rainfall.

In the field tests, columns with a diameter of 30 cm and height 60 cm were used. The sample, with a grain size range of 3 – 18 mm after sieving, was placed in the column with a volume of 0.071 m^3 and the sample height in the column of 50 cm (Figure 3). An automatic rain gauge was installed on the experiment location to continuously measure the rainfall.

On both test scales, the leachate water in the collecting bottle/gallon was collected once a week and physical parameters such as pH, electric conductivity, oxidation-reduction potential and total dissolved solids were measured prior to further analysis of the ion and metal contents. In addition, rainfall water was also analyzed in a similar manner for comparison.

RESULTS AND DISCUSSION

Inflow Characteristics

In the kinetic tests, one of the important factors that will control the acid formation characteristics of the sample is the wet and dry cycles; these are a result of the cycle of water flushing in the laboratory test, the occurrence of rainfall in the field test, and of course, the effects of evaporation. Wet and dry cycles simultaneously affect both physical and chemical processes that occur in the column sample. Physically, wet and dry cycles will initiate the occurrence of physical disintegration of the rock. Hence, the rock will experience deterioration and consequently the particle size of rock

matrix will decrease. This condition will increase the total area of reactive surface and will further accelerate the chemical process, both the oxidation rate of sulfide and also the neutralizing reaction (Davis and Ritchie, 1987). On the other hand, from a physical condition point of view, a finer-grained material, in addition to result in low permeability due to small pore size, also has a much higher water holding capacity than the coarse-grained rock (Desavahayam, 2006). The existence of water -as water content in pore space- will control the oxygen diffusion, slaking, and furthermore the reaction rate, both of sulfide oxidation and alkali dissolution, of minerals contained in the rock (Gosselin et al., 2007).

In the laboratory scale tests, the volume of water flushing was 1,000 ml, which represented a rainfall depth of 56 mm. The flushing interval was fixed at 1 week (7 days), which resulted in a fixed dry condition interval of 6 days for each cycle. In the field scale tests, the cumulative rainfall which infiltrated as the flushing water source varied in the range of 23.14 - 192.68 mm, with an average of 67.50 mm within a week (maximum daily was 50.8 mm/day), as shown in Figure 4. These rainfall events resulted in a dry condition interval in the range of 1 – 3 days. Moreover, if the net infiltration is assumed to only occur when the rainfall > 5 mm/day, the dry interval will be increased to 3 – 8 days.

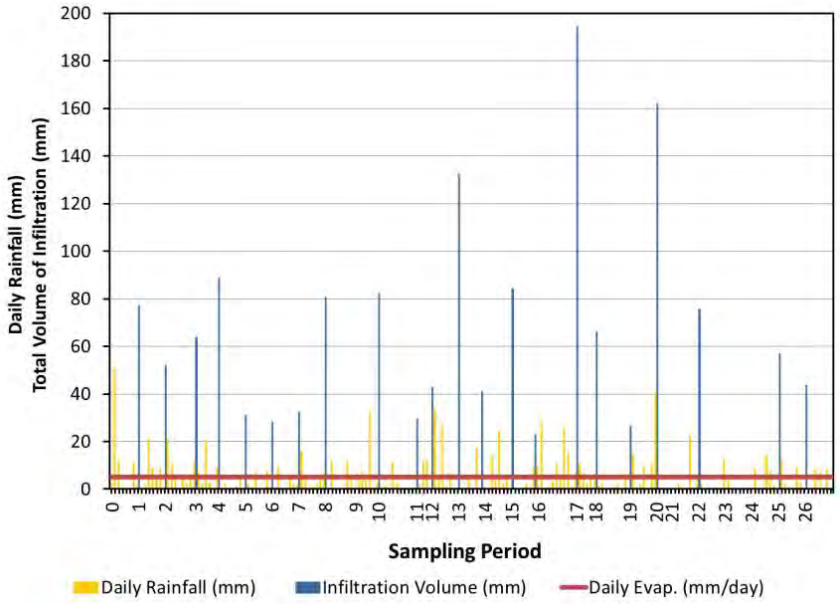

Figure 4 Daily rainfall characteristics during the field kinetic test and Total Infiltration Volume in the Blank Column

The leachate volume from each column throughout the test, and the ratio to rainfall or flushing volume, is summarized in Table 2. In the laboratory scale tests, the leachate volume is similar for each column; within the range of 300 – 800 ml/week, with ratios in the range of 27 – 87%. On the other hand, the field scale tests have various leachate volumes from each column with a minimum leachate volume ranging from 330 – 750 ml and the maximum volume in the range of 11.000 – 12.610 ml, with ratios of leachate volume to rainfall of 8 – 95 %. The column with mudstone in the upper layer tended to be more resistive in water infiltration compared to the column with the

sandstone layer, hence resulting in less leachate volume. However, for some cases in the cycle period with long intervals, the column with a thicker sandstone layer may produce less leachate volume due to the store and release effect (e.g. C05). This result has shown that in the field scale tests, the deep infiltration of water that will become leachate is very dependent on the physical properties of the sample (i.e. particle size, permeability, etc.), as they experienced similar weather conditions.

Leachate characteristics

The summary of several water quality parameters (e.g. pH, Electric Conductivity and Sulfate content) for 26 weeks of monitoring is summarized in Table 3. In general, both laboratory kinetic and field kinetic tests resulted in similar time series trends in pH as seen in Figure 5 to Figure 7, with a slight difference in the occurrence period of acid formation among those kinetic test.

Table 3 pH, Electric Conductivity and Sulfate contents of column leachates

Column	Material Composition (%)	Test	pH		EC mS/cm		Sulfate (mg/L)	
			Min	Max	Min	Max	Min	Max
C01	100 % PAF	Lab	5.99	7.80	2.19	6.47	1198	5069
		Field	3.53	6.76	3.43	7.10	960	1340
C02	25% NAFms over 75% PAF	Lab	6.26	7.73	1.26	5.74	1176	4333
		Field	4.71	7.70	1.77	6.44	860	1320
C03	50% NAFms over 50% PAF	Lab	7.02	8.28	0.42	5.47	237	3749
		Field	7.20	8.01	1.20	5.91	600	1340
C04	25% NAFss over 75% PAF	Lab	2.20	7.12	1.82	9.52	3277	7392
		Field	3.32	8.26	2.11	7.14	900	1480
C05	50% NAFss over 50% PAF	Lab	2.63	7.96	1.49	6.09	1922	4846
		Field	3.59	8.87	1.86	6.62	1020	1380
C06	100% NAF	Lab	7.07	9.15	0.33	1.45	19	266
		Field	7.23	9.19	0.32	6.62	20	1260

Comparing the columns containing 100% PAF Mudstone, similar trends have been shown for the first eight weeks and the pH values are the neutral condition (see Figure 5 left). Afterward, the pH values in the field columns decreased significantly to below 5, indicating an acid formation. In the laboratory columns, the pH values remain neutral, probably because of the water holding capacity in the fine-grained sample is preventing oxidation during the dry cycle due to regular flushing. In the 100% NAF Mudstone column the pH values in the field test and in the laboratory are quite consistent with the results of NAG pH and paste pH, i.e. in the range of 7 to 9.

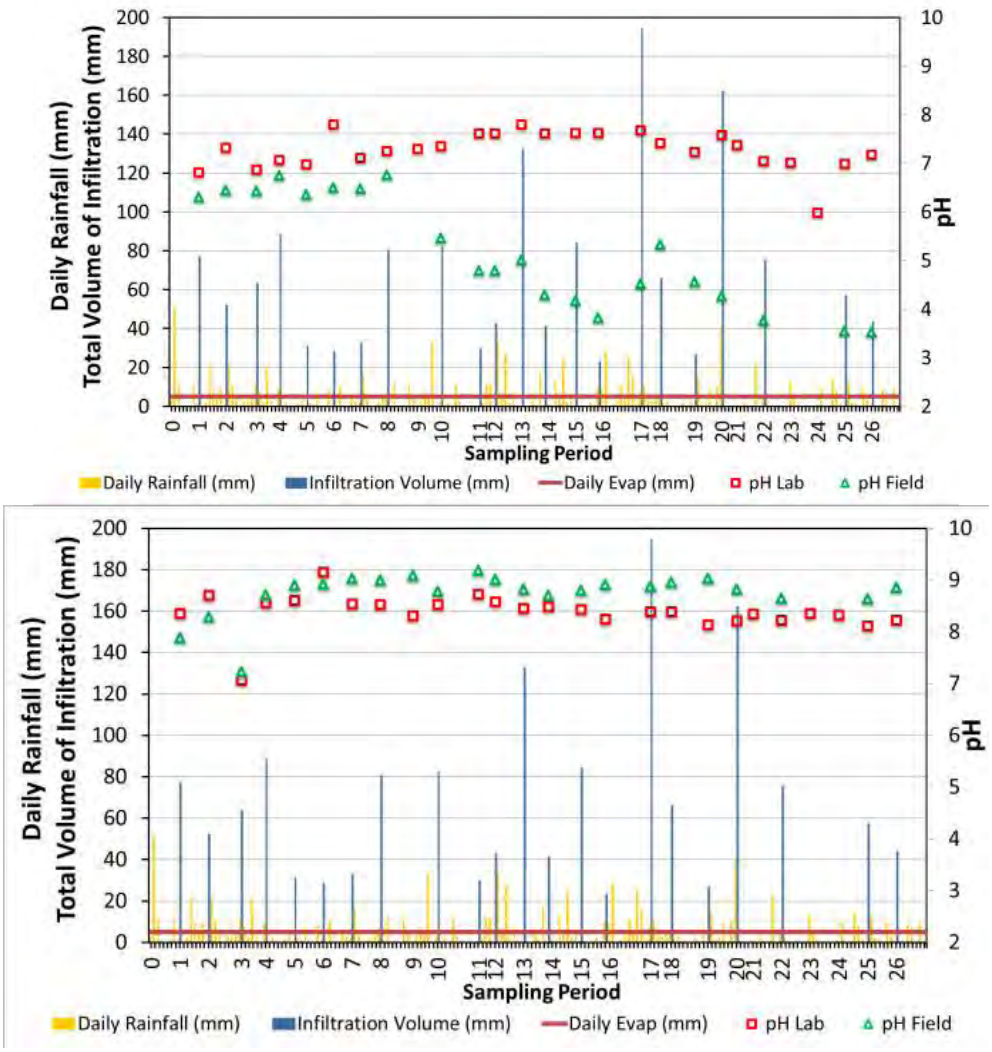

Figure 5 kinetic test result of the C01 column-100% PAF (left) and the C06 column-100% NAF (right)

Figure 6 shows the results of column C02 and C04 containing 75% of PAF material capped by 25% NAF Mudstone and 25% NAF Sandstone whereas Figure 7 shows the results of column C03 and C05 containing 50% of PAF material capped by 50% NAF Mudstone and 50% NAF Sandstone respectively. These columns are aimed to identify the capping characteristics of both NAF materials.

Fine-grained NAF Mudstone has the capacity to prevent oxygen diffusion into the PAF layer due to its water holding capacity but after 24 weeks the pH values decreased (see Figure 6 left). It seems that the thin NAF Mudstone layer is not sufficient for maintaining a consistent capping characteristic (as well as not enough in buffering capacity), compare with the capping performance of 50% NAF Mudstone which indicated no net-acid generation along the test period as shown in Figure 7 left.

On the contrary, acid formation in the laboratory column that had 25% and 50% of NAF Sandstone over the PAF material occurred starting in the 6th week, and the pH value decreased from around 7 to as low as 2.2 (see Figure 6 right and Figure 7 Right). Sandstone seems unable to prevent oxygen diffusion below the level where the acid product can be buffered by the low ANC (1.51 kg H_2SO_4/ton of rock). Similar trend of pH value

decreasing were also observed from field test, although had a lower decreasing rate compare with the laboratory test. An anomaly also can be observed where the pH value in the column with 25% NAF Sandstone started to decrease almost 13 week later than the column with 50% NAF Sandstone, which indicate a slower rate of acid formation. This anomaly is being observed along with the continuously monitored field kinetic test.

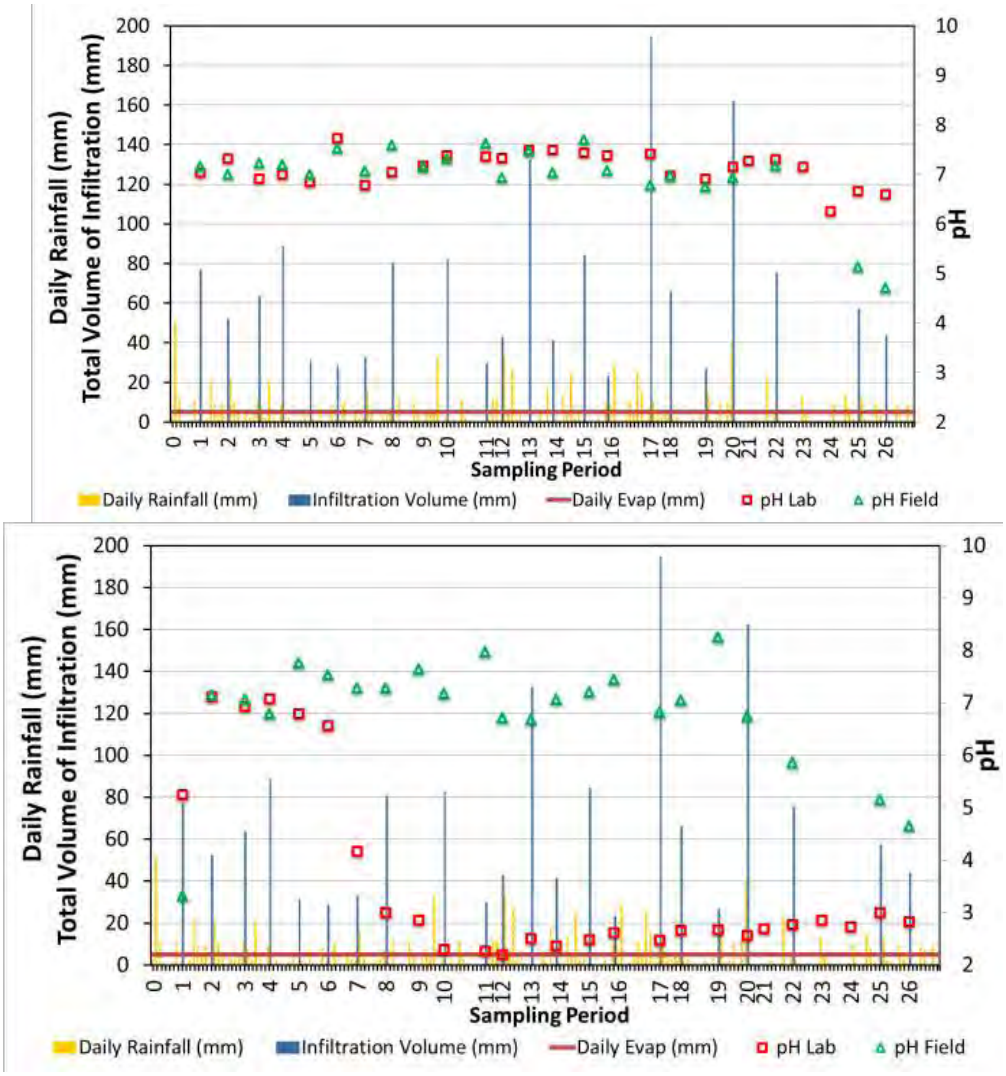

Figure 6 Kinetic test results of the C02 column with 25% NAF Mudstone (left) and the C04 column with 25% NAF Sandstone (right) over 75% PAF

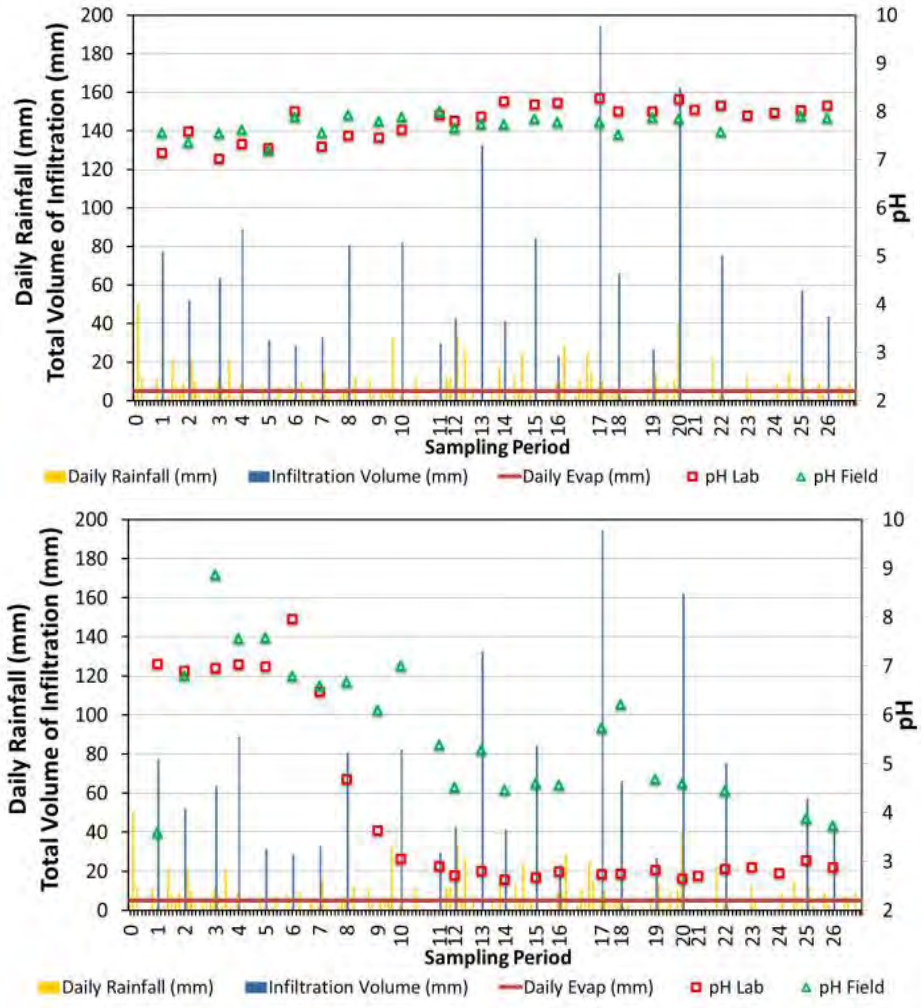

Figure 7 Kinetic test results of the C03 column with 50% NAF Mudstone over 50% PAF (left) and the C05 column with 50% NAF Sandstone over 50% PAF (right)

CONCLUSION

A kinetic test using free draining column leach tests has been conducted in the laboratory and on site using the samples taken from Lati coal mine in Berau, Kalimantan. Samples consisted of potentially acid forming mudstone and non-acid forming mudstone and sandstone. Columns with different configurations, namely 100% PAF mudstone, 100% NAF mudstone, 25% of NAF mudstone over PAF, 50% of NAF mudstone over PAF, 25% NAF sandstone over PAF and 50% NAF sandstone over PAF, were analysed in order to compare the results in the laboratory and on site. In general, similar trends were observed in the experiment, in the laboratory, and on site kinetic test.

The water inflow pattern, i.e. regular flushing versus natural rain condition, is playing an important role in characterizing the leachate chemistry. In fine grain material, the regular weekly flushing could retain water in the sample pores in a relatively saturated condition, and consequently prevent or minimize the oxygen diffusion in addition to the existence of acid buffering capacity of the

capping layer. These characteristics could be beneficial when using fine grain material as capping in PAF encapsulation prevention method.

Since the analysis is only conducted for 26 weeks, more interesting results are expected when longer monitoring data can be obtained, particularly from on-site experiments.

ABSTRACT

The construction of a large-scale hydroelectric project will result in the excavation of approximately 8 million cubic meters of sulfidic bedrock that will be permanently stockpiled. As part of a comprehensive geochemical characterization program, two Field Leach Pads were constructed to gain an understanding at a field scale of the relationship between physical and geochemical processes that may affect differences water quality between compacted and un-compacted material, during and after construction.

The Field Leach Pad 1 (West) is 2.4 meters high and was constructed in two 1.2 meter compacted lifts. Field Leach Pad 2 (East) is 2.1 meters high and was construction in two 1.05 meter uncompacted lifts. The sulfidic bedrock material used for Field Leach Pad construction was obtained from fresh excavated material. The lift height was selected based on engineering design at the time of Field Leach Pad construction. Both Field Leach Pads were instrumented with continuous multichannel tubing (CMT) multilevel systems (for oxygen and carbon dioxide monitoring and porewater sampling); temperature probes; water content sensors; and matric potential sensors. Information gained from the instrumentation will be used to evaluate site-specific factors and properties on sulfide oxidation rates and seepage chemistry.

This paper describes Field Leach Pad construction, instrumentation, and the preliminary results that includes: two leachate sampling events that (May 2013 and September 2013), one oxygen and carbon dioxide monitoring event that (September 2013), and the results from the sensors spanning the time period of August 2013 to April 2014. The preliminary results support the benefit of placing and compacting excavated shale. The gas concentrations and moisture content values suggest that the compacted Field Leach Pads should show lower reactivity over time and lower loading rates to the environment.

INTRODUCTION

The complexities of physiochemical processes that occur at the field-scale in waste rock piles and the scaling of laboratory reaction rates has been the subject of intensive and extensive research. At the 2012 ICARD conference, for example, many papers were focused on presenting on this subject (Andrina et. al., 2012; Kempton, H, 2012; Shaw and Samuels, 2012; Smith et. al., 2012a; Smith et. al., 2012b). While considerable debate remains on what methods are most appropriate for scaling, what is recognized is that field scale kinetic tests, at varying scales, can provide insights into key site-specific factors affecting the geochemical behavior of sulfidic waste materials and the subsequent loading rates and water quality.

A geochemical characterization program was established in 2009 to assess the potential for acid rock drainage and metal leaching (ARD/ML) from sulfide-bearing bedrock. As part of this program, Field Leach Pad (FLP) testing was undertaken as part of a larger effort to inform waste management strategies. Two FLPs were constructed in late 2012 using excavation sulfidic shale with minor siltstone (hereafter referred to as shale) with the objectives of:

- Assessment leachate quality generated under site-specific field conditions during the first year of operation,
- Comparison of leachate quality to kinetic tests at other scales,
- Gaining an understanding of the physical processes acting within the FLPs, and
- Asessment of the initial effectiveness of placing and compacting materials in 1 m lifts on oxygen ingress and water infiltration as an engineered management strategy to mitigate ARD/ML.

Preliminary results are presented for the FLPs that include:

- two leachate sampling events that occurred in May 2013 and September 2013,
- one oxygen and carbon dioxide monitoring/sampling event that occurred in September 2013, and
- data and results from the instrumentation sensors from August 2013 to April 2014.

METHODOLOGY

The types of sampling, measurements and testing carried out for the FLPs were: sampling and analysis of leachates; measurement, sampling and analysis of gases; measurement of changes in moisture content, and temperature measurements. Analytical testing of leachates and gases were carried out at Maxxam Analytical in Burnaby, British Columbia, Canada.

Field Leach Pad Construction and Instrumentation Installation

Field Leach Pad 1 (West) is 2.5 metres (m) high, and was constructed with sulfidic shale placed and compacted in two 1.25 m high lifts. Field Leach Pad 2 (East) is 2 m high and was constructed with the same material but uncompacted in two 1 m high lifts. Table 1 provides a summary of the instrumentation installed. Figure 1 shows a cross-section of each FLP and the location of the wells and instruments.

Continuous multichannel tubing multilevel piezometers (CMTs) were installed to monitor oxygen (O_2) and carbon dioxide (CO_2). Two CMT were installed in FLP 1 (West) with seven ports in each. Two CMTs were installed in FLP 2 (East) with six ports each. Temperature probes were attached to

the CMTs to monitor temperature. Three probes were installed per CMT and, where possible, were attached at the same depth as a CMT port. Campbell Scientific model CS650-L water content reflectometers were installed to measure the volumetric moisture content. A total of 10 reflectometers were installed in each FLP.

Table 1 Field Leach Pad Instrumentation Installation Summary

Instrument	Description	Supplier	Parameter
CS650-L	Soil water content reflectometer	Campbell Scientific	Volumetric water content
229-L	Water matric potential sensor	Campbell Scientific Canada Corp.; calibration O'Kane Consultants	Water flux
109-L	Temperature probe	Campbell Scientific	Temperature
CMT Multilevel System	Continuous Multichannel Tubing piezometer	Solinst Canada Ltd.	Porewater quality, O_2, CO_2
CR1000 Datalogger	Measurement and control system for data acquisition	R.S.T. Instruments Ltd./ Campbell Scientific.	-
Remote Multipexer	Increases number of sensor inputs.	R.S.T. Instruments Ltd.	-
Weather Station	Provides meteorological measurements	R.S.T. Instruments Ltd./ Campbell Scientific Canada Corp.	Precipitation, temperature, barometric pressure, wind speed/direction

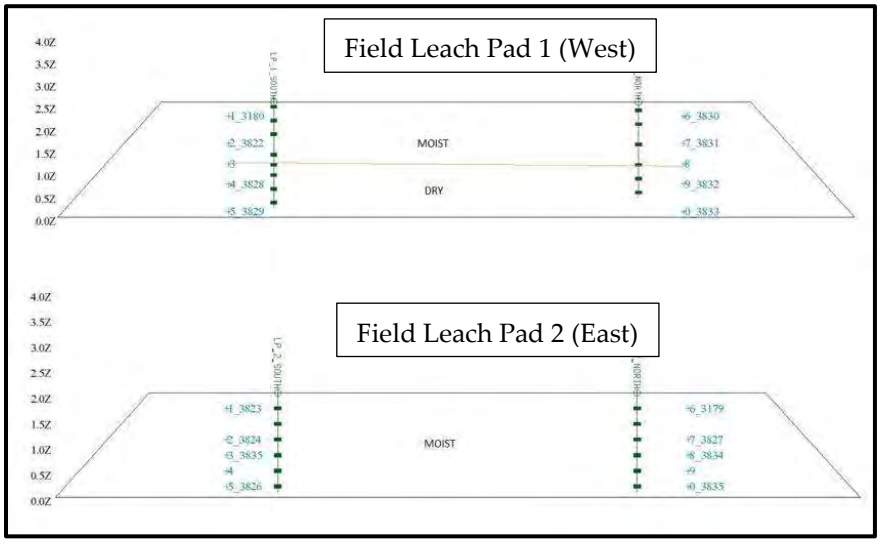

Figure 1 Field Leach Pad Sections: Green bars represent CMT ports. Blue crosses represent 650 and 229 sensors.

Surface Runoff and Infiltration Seepage Sampling

Leachate samples were collected from two locations: collection barrels (designed to collect infiltration seepage only) and collection ponds (designed to collect surface runoff and infiltration seepage). The following parameters were measured or analyzed: pH, electrical conductivity, oxidation-reduction potential, acidity, sulfate, total alkalinity, fluoride, chloride, total suspended solids, total dissolved solids, turbidity, and 54 total and dissolved metals suite. The CMTs were installed to collect porewater samples from within the FLPs; however, no porewater was present during the first year.

Instrumentation Monitoring and Data Logging

Instrumentation data logging commenced in August 2013 following installation and consisted of temperature, soil water content and soil matric potential. Monitoring data collected from August 2013 to April 2014.

Oxygen and Carbon Dioxide Sampling

The CMTs were used for the purpose of monitoring O_2 and CO_2. The first gas sampling/monitoring event took place from September 17th to September 18th, 2013. A GEM2000 gas monitor was used to take in-situ readings at each CMT port. Samples were also collected at select CMT ports to confirm in-situ readings. The samples were collected in Summa canisters and sent for analysis of gas composition.

RESULTS AND DISCUSSION

When sulfide minerals such as pyrite are exposed to water and oxygen; acidity, sulfate and elevated metals concentrations of are produced. Understanding the physical characteristics and processes acting on the material on site, can aid in scaling the laboratory water quality results and loadings to the field, and inform the waste management strategies. These physical processes include water infiltration, oxygen transport, multiphase flow and heat transfer (Lefebvre et. al., 1998; Wels et. al., 2003; Lahmira & Lefebvre, 2007).

The key parameters monitored by the instrumentation in the FLPs include oxygen, carbon dioxide, temperature, moisture content and matric potential. It is important to evaluate the relative influence of these parameters on sulfide oxidation and weathering reaction rates. For example, an oxygen supply is required for sulfide oxidation. Oxidation is an exothermic reaction and results in increased temperature. Changes in temperature and/or pressure may modify the oxygen transport mechanism from diffusion to advection (Wels et. al., 2003). Advection is more efficient at supplying oxygen and sustains higher oxidation rates at greater depths (Lahmira & Lefebvre, 2007).

Comparison of Cumulative Loadings

Precipitation that falls onto the FLPs eventually reaches the collection ponds either as infiltration or runoff. The collection ponds are open to the environment and, as a result, receive additional precipitation and also undergo evaporation. The leachate collection barrels are closed to the environment and only receive seepage that infiltrates through the FLPs.

The flows into the collection barrels and ponds were not measured therefore a number of methods for estimating output volumes for both the collection barrels and the sumps were investigated

based on measured and theoretical values. Loadings were calculated using the different outputs and compared. The most appropriate methods were selected and used to calculate the loadings presented here. The parameters presented here are based on previous shake flask extraction, humidity cell and Field Leach Barrel results for the shale unit.

The results show that the seepage loadings are up to one order of magnitude less than the runoff and seepage loadings combined. It can be inferred from this comparison that an increase of water volume from runoff will increase the loadings in the runoff and seepage combined while the concentrations will decrease.

As discussed earlier, the FLPs were constructed predominantly shale (Unit A) with minor siltstone (Unit B). Cumulative loadings for sulfate, calcium and magnesium over the first year of operation are presented for humidity cells, FLBs, and the seepage and combined seepage and runoff loadings from both FLPs in Figure 2. Overall, there was a clear decreasing sequence of cumulative loadings from humidity cells, to FLBs to FLP runoff and seepage to FLP seepage only (Figure 3 and Figure 4). Differences in cumulative sulfate loadings between humidity cells and FLPs were 4 to 7 times lower. Cumulative calcium loadings between humidity cells and FLPs were similar to sulfate and cumulative calcium magnesium loadings were up to 19 times lower (Figure 2a).

The differences in key metal cumulative loadings was more pronounced, with cumulative loadings up to more than one order of magnitude lower for aluminum, arsenic, cadmium, iron and zinc (Figure 2b).

This relative behavior is expected as the humidity cells have the smallest particle size (more surface area available for reacting), the highest water to solid ratio, and humidity cells are flushed weekly. The FLPs have the largest particle size overall, the lowest water to solid ratio, and are subject only to natural precipitation.

Both FLPs showed similar cumulative loadings. The compacted lifts of Field Leach Pad 1 (West) do not appear to have had a significant impact on cumulative loadings relative to Leach Pad 2 (East). However, it can be observed that seepage only cumulative loadings from Field Leach Pad 1 (West) were lower for sulfate, iron and aluminum.

Instrumentation

Oxygen and Carbon Dioxide

Sulfide oxidation consumes oxygen (O_2) and produces sulfuric acid, which can react with carbonate minerals, if present, to produce carbon dioxide (CO_2) gas.

There is a good correlation between O_2 and CO_2 readings (Figure 3). In 3 of 4 CMT's there was a corresponding decrease in O_2 with increasing CO_2. Overall, the FLPs represent an oxidizing ARD environment where O_2 is being consumed via pyrite oxidation, which produces acid that reacts with carbonate minerals to produce CO_2 gas.

The O_2 and CO_2 profiles for the north CMT of FLP 1 (West) suggest that compaction has not had a significant effect on oxygen infiltration. The O_2 and CO_2 concentrations at the bottom of the FLP may have been the result of oxygen flow through the dry zone located between 1.4 and 2.2 m depth. Overall, there was an increasing O_2 consumption and CO_2 production with depth to 1.8 m depth. The moist-dry contact observed during installation does not appear to have had any effect on the O_2 and CO_2 concentrations. Overall there was an O_2 consumption and CO_2 production to a depth of 0.8 m depth, below which concentrations remained constant.

The O_2 and CO_2 profiles for the north CMT of FLP 2 (East) suggests no compaction has not had a significant effect on limiting oxygen infiltration. Overall there was steady O_2 consumption and CO_2 production to a depth of 1.8 m depth, the maximum depth monitored. However, both profiles suggest that rapid surface weathering of the shale may have results in a weathered skin that may act as a cover at limiting O_2 consumption and therefore CO_2 production.

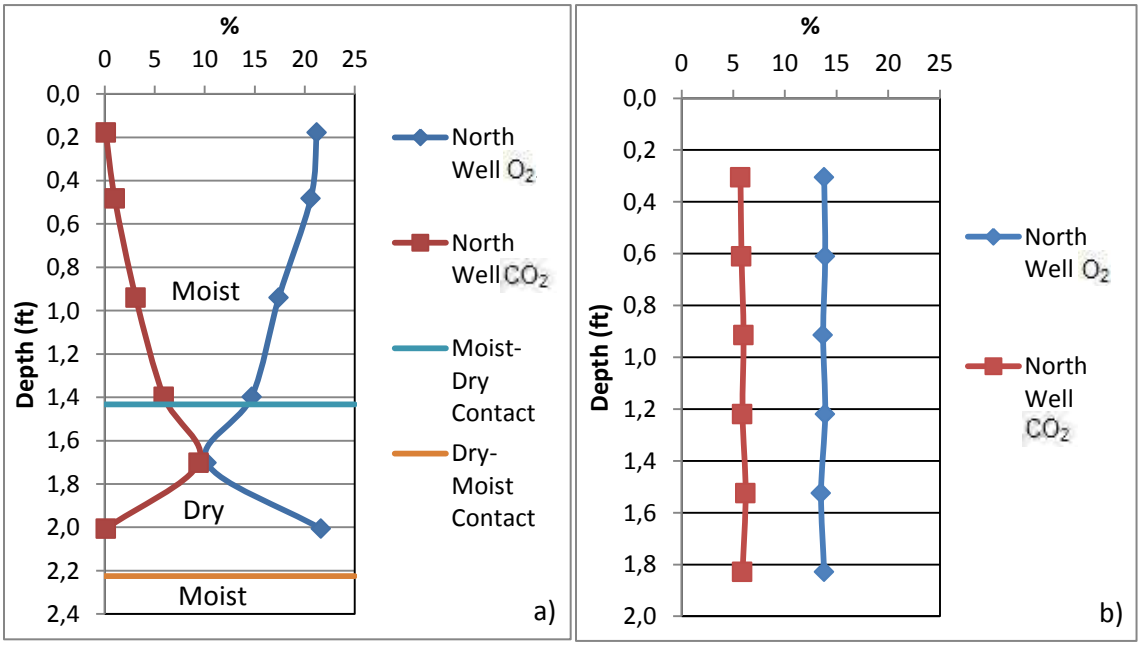

Figure 3 Oxygen (O_2) and Carbon Dioxide (CO_2) Profiles: **a)** Field Leach Pad 1 **b)** and Field Leach Pad 2

Notes: Moist and dry zones were observed at the time of installation and are included for reference only. It is unknown if they have changed.

Temperature

Temperature can be an indicator of sulfide oxidation. The temperature profile in a waste stockpile depends on the rate of heat produced from pyrite oxidation (an exothermic reaction), on ambient temperature changes at the surface of the waste stockpile and by heat diffusion (Ritchie, 1994; Lahmira et. al., 2007). If there are temperatures significantly higher than ambient within the waste stockpile, this suggests that rates of sulfide oxidation are high.

Figure 4**¡Error! No se encuentra el origen de la referencia.** shows an example of the monthly average temperature profiles within the FLPs. The temperatures within the FLPs were generally warmer than the ambient air temperatures at surface, primarily due to sulfide oxidation. In the summer months, temperatures decreased with depth, but overall were warmer than ambient air temperature. The highest temperatures within the FLPs occurred in August with a maximum of 20 °C. In the winter months, temperatures increased with depth with up to 20°C difference between the ambient air temperature and the base of the FLPs.

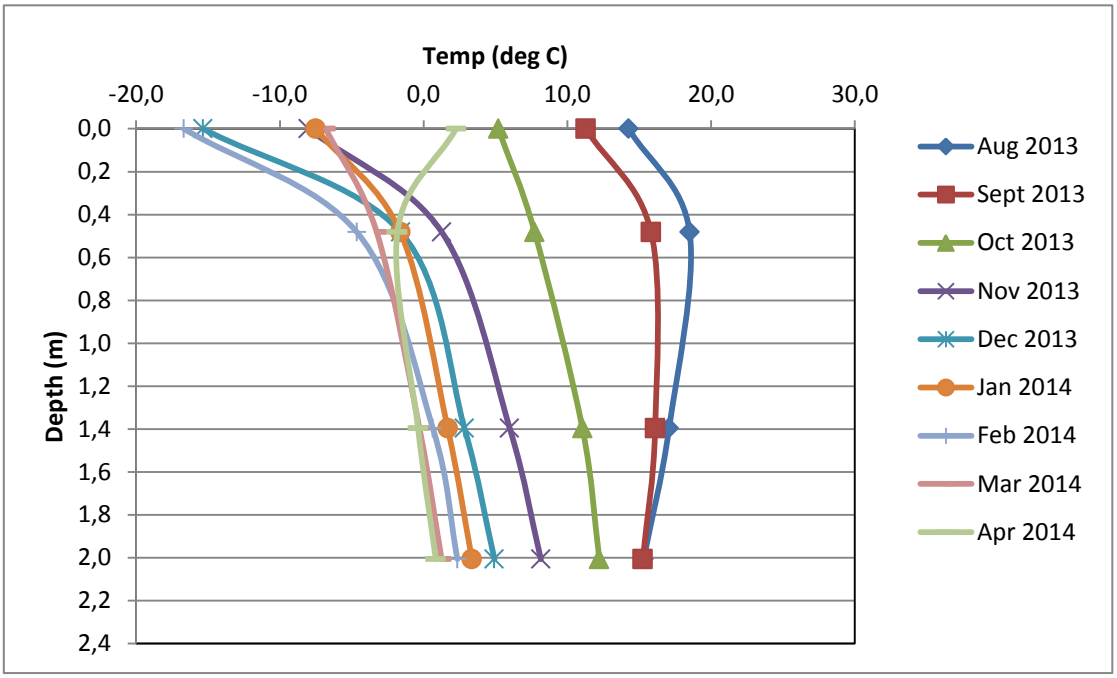

Figure 4 Average Monthly Temperature Profile for Field Leach Pad 1 (West) North CMT

Moisture Content

Moisture content can be used to evaluate the degree of saturation and the permeability of the material in response to precipitation events and seasonal variation.

Figure 5 shows the average monthly moisture content profiles. At the north end of FLP 1 (West), the water content increased with depth until the upper contact of the observed dry zone at 1.37m and then decreased slightly. In FLP 2 (East), water content increased with depth at both the north and south ends. In both FLPs, the uppermost sensors showed greater seasonal variability and the lower-most sensors were relatively stable throughout the year.

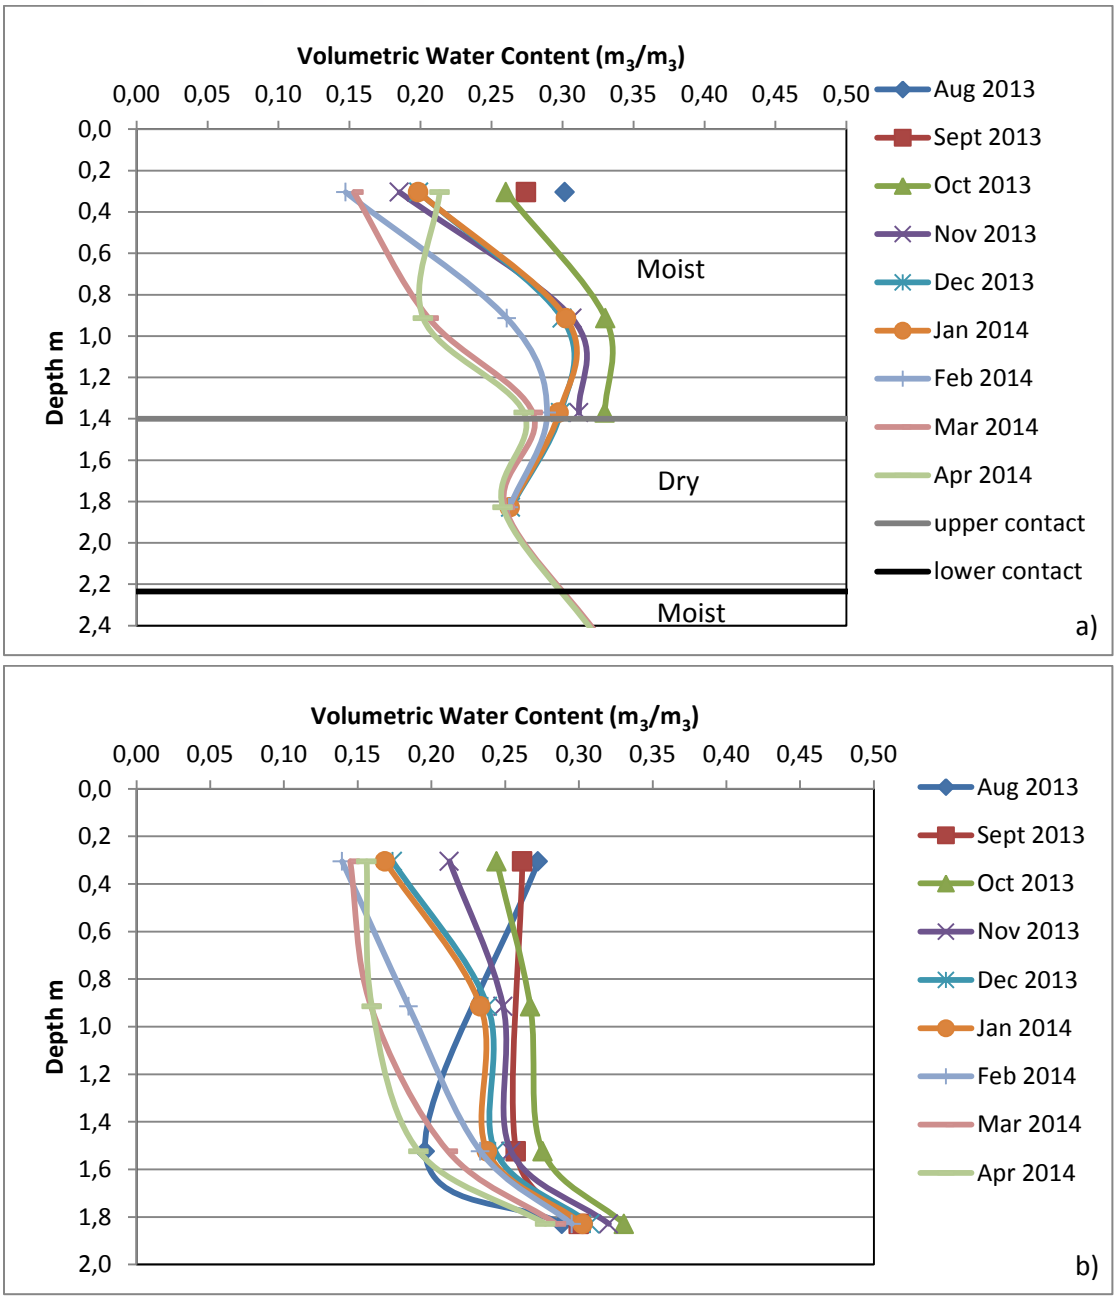

Figure 5: Average Monthly Volumetric Water Content Profile: a) Field Leach Pad 1 b) and Field Leach Pad 2

CONCLUSION

The compacted lifts of FLP 1 (West) does not appear to have had a significant impact on water infiltration or influenced corresponding water quality and cumulative loadings in the first year of monitoring. Both FLPs show similar water quality and cumulative loading rates, despite field observation of moist and dry zones at the time of instrumentation installation. However, the cumulative loadings of sulfate, iron and aluminum from FLP 1 (West) were notably lower than for

FLP 2 (East) Therefore there is some indication that compaction may result in measurable performance change over time.

The compacted cover of FLP 1 (West) may affect oxygen ingress. The north CMT showed oxygen gradually decreasing with depth as would be expected; but the south well shows a dramatic decrease at approximately 0.6m with a corresponding increase in carbon dioxide. This is likely attributable to the compacted cover or it may be the result of variability in grain size and material composition. In general, laboratory oxygen and field oxygen measurements were in agreement and support the observed field trends.

Both FLPs showed similar moisture content ranges, with greater seasonal variability near surface. However, the compacted lift in FLP 1 (West) may impact water content below the upper lift at approximately 1.2 m by impeding infiltration. This is seen by the decreasing trend in measured water content below 1.2 m. In addition, there were field observations of a dry zone at the time of instrumentation installation. FLP 2 (East) showed an overall increasing trend in measured water content with depth.

The preliminary results support the benefit of compaction and lifts. The gas concentrations and moisture content values suggest that the compacted FLPs should show lower reactivity over time and lower loading rates in seepage and surface runoff to the environment. The results also indicate that cumulative loadings are variable but more than one order of magnitude lower for aluminum, arsenic, cadmium and zinc than determined from humidity cells of the same material.

ABSTRACT

Following successful small-scale compost-based bioreactor (tank size 3.75 m^3; flow rate 1.1 L/min) metal mine treatability trials undertaken by Newcastle University, a full-scale vertical flow pond treatment system was constructed in 2014 at the abandoned Force Crag Mine (Cumbria, UK). Metal concentrations in the mine water are sufficiently high to cause the receiving water course, the Coledale Beck, to fail UK environmental quality standards. The innovative system remediates the baseflow of mine water (6 L/s), which contains elevated concentrations of zinc (3.8 mg/L) in a treatment area of 1250 m^2 with a target residence time of ~14 hours.

Force Crag is a remote site located within a National Park that is popular with tourists and walkers. The mine site, including the underground workings, buildings and mine surface, are owned and managed by the National Trust (a UK historical conservation charity). Construction of a treatment system in this isolated, open access, rugged area resulted in challenges that needed to be considered in the design process. The novel nature of the treatment technology deployed at the site required any scheme to be designed to enable rigorous scientific investigation of the system to prove the design concept. Furthermore, operational issues (*e.g.* quantities of gas release) that could result from the full-scale system also needed to be addressed.

All of these challenges were overcome, resulting in the successful delivery of a new treatment technology. This paper highlights the engineering and permitting aspects of up-scaling from a trial system to a full-scale novel treatment methodology.

Keywords: mine water, treatment, construction, full-scale, metal mines

INTRODUCTION

Novel mine water treatment technologies are continually being developed in both the academic and commercial sectors to tackle the problem of removing dissolved divalent metals from base metal mine discharges. Although well-established methods exist for the passive removal of iron, *i.e.* aeration cascades, settlement lagoons, aerobic reed beds and reducing alkalinity producing systems (RAPS) as described in the PIRAMID Guidelines (2000); passive techniques designed to remove other common contaminant metals such as zinc, cadmium, copper, lead etc., which are more difficult to precipitate from mine waters than iron, are less common. Active treatment methods, such as the lime dosing plant currently operating at Wheal Jane Mine in Cornwall, UK (Wyatt *et al.*, 2013), add an alkali to the water to increase the pH sufficiently to allow the formation of carbonate and/or oxy-hydroxide mineral species to precipitate, producing an ochre sludge. Systems such as these are expensive to operate however, requiring continuous staffing levels with high electricity consumption, in addition to the use of large quantities of chemical products. Furthermore, active systems often generate significant volumes of metal-rich sludge, which not only contain the metals themselves, but also the supplementary component of the chemical additions; which in the case of lime dosing, can be considerable. Consequently, active treatment systems, although a very successful option, often have both high capital and operational costs; the typical operational costs for the Wheal Jane mine water treatment facility for example, are £1.5M per year. For schemes that are in effect required for perpetuity, such systems are far from ideal. The desire to reduce high capital investment and high operational costs are two of the main drivers for researchers to develop alternative, more passive and accordingly more cost effective, treatment methodologies.

Laboratory scale trials are the first stage in the development process of any passive mine water treatment technology, which if proven successful, progress forwards to pilot-scale trials. However, for the often small-scale nature of pilot trials, important issues such as supply of materials, size of treatment areas, construction requirements, operational needs, variable or flashy flow rates, regulatory permits and local climatic variations are generally readily overcome. When attempts are made to scale-up a pilot-sized system to a full sized operational site however, these are factors that must be considered and addressed. Subsequently, although many successful pilot-sized treatment systems are described in the literature, the practicalities of the 'real world' can result in relatively few of these methodologies being successfully deployed in the field at the full-scale.

This paper discusses the challenges that can occur when a successful small trial passive system is up-scaled to a full sized, operational system situated in the natural environment.

Dealing with abandoned metal mining pollution in England

Throughout England, there has been historic mining of metals across many regions. However, in contrast to the legacy resulting from the coal mining industry, which is subject to legislation in the UK, there is no one single body responsible for metal mining pollution.

Following the transposition of the European Water Framework Directive (WFD) (2000/60/EC) in to UK national law in 2003, the Department of Environment, Food and Rural Affairs (Defra) has taken measures to establish a remediation program for water pollution from non-coal (predominantly metal) mines which affect up to 2 500 km of rivers in England. In 2012, a consortium published a report (NoCAM) identifying and prioritizing the principle non-coal mine water impacts present in England (and Wales) (Jarvis and Mayes, 2012). In 2011, Defra allocated funds to the Coal Authority (CA), based on the organization's *c.* 20 years experience in mine water remediation, in conjunction with the Environment Agency (EA), to deal with pollution from abandoned non-coal mines.

Force Crag Mine, Cumbria, UK

Force Crag Mine is an abandoned lead-zinc-barites mine located in the Lake District National Park in Cumbria (North West England), near the village of Braithwaite (Figure 1). Situated 7 km West of Keswick, in the headwaters of the Coledale Valley, the mine site covers an extent of approximately 1.2 km long from the banks of the Coledale Beck westwards towards the ridge of Grisedale Pike. Hosted in Ordovician siliciclastic sediments (Kirk Stile Formation), the east-west trending, vein-hosted mineralization present at Force Crag is a zoned ore body dominated by galena (lead-ore) and sphalerite (zinc-ore) with barite and quartz gangue (Tyler, 2005).

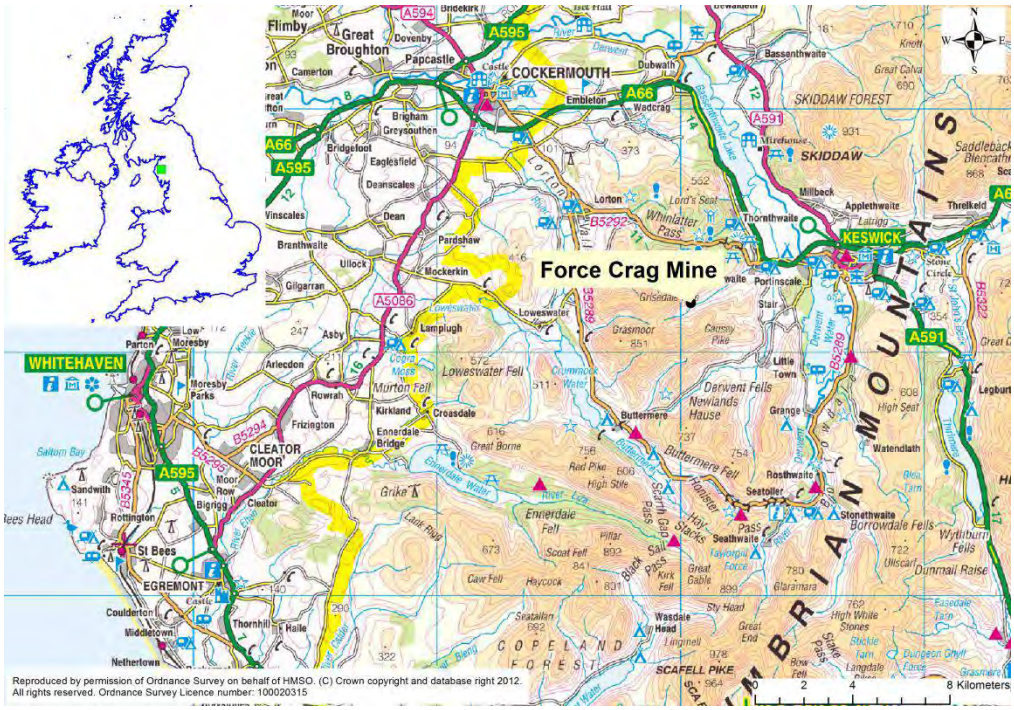

Figure 1 Location map for Force Crag mine and surrounding area

Mining has occurred at Force Crag since at least the 15th Century, although the most intensive period was during the 19th Century when the mine was worked intermittently for lead-ore and barite; operations finally ceased at the site when the mine closed in 1992 (Tyler, 2005).

Force Crag mine workings comprise of a series of nine individual levels driven into the mountainside. Level Zero forms the lowest level near the valley floor, and the workings are currently drained from both Level One and Level Zero. Despite the occurrence of some diffuse contamination originating from the processing and mining waste at the site, the Level One discharge has been have identified as the main point source of metal contamination in the Coledale Beck at Force Crag. The Coledale Beck is one of the main tributaries to the Newlands Beck and the impact of the pollution resulted in the Newlands Beck being ranked at number 16 in England and Wales (Jarvis and Mayes, 2012) on a priority list; in 2013, the EA raised Newlands Beck to rank 1 in England after collection of further data.

Mine Water Chemistry

The mine water at Force Crag is circum-neutral with elevated concentrations of zinc and cadmium, combined with relatively low concentrations of iron. Consequently, the receiving watercourses, the Coledale Beck and Newlands Beck, fail the UK environmental quality standards (currently classified as failing with moderate status under the WFD) for zinc (~12 µg/L) and cadmium (0.08 µg/L) for a reach of at least 10 km. A summary of the chemical characteristics of the mine water from Level One is provided in Table 1. The flow from Level One is relatively flashy in nature; on average, the flow rate is 8-10 L/s, although flow rates of >40 L/s have been recorded after storm events in 2014.

Table 1 Typical mine water chemistry (total metals) of the Level One discharge, Force Crag Mine (n=11 samples, data collected in 2014)

	pH	EC µs/cm	Alkalinity mg/L	Calcium mg/L	Magnesium mg/L	Iron mg/L	Zinc mg/L	Cadmium µg/L	Lead µg/L	Sulfate mg/L
Mean	7.1	150	25	13	5	0.63	3.8	18	40	31
Min	6.9	119	13	7	3	0.34	2.1	11	27	18
Max	7.4	270	56	15	5	0.80	4.9	22	66	38

Stakeholders

To facilitate the successful deployment of a novel mine water treatment system at the Force Crag mine site, a large number of stakeholders were required to work together. A group comprising of four organizations (CA, EA, Newcastle University and National Trust), formed the main body of stakeholders that collaborated closely to deliver the mine water treatment scheme. Overall however, a total of eleven different organizations (including 3 regulatory bodies) were involved in the project to differing extents. For further information on the methodology adopted by the CA on stakeholder management for this site, the authors direct the reader to Harris *et al.* (2014).

TREATMENT METHODOLOGY

The passive treatment methodology that has been deployed at Force Crag has been developed from laboratory and pilot scale trials undertaken by Newcastle University (NU) funded by Defra and published by the EA (Jarvis *et al.*, 2014). This technique employs an anaerobic compost bio-reactor where sulfate reducing bacteria are exploited to remove metals from circum-neutral mine waters. A key component of this methodology is to ensure that there is sufficient carbon present in the media to sustain the desired microbial community, without promoting competing methanogenic communities which would not attenuate the metals. Over a period of 40 months, the Newcastle team executed a series of simultaneous laboratory column experiments, laboratory-style field column experiments and pilot-scale reactors. One pilot-scale reactor which operated for 24 months, was deployed at Nenthead Mine; an abandoned lead-zinc mine in the North Pennines (Cumbria), located 7 km SE of Alston, with a circum-neutral mine water typically containing ~2 mg/L of zinc.

Pilot-scale systems installed in the field, particularly those which harness biological processes, often require time to allow the system to establish and reach a steady state. In addition, they must also be small enough to provide information on when the system reaches saturation, resulting in breakthrough of the metal contaminant. Important factors which require consideration when

building full scale treatment systems is the longevity of the system, in addition to the size of treatment area required. Consequently, it is crucial that pilot-scale systems provide the necessary data to address these important issues; the system deployed at Nenthead fulfilled these criteria.

Using a down-flow system, the Nenthead reactor treated an average flow of 1.1 L/min for a period of 24 months, successfully removing on average *c.* 70 % of the total zinc concentration, with a mean residence time of ~14 hours. Containing 2.25 m^3 of media mix, comprising of compost (PAS100 British Standards Institution), woodchips and activated digested sewage sludge with a limestone chip under drain, the Nenthead reactor was 2.5 m long, 1.5 m wide and 1.0 m deep (Jarvis *et al.*, 2014). Mixing of the four components, which were sourced locally, occurred on site to reduce heterogeneity in the media. Based on the success of the Nenthead reactor, and particularly the excellent zinc removal rates observed despite the short residence time, the full-scale vertical flow pond (VFP) system at Force Crag was proposed; however, the complexity of building a full-scale system presented a different set of challenges than those typically faced in small-scale systems.

DISCUSSION

Force Crag Mine site has a number of designations, including Site of Special Scientific Interest (SSSI), Special Area of Conservation (SAC) and Scheduled Monument; the site is also a popular tourist region in an area of open access (an area where free access is granted to the public). Furthermore, the Coledale Beck, which flows through the site, is a tributary of the Newlands Beck, which contributes to Bassenthwaite Lake and subsequently, the River Derwent; areas designated as SSSI, SAC and a National Nature Reserve. Contamination from abandoned metal mines has a negative impact on these environmentally sensitive areas; consequently, the remediation of the mine water discharge at Force Crag was identified as being able to deliver significant benefits to the whole catchment. Many of the challenges associated with constructing the system were related to the designations assigned to the site, in addition to the requirements for environmental permitting. This paper focuses on the issues pertaining to the construction and permitting of the scheme.

Construction

Some of the key challenges associated with the up-scaling from a pilot to a full-scale system are related to the construction, engineering and operational considerations for the scheme. This section focuses on some of these issues that occurred at the Force Crag site, and how they were addressed.

Mine water collection and scheme layout: the precursors to construction

Extensive investigations were undertaken by the EA, in conjunction with NU (funded by Defra), prior to construction of the treatment scheme, examining the point sources and diffuse pollution of the Force Crag site and the environmental impact on the Coledale Beck and Newlands Beck. This unpublished work identified the Level One discharge as the main point source of metal pollution at the site and concluded that remediation efforts should be focused on this primary source of cadmium and zinc. In 2013, a system of buried pipework was installed to take the Level One mine water from its original discharge point to the Coledale Beck; a flow measurement weir was also installed with the ability to allow diversion of water to the proposed treatment site.

Discussions with the National Trust and English Heritage were also ongoing during this period to finalize an agreement for the siting of the scheme within the site. Following negotiations between the CA, EA, National Trust and English Heritage, the area of the former tailings pond, located

between the old mine workings and the Coledale Beck, was chosen. This agreement was reached with the understanding that the remediation of the mine water discharge from Level One was part of the 'evolution' of the site from an area of active mining to one of environmental remediation.

Once the scheme location was established, plans were submitted to the local administrative authorities to obtain planning approval. When assessing the impact of a new development, planning officers need to understand the scale of the development and what the visual impact will be, especially in a sensitive region such as a National Park. At this point in time however, the trial at Nenthead was still ongoing; concept designs were therefore produced to provide the authorities with a high level plan using the layout and performance of the Nenthead reactor as a guide. Figure 2 shows the final layout of the scheme, which is not dissimilar from the plans originally submitted to the local planning authorities. The original plan envisaged a single treatment pond; however, a decision was subsequently taken to have two VFPs in parallel, to enable future variations in flow rates in each pond to investigate the influence of residence time on metal removal performance. At the time of engaging the local authority, some uncertainty still remained about the size of the new scheme and the amount of flow to be treated. Nominal guidelines were therefore provided to the CA by NU to size the scheme based on the results their team had obtained from the Nenthead trial. Furthermore, using the results obtained from the catchment monitoring undertaken by NU, a baseflow rate (6 L/s) for the scheme was also agreed that would result in a measureable improvement to the Coledale Beck while ensuring a consistent flow to the VFP. Further details of the Force Crag treatment scheme are provided in Jarvis *et al.* (2015).

Treatment Media

An important component of the VFP system is the treatment media. Following finalization of the system design, it was initially assumed by the design consultants that placement of the media (a mixture of PAS100 compost, woodchips and activated sewage sludge) into the ponds would be achieved by driving heavy plant machinery directly into the cells, using the media as a traversable surface. However, it became clear that this would have a detrimental impact on the material, reducing the porosity and permeability of the media by compaction and potentially damaging the under drain network. A key part of this system is the even down flow of water; any damage to the under drain or reduction in the porosity and permeability of the media, could result in water short circuiting, thereby decreasing residence times and reducing system performance. Discussions onsite with the contractor, design consultants and NU, resulted in the layout of the ponds being amended; the road way between the ponds was widened to facilitate the use of a long-reach excavator that could work from the pond edges.

Under drain

A complex under drain system, briefly mentioned above, is another key component of the system. This network of pipes divides each pond into four quadrants (each of which can be sampled individually at the discharge point), to facilitate the assessment of metal removal in each sector of the pond. The original under drain design drafted by NU included specific sizes for limestone chips and the number of perforations in the pipework. In preference to using customized products, it was decided to use commercially available pipes combined with larger limestone chips to achieve the same levels of permeability, whilst minimizing costs. Comprising of 770 m of standardized perforated drain pipes, the resulting network is encased in limestone gravel (20-40 mm), which protects the pipework and reduces the potential for the compost material to obstruct the system.

Initially it was proposed that the scree and spoil material readily available on site could be used for the gravel layer in lieu of limestone, as the only function of the drain was to facilitate the drainage of the treated water out of the system. However, this option was dismissed as this material would have introduced fresh metal contamination into the system following the removal of metals in the mine water by the media. It was therefore agreed that a limestone under drain would be installed. A local source of limestone was identified by the contractor, however on sampling by NU, it was found to contain slightly elevated concentrations of water-soluble sulfate. As some limestone dissolution is expected to occur, and it was important to be able to measure the amount of sulfate being removed by the system, a calcium carbonate limestone that contains fewer impurities was therefore imported from further afield.

Wetland

An aerobic wetland for the purpose of aerating the water exiting the anaerobic ponds and filtering any fine particulates that may remain in the water was required for the scheme. In preference to *Phragmites sp.* reeds that are typically used by the CA in constructed wetlands, it was decided to use metal-tolerant rushes (*Juncus sp.*) already established in the area to reduce the visual impact of the wetland. During construction, the plants were temporarily relocated before being placed in their final position in the wetland. There was some concern that although these plants prefer water-logged conditions, they would not survive submerged in a water depth of 300 mm; water levels were therefore lowered to 100 mm and to date, the plants are thriving in their new environment. It is intended to use similar wetland systems at future schemes employing this technology, although such wetlands will need to be larger in size compared to the small unit installed at Force Crag.

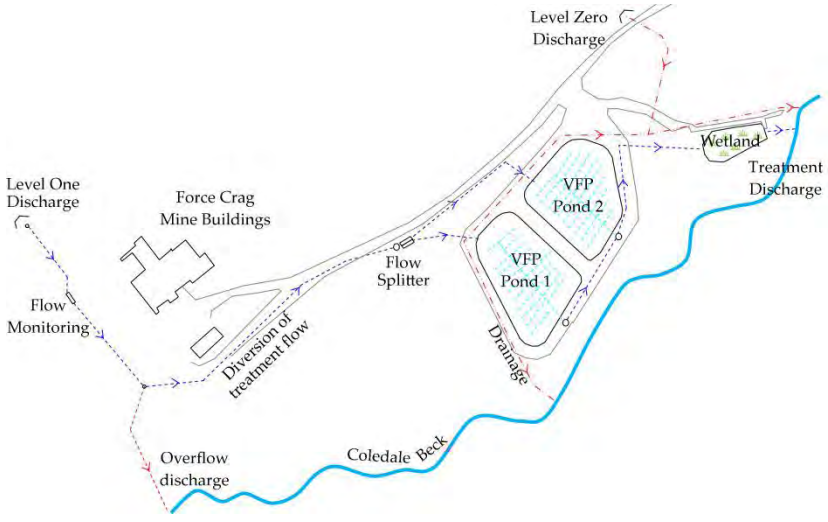

Figure 2 Schematic diagram of the treatment system at Force Crag mine (not to scale)

Flow rates

Low flow rates (typically L/min) in small scale systems are easily controlled and manipulated. In a full scale-system however, flow rates are less easy to regulate, yet in a trial setting it is vital to accurately control them to rigorously assess the performance of a system. The CA standard designs,

although adequate for coal mine water treatment schemes, do not provide sufficient control to accurately regulate flow rates through the ponds installed at Force Crag. A new system was therefore devised which can accurately capture a designated baseline flow from the Level One discharge, dividing the flow equally between the two ponds. This system also provides the ability to investigate effects on performance of increased flow rates and thus reduced residence times.

Gas

A potential by-product of harnessing sulfate reducing bacteria (SRB) is the generation of hydrogen sulfide (H_2S) gas. Although it was expected that some H_2S gas would be produced by the system (H_2S could be smelled at the Nenthead reactor and can also be smelt at the CA's RAPS unit installed at Tan y Garn in South Wales), it was unclear what the exact impact at the site would be. Force Crag is situated in a remote, upland, un-inhabited area, and although ramblers and walkers are frequently in the vicinity of the treatment system, it was decided that to install a cover would be prohibitively expensive and would not be aesthetically acceptable in the National Park. To mitigate the problem the following measures were taken; the water depth of the ponds was increased to ~400 mm (from 300 mm); open manhole covers were installed to limit gas build up in any confined spaces which require regular access; a rigorous gas monitoring regime has been instigated to examine gas production and where the 'hot-spots' are located; continuous gas monitors have been installed to assess the risk posed to maintenance operators and the public. Future treatment systems may be required to be sited in populated areas; the data collected from this pilot system will therefore be used to demonstrate the impact of H_2S gas and inform planning authorities about the risks associated with this type of system and the measures that can be taken to mitigate them.

Permitting

A second key challenge associated with the up-scaling from a pilot to a full-scale system in addition to the construction is the environmental permitting of a scheme. This section focuses on some of the permitting solutions that were implemented at the Force Crag site.

Treatment Media

In contrast to the small-scale reactor trial at Nenthead, where the bulk of the treatment media components were purchased from the local garden center and mixed on site in a bucket (A. Jarvis, 2013, *pers. comm.*), the importation and mixing of the media for the full-scale system deployed at Force Crag, caused obstacles which the CA needed to address. It quickly became apparent that in order to use a media containing activated sewage sludge, a waste permit would be required from the EA. Although PAS100 compost and woodchips are not individually classified as waste materials, the inclusion of activated sewage sludge within the mix results in the treatment media being classified as a waste material under EU law; and is therefore subject to the Environmental Permitting (England and Wales) Regulations 2010, which legislates for the movement, importation and placement of waste material(s).

To successfully achieve a homogenous mix of ~650 tonnes of media, large machinery were required to manage the volumes involved; as a suitable mixing area was not present at Force Crag, the materials were mixed off-site. Using a contractor with an existing waste permit to accept the sewage sludge (and willing to apply for the necessary extensions to their license to undertake the media mixing), removed the requirement to apply for these permits directly; saving both time and

reducing costs. Ultimately, the only regulatory requirements the CA were obliged to fulfill was to obtain the necessary permits to import and position the media into the VFP cells.

The long term placement of the media within the treatment ponds was an issue that the regulator was required to consider carefully, to ascertain under what conditions the CA could surrender the waste permit necessary for the placement of the media. It was desirable to surrender the permit upon completion of the construction work to ensure that the ongoing yearly obligations associated with holding waste permit were not incurred, thereby minimizing costs to the UK government. In order to accept the surrender of the permit, the EA had to be confident that the waste placement was a 'low' risk. Under normal circumstances this requires the waste material to be capped to prevent water ingress. At Force Crag, it was agreed that by preventing any mine water ingress into the surrounding ground from the ponds (through the use of impermeable liners), the capping of the treatment media by the overlying layer of water combined with the requirement for the water discharging from the treatment system being subject to monitoring under an environmental permit, the regulator agreed that the waste permit could be surrendered.

In addition to the waste permit requirements, the long term disposal of the spent metal-rich compost media also needed to be considered. Although some measures have been suggested which may increase the longevity of the system (*e.g.* 1. increase the working head of the water in the system to encourage the down flow of water if the permeability of the media reduces; 2. introduce a fresh carbon supply to replenish the food source for the bacteria), it is inevitable that eventually, the media will no longer be effective and require replacement. At some point in the future, the ~650 tonnes of material in the Force Crag VFPs will require permanent disposal, almost certainly off-site. At present, the precise chemical composition of the spent media is unknown. To compensate for this lack of knowledge, the material used in the Nenthead reactor has been used as a proxy to determine the most probable disposal route for the media used at Force Crag. The regulations pertaining to the disposal of waste requires that such material is categorized within a classification system that limits the disposal routes for certain types of wastes. Due to the high concentration of metals in the media, the material is likely to be classified as hazardous waste. However, the high organic content of the compost-based media limits the avenues for disposal; hazardous waste landfill sites within Europe are not permitted to accept wastes with an organic content in excess of 6 %. While there may be options to pre-treat the media prior to disposal the practicalities (both technical and financial) remain uncertain. Consequently, it was decided that a 'worst case' disposal option would be included in the whole-life cost of the system to ensure that future funds were available to dispose of the media at the end of its operational life should they be required.

Discharge Permit

It is recognized by the EA that there is a low risk of pollution from short-term pilot treatment systems at abandoned metal mines. Small-scale experimental mine water treatment plants can therefore be operated without an environmental permit provided the system is carefully monitored, the EA is notified of the trial and its duration and no pollution occurs. For full scale-systems however, environmental permits are required. In the UK, owners or operators of mines abandoned before 2000 cannot be held liable for permitting water pollution, and so public funds are being used to build and operate treatment systems at prioritized long-abandoned mines. Passive systems do not provide the same certainty of effluent quality as active systems, but should lead to significant improvements in river water quality. The EA has therefore decided that in specific circumstances, the numeric emission limits normally applied to effluents may not be appropriate for passive

treatment systems at abandoned metal mines. For the Force Crag system, the EA agreed to issue a permit that requires the CA to carry out detailed monitoring to demonstrate the performance of the VFP and to ensure that there is no increase in pollution, without numerical targets for metals.

CONCLUSION

This paper has focused on some of the construction and permitting issues that can result when taking a small-scale pilot system into the 'real world' as a full-scale operating scheme. Although challenging, these issues can often be overcome by being flexible with design and the sourcing of raw materials, in addition to engaging with numerous stakeholders to ensure a pragmatic approach is taken. In summary, the main challenges identified in this example are as follows:

- Provide local planning authorities with outline plans for designs whilst communicating the message that some modifications to the system may be required.
- Being flexible in the design process, as unforeseen problems will occur during the construction process.
- Clearly specify the materials and methods required and determine the detailed layout of the treatment system before construction commences.
- An adaptable operational monitoring program is required that can change to monitor unexpected issues (*e.g.* H_2S gas) that may arise in the first years of operation.
- Detailed discussions and agreement with the environmental regulator are required in the early stages of the project to ensure the correct permits can be attained.

Using Oxygen Consumption Rates as a Guide to Scale Up Laboratory Kinetic Data to Field Conditions

L.E Eary
Hatch, USA

ABSTRACT

Field and modelling studies of sulfide oxidation in waste rock from the scientific literature indicate that O_2 penetration is typically less than about 50 m and commonly less than 20 to 30 m due to consumption by reactions with sulfide minerals. A compilation of data from a range of field and simulation modelling efforts indicates a consistent trend of increase in the intrinsic oxidation rate (IOR) with temperature over range of 2 to 57°C, yielding an activation energy of 91 kJ/mole. This value is consistent with the value of 92 kJ/mole determined for pyrite oxidation by ferric ion. This activation energy indicates an increase in IOR of about 3.7 times per increase in temperature of 10°C.

The O_2 consumption rate data provide a potential guide to scaling kinetic data collected in laboratory experiments to field conditions. A comparison of the field data to O_2 consumption rates for 594 laboratory tests from the International Kinetic Database (Morin et al. 1995) shows that ratios of the laboratory IOR to field IOR range from 23 at the 25th percentile to 58 at the 50th percentile to 206 at the 75th percentile or about one order of magnitude. If the potential exists for a waste rock to increase in temperature by 20°C due to exothermic oxidation reactions, the potential increase in IOR based on an activation energy of 91 kJ/mole is about 13.7 times. If this factor of temperature increase is considered in the scaling approach, the range in ratios of laboratory IORs to field IORs decreases to 1.7 to 15 at the 25th to 75th percentiles. With this scaling approach, no other scaling factors are needed because the IOR values here are based on field data and therefore include the various effects of particle size, water-rock ratio, and elemental content.

Keywords: oxygen, consumption, kinetics, waste rock

INTRODUCTION

One of the most common and often problematic tasks facing geochemists using predictive models of future water quality for mine wastes is developing approaches to extrapolate or scale up results from laboratory experiments conducted on small sample sizes (typically 0.5 to 1 kg of material) to represent reactivity in storage facilities that will contain tens of millions to billions of tons of material. Making this scale up effort especially difficult in many cases is the fact that the extrapolations for mine permitting are generally carried out prior to the placement of any material in the storage facilities, meaning that direct observations of reactivity are not available at the time of study.

In most cases, estimations of reactivity are focused on the rates of oxidation of sulfide minerals with respect to their potential to cause acid generation and metal leaching and thereby affect water chemistry. Even when leachates do not become acidic, sulfide mineral oxidation will produce some amount of metal leaching. Humidity and column leaching kinetic tests are the most common laboratory tests used to determine reactivity of mine waste materials. Different approaches have been used to scale up the laboratory kinetic tests to field conditions, such as water-to-rock ratios, water contact time duration, reaction kinetics for individual minerals comprising rock types, particle size, and surface area. The surface area approach may make the most technical sense in that reaction kinetics should be a function of surface areas of minerals and their degree of exposure to air and water; however estimating reactive surface areas for different minerals within a larger rock matrix of variable particle size often requires considerable estimation (Morin, 2013).

Scaling factors developed by various procedures indicate that laboratory rates may range anywhere from 2 to 8 times (Drever and Clow, 1995) to 100 to 1,000 times faster (Malmstrom et al., 2000; Smith and Beckie, 2003; Ritchie, 1994) faster than field rates. These ranges are very wide and difficult to apply with confidence to mine wastes containing sulfide minerals due to the many complicating factors of mineralogy, reactive surface area, particle size distribution, secondary mineral formation, and microbial activity. The purpose of this paper is twofold: 1) assess the effect of temperature on sulphide oxidation rate, and 2) provide a summary of oxidation rates interpreted to occur in existing waste rock storage facilities and compare those rates to laboratory rates in an effort to provide a narrower, statistically based range for typical scaling factors. It is important to note that while O_2 consumption rates provide an indication of the reactivity of sulfide minerals and potential for acid production, they are not necessarily a reliable indicator of leaching rates of all solutes that might be released from all mineral forms.

OXYGEN CONSUMPTION RATES IN WASTE ROCK

Intrinsic Oxidation Rate

A review of the literature shows a number of field-scale studies focused on deriving O_2 consumption rates in sulfidic waste rock (Table 1). The list in Table 1 is not meant to be exhaustive of all the geochemical literature, but is reflective of those found in peer-reviewed journals or easily found sources. Most of the studies in Table 1 involved the development of simulation models of complex air-water-mineral processes in waste rock where the rate of O_2 consumption is a key component for understanding reaction rates and in situ temperature. The rate of O_2 consumption is often referred to as the intrinsic oxidation rate (IOR) with units of kg O_2/m^3-yr where the m^3 term

indicates a cubic meter of waste rock. The IOR can be converted to an all mass set of units by dividing by the bulk density (kg/m^3).

In the simulation modelling studies cited in Table 1, the IOR is typically a parameter determined either through a calibration process by comparison of model results to temperature profiles, O_2 depth profiles, and/or rates of SO_4 production. Hence, in all cases, the IOR values in Table 1 are essentially empirical values that are indicative of sulfide mineral oxidation primarily in the outer portions of waste rock piles where sufficient O_2 is available to cause oxidation. For waste rock with high contents of reactive sulfides, O_2 penetration may produce heating and convective air flow, which may speed air transport into the pile, but the reactive nature also more rapidly consumes the O_2, limiting penetration depth. For waste rock with low sulfide content, O_2 may penetrate much farther before it is consumed. In addition, the method of dumping will affect O_2 penetration with end dumping more favourable to promoting air circulation than paddock dumping. For the most part, the results from the simulation models suggest that the depth of O_2 penetration will typically range from 5 to 50 m. This outer rim is the portion of the waste rock pile where oxidation occurs.

Effects of Temperature

The studies given in Table 1 show a wide range of IOR but they include both young and old waste rock located in a variety of climates some of which have sufficient sulfide mineral oxidation to

produce exothermic heating and elevated temperatures. The range of IOR from these various studies allows examination of the effect of temperature (Figure 1). The data in Figure 1 show a clear trend of increased rate with increased temperature with the exception of the rates derived from Linklater et al. (2006), which deviate significantly from other data for low temperature. The slope of the regression line implies an increase in IOR of 3.7 times per increase of 10°C, not including the IORs from Linklater et al. (2006).

If the same data are re-cast in an Arrhenius type plot, then it becomes possible to calculate an apparent activation energy. Figure 2 shows an Arrhenius plot of the logarithm of IOR as a function of the inverse of temperature. A regression of the data in Figure 2 results in a slope of –4,914.7 and an R^2 of 0.71, which yields an activation energy of 94 kJ/mol.

It should be noted that the regression analysis did not include three IOR values from Linklater et al. (2006) for 2°C because they appeared to deviate significantly from the trend established by the other data. The Linklater et al. (2006) IORs show there can be significant differences in rates, depending on conditions and mineralogy.

It seems reasonable to expect that IOR should be a function of the sulfide mineral content; hence, Figure 3 shows another Arrhenius plot but with IOR divided by the average pyrite content reported in the studies listed in Table 1. Linear regression of the data in Figure 3 produces an activation energy of 80 kJ/mole and a R^2 of 0.74, indicating that normalizing the IOR to pyrite content yields only a minimal improvement in the regression statistics.

The average of the two regression curves gives an activation energy of 87 kJ/mol. This average value is at the higher end of most of the values reported in experimental studies (Table 1). It is consistent with the activation energy of 92 kJ/mol determined by Wiersma and Rimstidt (1984) for pyrite oxidation by ferric ion, which is not surprising given the generally accepted concept that ferric ion is the primary oxidant in acidic systems with rapid enough sulfide mineral oxidation to produce an increase in temperature.

Comparison of Field and Laboratory IOR

The International Kinetic Database (IKD) from MDAG Publishing (Morin et al. 1995) contains a compilation of a kinetic leaching data from a large number of laboratory studies over a range of rock types and sulfide mineral contents. Figure 4 shows the distribution of IORs from the IKD where the IOR values were calculated from the rate of SO_4 production (mg/m^3-week), assuming a bulk density of 2000 kg/m^3, all sulfide-sulfur is FeS_2, and the following reaction stoichiometry:

$$FeS_2 + 7/2\ H_2O + 15/4\ O_2 \longrightarrow Fe(OH)_3 + 2\ SO_4^{-2} + 4\ H^+ \quad (1)$$

The distribution of IORs from the IKD data set range from 0.03 at the 5th percentile to 2.21 at the 95th percentile and median of 0.95 kg O_2/m^3-year/%Pyrite (Figure 4). The range of percentile values from the IKD is shown in Figure 5 relative to the field-derived rates from Table 1, assuming a laboratory temperature of 25°C. The ratios of the IKD laboratory IORs to field IORs range from 11 at the 5th percentile to 58 at the 50th percentile to 660 at the 95th percentile. The range in ratios from the 25th to 75th percentiles is 23 to 206 or about one order of magnitude. This range is greater than that observed in a series of laboratory to field scale tests conducted by Andrina et al. (2012), who found laboratory rates ranging from about 2 to 10 times field-scale measurements.

Generally, it is the intent and expectation that rates derived from laboratory tests should be significantly faster than field rates. The laboratory to field ratios discussed here based solely on IOR indicate that factors for extrapolating laboratory-derived oxidation rates to field scale can typically range from one to one and half orders of magnitude. However, it should be noted that if this approach is used for scaling up from laboratory to the field, then no other scaling factors are needed because the IOR values here are based on field data and therefore include the various effects of particle size, water-rock ratio, crystallinity, and elemental content.

Another consideration is for cases where kinetic testing data and numerical modelling predict that sulfide oxidation will be rapid enough to result in exothermic heating, then scaling factors should be reduced. For example, if the potential exists for a waste rock to increase in temperature by 20°C more than the temperatures of relevant laboratory tests, such as from 25°C to 45°C, the potential increase in IOR based on an activation energy of 91 kJ/mol is about 13.7 times. If this temperature effect is considered, the range in ratios of laboratory IOR to field IOR is reduced substantially from 1.7 (=23/13.7) to 15 (=206/13.7) at the 25th to 75th percentiles. The converse is also true for field conditions substantially colder than the relevant laboratory testing conditions, such as would be appropriate for northern or high altitude locations where average field temperatures are less than standard laboratory temperatures of 20 to 25°C.

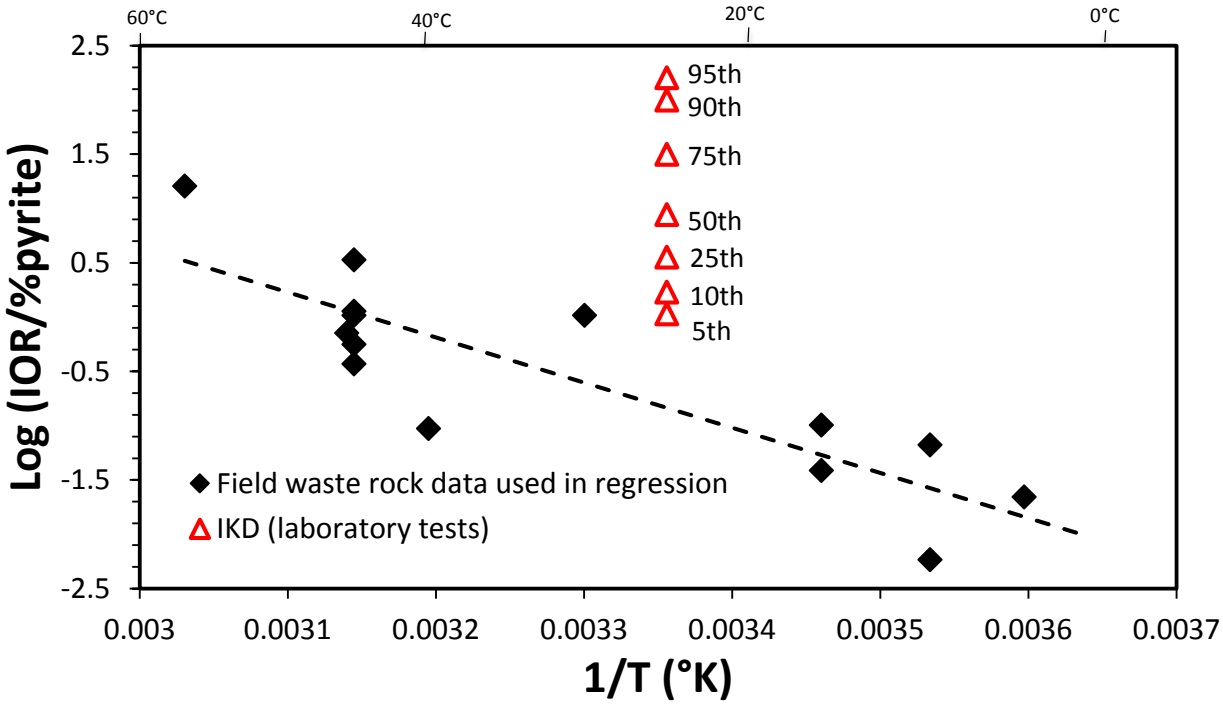

Figure 5 Comparison of IORs from laboratory tests (IKD) to field-derived IORs divided by percent pyrite

CONCLUSIONS

The validity of including temperature effects in approaches for scaling up results from laboratory tests to field scale for modelling oxidation processes in waste rock dumps has never been well established. The IOR data compiled here from a range of field and simulation studies show a consistent and significant effect of temperature, indicating temperature is a significant factor that should be included in scale up estimations. If field temperatures are expected to be substantially different than laboratory temperatures, perhaps greater than 10°, including a temperature factor in scale-up calculations is a reasonable approach. However, if a temperature factor is included as described in this paper, there is no need to add additional scaling factors because the temperature effects on IOR examined here inherently include many other water-rock reaction factors because they are based on observations and interpretations of field-scale systems,

Approach to Scaling Up from Laboratory Humidity Cells through a Field-Scale Unit to a Waste Rock Dump

Carla Calderón Rosas, María Carolina Soto, Natalia Farfán and Angela Oblasser
Fundación Chile

ABSTRACT

Humidity cells are kinetic tests designed to predict long-term weathering rates and the potential for mine waste and geologic materials to release discharges that may have impacts on the environment (GARD Guide, 2010). These tests are performed at the laboratory scale in a controlled environment. By developing humidity cell tests it is possible to determine the response of a given sample to cycles of moisture and flooding in terms of mine drainage generation and metal loading in laboratory conditions. However, laboratory conditions are very different from those that occur in a mining operation; in terms of volume of materials, granulometry, climatic conditions and time. Consequently the scaling up from laboratory results to real mining wastes facilities can become difficult.

Thus, in recent years, the medium and large scale field tests have become more common in mining operations around the world; nevertheless, no systematic analysis has been done in order to assess the improvement of the scaling challenge.

In this study, an initial analysis of development and comparison between standardized and modified humidity cells is presented, in order to find relevant information that allows a more realistic and close to the waste rock dump characteristics scaling approach in the future.

CHAPTER 11

RELIABLE MINE WASTE MANAGEMENT

The Canadian MEND Program – The First Twenty-Five Years

Gilles Tremblay and Charlene Hogan
Natural Resources Canada

ABSTRACT

Acidic drainage has long been recognized as the largest environmental liability facing the mining industry, and the public through abandoned mines. In 1989, provincial and federal governments, and the Canadian mining industry formed a consortium called Mine Environmental Neutral Drainage (MEND), to develop technologies and strategies to prevent and reduce acidic drainage.

The MEND program focussed the effort to develop technologies to reduce the effect of acidic drainage, and examined four key areas; prediction, prevention and control, treatment and monitoring. A toolbox of technologies was developed to plan for, operate and decommission mines in an environmentally acceptable manner. In 2002, a multi-year research strategy was put in place, based on regional priorities established by an extensive network of Canadian experts. On the world stage, through the Global Alliance, MEND has forged international partnerships among other organizations involved in acidic drainage research.

MEND's continued success lies in its collaborative multistakeholder approach, with members from two levels of government, the mining industry, and non-governmental organizations working on a common problem. Today, the MEND model of co-operation is copied in Canada and internationally to tackle both policy and science-based challenges.

Technology transfer remains central to MEND's activities. MEND has published over 200 technical reports and guidance documents; these are now all available on the MEND website. Workshops are considered the best route for timely and efficient transfer of technologies and case studies, and MEND has sponsored or co-sponsored over 40 workshops, including the hosting of three ICARDs. As a result of the efforts of MEND and other partners, our understanding of acidic drainage has greatly increased, and significant advances have been made in environmental stewardship.

Keywords: Multistakeholder, consortium, MEND

CANADA'S ROLE IN ACIDIC DRAINAGE AND THE MEND PROGRAM

Canada's research into acidic drainage technologies started in the 1970's and 1980's and focussed on tailings from metal mines. Canadian mining companies and the Government of Canada recognized the serious impacts of acidic drainage from mining activities on the environment, and the projected enormous liabilities for Canada and the mining industry. Extensive research was undertaken to develop methods to establish vegetative growth on tailings in an attempt to alleviate and prevent acidic drainage. These efforts were successful in revegetation of tailings sites, but did not improve water quality. There was a realization that this was not a sustainable solution – and the mining industry was left with few options to deal with acidic drainage, namely perpetual lime treatment. There was need for a better understanding of processes involved, and for new remedial technologies to be developed and demonstrated; a concerted effort was required.

The National Uranium Tailings Program (NUTP) (1983-1988) provided an early model for an acidic drainage program. NUTP's mandate was to develop predictive models to reduce liability for uranium mine tailings, the primary concern being the isolation of low levels of radioactivity. However, the research soon concluded, as it was realized that the real concern was acid generation from the residual sulphides in Ontario uranium tailings. This realization combined with the concerns of base metal and gold mining companies and government agencies led to the establishment of the Reactive Acid Tailings Stabilization (RATS) Task Force in 1986. One of the key lessons learned from NUTP was that more stakeholder involvement was necessary for any future multistakeholder program. The RATS Task Force was created with representatives from the mining industry, and federal and provincial governments. They produced a multi-year research plan and recommended that a coordinated approach be used to carry out the program. In addition to acidic drainage from tailings, it was quickly realized that waste rock was also a major source that had to be dealt with. Consequently, a new name was adopted, the Mine Environment Neutral Drainage (MEND) program. In 1988 the MEND consortium was launched and charged with the following two key objectives; (i) to provide a comprehensive information base to allow the mining industry and government agencies to establish long-term management requirements for reactive tailings and waste rock; and (ii) to establish techniques that permit the operation and closure of acid generating mine waste disposal areas in a predictable, affordable, and environmentally acceptable manner.

MEND (1987 - 1997)

Initially, a budget of $12.5 million Canadian over five years (1989-1994) was allocated for MEND research. MEND was a tripartite consortium that included the Canadian mining industry, 5 provincial governments and the Federal government of Canada. MEND was an unusual consortium, driven primarily by the 130 volunteer representatives of the different participating agencies; including regulators, mining company managers and engineers, and government officials and scientists who freely contributed their time and expertise. The program adopted an organizational structure that included a Board of Directors, a management committee and several technical committees, and a coordinating secretariat. Roles were simple. The Board of Directors provided vision and approval of annual plans and budgets; the management committee provided "hands-on" management of the program; and the technical committees addressed technological issues and solutions. The Secretariat was essentially the "hub" of the organization and ensured

coordination of the elements within, and external to MEND. NRCan, with a long history of mining R&D and mineral economic policy and an extensive network across Canada, was a natural fit for the Secretariat.

The research and development program focussed on four cornerstones: prediction, prevention and control, treatment and monitoring. The objectives for each area were:

Prediction: To develop better techniques to predict acid generation from mine waste material, as well as the rate and effect of acid generation, and to develop mathematical models to simulate acid generation processes.

Prevention and Control: To develop techniques to minimize or prevent acid generation, and to demonstrate these techniques in the field.

Treatment: To develop and demonstrate chemical and passive treatment systems, and to examine lime treatment sludge stabilization methods.

Monitoring: To develop new technologies to improve site monitoring of acid drainage, to develop field sampling methods and analytical reference standards, and to develop closure criteria.

In 1992, MEND revised its research plan to narrow its focus, solicit research on a competitive basis, increase its technology transfer and international liaison roles, and encourage innovation and the testing of new ideas. The plan extended MEND to a 9-year program, with an expanded budget of $18 million C$.

The Liability and the Results

In 1994, Natural Resources Canada surveyed mining companies and provincial databases to determine the amount of acid generating materials; an estimate of 1,900 Mt of tailings and 750 Mt of waste rock was obtained (MEND 5.8e, 1994). Geocon (MEND 5.8.1, 1995) estimated the associated liability at between $1.9 billion and $5.3 billion C$.

An evaluation of the MEND program was undertaken in 1996 by Young and Wiltshire (MEND 5.9. 1996). The survey concluded that liability had been reduced by $340 million C$ for five mine sites, alone. It was also acknowledged that the reduction in liability is significantly higher than this quoted value, with a minimum of $1 billion C$ commonly accepted by the mining industry. This was an impressive return on an investment of $17.5 million C$ over eight years. Other observations underline the value of the MEND program to Canadian science and policy:

- Increased diligence by regulators, public and industry
- Greater common understanding of issues and solutions
- Research has led to reduction in environmental impact
- Recognition of MEND as a model for industry-government co-operation
- The need to continue and strengthen international connections

As a result of MEND and associated research, technologies are in place to open, operate and decommission a mine property in an environmentally acceptable manner, both in the short and long term. This can have a major impact on new mine financing and development. Moreover, mining companies and consultants have acquired a great deal more capacity to deal with water contamination from mine wastes, including acid generation. Canada gained a reputation for expertise in dealing with acidic drainage issues, and that advisory expertise was sought internationally. MEND fostered working relationships with environmental groups, ensuring that they are an integral part of the process.

Over the first ten years, the two levels of government, together with the Canadian mining industry, spent over $17.5 million C$ within the MEND program to find ways to reduce the estimated liabilities. Planned funding for MEND was divided equally among the three major partners: the mining industry, the federal government and five provincial governments. When the first round of funding ended in December 1997, the federal government had contributed 37% of the funding, the provinces 24%, and industry 39%.

By 1997, about 200 MEND projects were completed across Canada. Some of the key technical results and observations are noted below; these are still important areas for MEND research today.

- Prevention is the best strategy. Once sulphide minerals start to react and produce contaminated runoff, the reaction is very difficult to stop.
- Prediction ensures that extraction of minerals occurs with minimal impact on the receiving environment. Chemical prediction methods, procedural manuals, and predictive models were developed and applied to predict the geochemical behaviour of wastes.
- In Canada, the use of water covers and underwater disposal are being confirmed as the preferred prevention technology for unoxidized sulphide-containing wastes. This technology is well suited to Canada geography and climate.
- Dry covers can be applied as effective oxygen and infiltration barriers. Innovative research has shown that a range of materials, including low cost waste materials from other industries (lime stabilized sewage sludge, paper mill sludge) may provide excellent potential for generating oxygen-reducing surface barriers. Non-acid generating tailings and membranes were also evaluated as covers.
- Studies verified that sludges will remain stable, if properly disposed. Concerns had been raised about the long-term chemical stability and the potential liability arising from dissolution of heavy metals contained in the sludge.
- In Canada, experience indicates that passive systems have niche applications for acidic drainage treatment. These range from complete systems for treating small seeps to secondary treatment systems, such as effluent polishing ponds.
- Several other disposal technologies were also investigated, including permafrost, using an elevated water table and in-pit disposal.

The MEND program cemented Canada's leadership in research into acidic drainage technologies applied to metal mines. Technology transfer activities were an important element of the 1987 – 1997 MEND program and were significantly expanded in its last few years. The dissemination of information on developed technologies to partners and the public is a major function of MEND and must continue.

MEND 2000 (1998 - 2000)

The MEND program concluded in 1997 and had achieved tremendous progress in reduction of liability. Partners agreed that additional work was needed to broadcast the research information, and to verify MEND-developed technologies in the field. A stream-lined program was established, funded by the Mining Association of Canada and Natural Resources Canada. The focus was on promoting technology transfer, monitoring and completing MEND-initiated projects, and providing an essential link among industry, governments and environmental organizations.

One of the key deliverables for MEND 2000 was the six-volume MEND Manual. This manual consists of a detailed summary volume, and five technical volumes addressing acidic drainage issues: sampling and analyses; prediction; prevention and control; treatment; and monitoring. The information from the more than 200 technical reports and workshop notes produced under MEND is compiled in this manual. The manual provides practitioners in the Canadian industry and government with a single reference on acidic drainage for the diverse and complex research undertaken during the MEND program. Given that acidic drainage is a highly technical area, where site-specific influences likely necessitate site-specific investigations and evaluations, the manual is not a "how to" document.

The transfer of information on developed technologies to partners and the public has always been an important part of MEND. A bilingual website http://mend-nedem.org was created in the 1990's and underwent several major updates as technologies advanced. For example, paper copies of MEND reports were originally ordered on-line; they are now all available electronically, for free, on the website. The website contains over 200 MEND reports and related publications, and features an advanced search function to enhance site accessibility.

Over its 25 years, MEND hosted over 40 workshops and conferences on key areas of technology at locations across Canada. These events were a successful and popular way to transfer current information. Each year the annual BC-MEND ARD/ML Workshop invites case studies and technical presentations from leading practitioners. In recent years, the workshop consistently attracted over 200 delegates. This workshop is regarded as one of best values for money events. Links were also established with international organizations involved in acidic drainage research, such as INAP (International Network on Acid Prevention), ADTI-USA (Acid Drainage Technology Initiative), and CETEM (Brazil).

MEND (2001 - 2015)

Sustainable development is a strong driving force for industry in dealing with environmental and societal issues such as water contamination from mine wastes. The MEND program focussed on developing technologies to reduce the effects of acidic drainage, and developed a toolbox of technologies to plan for, operate and decommission mine properties in an environmentally acceptable manner. Although the original MEND Program and its successor, MEND 2000, made major contributions to prevention and management of acidic drainage, it remained a significant environmental issue.

In 2001, funding was provided for a renewed MEND initiative focussing on regional and national needs. A Gap Analysis report (MEND 8.1, 2002) was completed to identify opportunities to advance acidic drainage research, along with a list of regional research needs. Subsequently, a multistakeholder expert Strategy Session was held in 2002, and a number of activities were proposed for a multi-year program (MEND 8.2, 2002). A questionnaire was distributed to the Canadian MEND network to help define research activities. The top-ranked priorities were closure management, verification of technologies, metal (neutral) leaching, passive treatment, early prediction, sludge management, cold temperature effects and paste backfill. Guidance documents and manuals, workshops and other technology transfer activities were identified as important issues that cut across all priorities.

Based on the widespread support from all stakeholders, a recommendation was made to move ahead with a renewed MEND with a research program that focused on these top priorities.

Funding was provided by the Mining Association of Canada, with support from other government departments and in-kind support from the project contractors.

Since 2003, the MEND Steering Committee developed an annual work plan to address many of the key research priorities. Many of these new projects re-examined issues and re-visited sites that were the subject of earlier MEND studies. Advances in technologies and knowledge made it timely to re-examine some of these issues. As well, several projects verified the full-scale application of MEND supported technologies, and investigated their long-term performance. There have been some shifts in priorities since 2003, with a greater interest in best management practices, cold temperature issues, guidance documents and more recently, regulatory concerns.

Several MEND reports, activities or project areas in the past five years are outlined below.

Accurate and timely prediction of acidic drainage and metal leaching is central to prevention of potential environmental impacts, and to minimize the high costs of mitigation. Prediction of drainage chemistry is a technically challenging subject, involving numerous methods, properties and processes. The *Prediction Manual for Drainage Chemistry from Sulphidic Geologic Materials* (MEND 1.20.1, 2009) provides a comprehensive document for use by technical experts or practitioners to conduct a prediction program and/or review the results. It is also a reference document for the public, educators or students studying or reviewing drainage chemistry.

With the large number of mines opening in Northern Canada, the effect of cold temperature on various technologies is of increasing importance. Research was conducted across a number of areas including dry covers. In 2004, MEND produced the *Dry Covers: Design, Construction and Monitoring of Covers Systems for Waste Rock and Tailings* (MEND 2.21.4), which integrated the best available technology for the design and construction of cover systems over mine wastes. One of the key gaps identified was the application of covers in the cold regions. Three projects were completed. The first, *Mine Waste Covers in Cold Regions* (MEND 1.61.1a, 2009), reviewed soil covers on mine waste in cold regions. Several dozen cold region processes were identified that could affect soil covers. In the second project, *Cold Regions Cover Research* (MEND 1.61.5b, 2010), cold region phenomena that could impact soil cover performance, including ground freezing, snow-distribution, and limits to revegetation were reviewed. The third report, *Cold Regions Cover System Design Technical Guidance Document* outlined the current state-of-knowledge of soil cover system design in cold regions, best practises on how a cover system design should be conducted, and a summary of information that should be provided during the design process (MEND 1.61.5c, 2012).

Climate change poses several risks to mining operations. MEND completed a high-level risk analysis on climate change, *Climate Change and Acid Rock Drainage – Risks for the Canadian* (MEND 1.61.7, 2011). It focuses on risks associated with acid rock drainage and metal leaching produced from mining activities. At mine sites, the prevention and management of acidic drainage includes the management of water, tailings and waste rock. Therefore, climate change risks related to acidic drainage arise from the impacts of a changing climate on water-management structures and activities, on waste-impoundment structures, and on the hydrologic/ hydrogeologic/ geochemical conditions affecting the flow of water and contaminants at mine sites. Previous studies on climate change impacts in Canada identified a range of potential impacts for the mining sector, including those on acidic drainage. This assessment builds on previous work by looking more closely at the impacts for specific infrastructure elements and determining which are most probable and significant for mining operations and for society.

Acidic drainage treatment and sludge management are important aspects of mine site environmental control practices. Sludge production is of increasing concern to industry, as the

inventory of sludge continues to grow from "perpetual pump and treat" operations. Several MEND projects were completed in sludge treatment and disposal, stability and re-use. The most recent is a survey of mine drainage treatment and sludge management practices titled *Acidic Drainage Treatment Operations in Canada – An Interactive Database* (MEND 3.43.1, 2013). Data on treatment practices and sludge management were collected on more than 100 Canadian and international sites. A comprehensive database, containing an extensive number of parameters, was developed to store the information. This report offers many potential uses and information for treatment processes with respect to planning and guidance.

MEND's latest report *Study to Identify BATEA for the Management and Control of Effluent Quality from Mines* identified the best available technologies economically achievable (BATEA) to manage and control effluent from metal, diamond, and coal mines in Canada (MEND 3.50.1, 2014). The study provided reference information for potential forthcoming changes to the Canadian mining effluent regulations. The study described the effluent management and treatment technologies and techniques currently employed at metal (base metal, precious metal, uranium, iron ore), diamond and coal mine operations in Canada. The study identified effluent treatment technologies that could be considered best available technologies (BAT) for the Canadian mining sector. The technologies were screened against a set of criteria, and those that satisfied them were carried forward for consideration as BATEA. Cost estimates were prepared based on capital and operating cost data from vendors and operations, in-house information and literature. Ultimately, BATEA for any given mining operation is site-specific. There are a multitude of geographic and operational factors to be considered that influence effluent quality, impact the technical feasibility of treatment technologies, and dictate financial constraints on capital and operating expenditures that can be borne by operations while still maintaining economic viability.

Another key and highly successful activity of the MEND program was hosting the 9th International Conference on Acid Rock Drainage (ICARD), in Ottawa in May 2012. The event attracted 526 delegates from 19 countries, and featured a conference program that was creative, thought-provoking and entertaining. The technical event covered eight pre-conference short courses (~ 250 participants), an exciting plenary session with experts representing industry, government and civil society, three-days of oral and poster paper presentations by world- leading practitioners (127 presentations and 43 posters), a trade show with 25 exhibitors and a two-day field trip to Northwest Quebec where four mine sites were toured. A social highlight was the banquet at the Museum of Civilization, with entertainment provided by the Painchaud Family assisted by several members of the audience. The proceedings and PowerPoint presentations are available on the MEND web site at http://mend-nedem.org/9th-icard/

CONSORTIUM APPROACH

In the 1980's, a collective approach for governments and industry to cooperate in technology development for advancing environmental management in the mining industry emerged in Canada. The MEND program was the first multistakeholder program to develop scientifically based technologies to reduce the effect of acidic drainage for metal mines. This approach allows policy decisions to be made based on sound science. Since then, this model of collaboration was used by both Canadian and international programs to address issues of national importance. For example, the National Orphaned and Abandoned Mines Initiative (NOAMI) adopted the MEND model to develop a policy-based program for remediation of orphaned and abandoned mine sites

in Canada (http://www.abandoned-mines.org). The success of these programs can be attributed to several factors.

- The partnerships developed among the two levels of government, the mining industry, and environmental groups working together to develop solutions to a major environmental problem.
- An extensive peer-review process, both formal and informal, resulted in enhanced credibility of the information base.
- A small dedicated secretariat that coordinated activities, managed the accounting, reporting and technology transfer, and served as the "glue" that held the program together.

GLOBAL ALLIANCE AND THE GARD GUIDE

Through the years, linkages with other international organizations were maintained by sharing information via conferences, workshops, reports and other publications. In 2002, INAP formally proposed an international model of interaction among organizations involved in acidic drainage research. In 2003, the Global Alliance (GA) partnership was launched. The GA brings numerous benefits to the partners, including minimizing research duplication, maximizing research dollars, worldwide links, and enhanced technology transfer capability.

One important example is the Global Acid Rock Drainage (GARD) Guide, which was published by INAP with support from the GA. The MEND Manual MEND 5.4.2 (2001), described earlier, was one of the key references used to develop the GARD Guide. The Guide described proven technologies to address ARD and ML, and considered climate, geographic and environmental factors and coverage for all stages of mine life. Another project is the Diavik Waste Rock Scale-up Study undertaken by three Canadian universities with support from the Canadian government, INAP and MEND. This project provides great value for Canada; many graduate students have completed their degree work at this site and a many publications have been produced.

CONCLUSION

MEND is a good example of a successful, multistakeholder initiative addressing a technical issue of national importance, and is a model for cooperation among industry, various levels of government and environmental groups. The MEND program provided a focus to develop solutions for environmental problems that face the mining industry across Canada and internationally. Through the 25 years of the MEND program, a significant reduction in environmental liability was achieved. MEND is now recognized world-wide for its contribution to the long-term sustainability of the industry and the environment. Although much progress has been made, new challenges are emerging that will require concerted efforts by MEND and other research organizations.

ACKNOWLEDGEMENTS

Thank you to the many dedicated volunteers who over the 25 years of the MEND program so generously contributed their time and expertise.

Managing the Waste Rock Storage Design, Can We Build a Waste Rock Dump that Works?

Rebecca Barritt and Peter Scott
O'Kane Consultants, Australia

ABSTRACT

For a waste rock dump to be managed both during operations and at closure, a thorough understanding of the rock material properties to be stored is compulsory. This is facilitated by the preparation of a comprehensive waste block model, with an appropriate materials management and placement plan developed in conjunction with the mining schedule. However, a waste rock dump's success is hinged on such elements being regularly updated through ongoing materials characterization over the life of mine. Failure to undertake this may potentially result in inappropriate material placement, and unnecessary costs to the mine and surrounding environment.

This paper examines waste management process at different mine sites and compares the different approaches, and the opportunities and constraints that are placed on operation and closure of the facility by the management process adopted.

Keywords: characterization, planning, design

INTRODUCTION

The construction of waste rock dumps (WRDs) is a common requirement for most open pit mines across the globe. Historically many of these WRDs are deemed to have failed through the use of an inappropriate design or construction techniques, both being hinged on their appropriateness to the materials available and local conditions at the site. 'Failure' may be considered in terms of failure to understand the geochemistry of the mine waste leading to release of contaminants to the environment; failure to support vegetation or an eco-system, or geotechnical instability (Mitchell, 2012). The timing of the failure may be during operations or many years following any rehabilitation and closure of such facilities, and subsequent costs to rectify any damage caused (socioeconomic or environmental) can vary by several orders of magnitude.

It must be determined what is required of the site in order for a WRD to 'work'. This is an approach that requires a conceptual design to be developed and refined through initial mine feasibility and material characterization studies. The conceptual model must then revisited regularly, and refined as necessary, to ensure that the site is continuing to manage the onsite materials and achieve any closure criteria that have been initially determined. If this process is applied any alteration to the anticipated conditions, or misinterpreted geochemical data, can be managed as the mining life progresses, rather than at the end of operations when costs to rectify any issues will be far greater and availability of personnel and equipment fewer.

If a WRD 'works' it can be considered a success from its initiation through to a given time following closure. In terms of appropriate handling and placement for the materials present, should techniques and planning initially proposed lead to WRD 'failure' within a project this can be remedied. However this cannot be completed without a change in either the WRD design or materials handling processes employed.

At the start of a given project it is fundamental that the design is appropriate to the specific site considered. It is commonly seen that a design for Mine Site A is applied to Mine Site B because they have the same owners and it was previously considered to have 'worked' at A. However, little attention has been paid to the differences in equipment available, climate and terrain or more fundamentally differences in the waste rock materials.

Laboratory testing is often biased towards the ore being mined and the scenario is often that little information is obtained on the waste rock, or sampling and subsequent laboratory testing is sporadic and data gaps are common. Alternatively, enthusiasm is high during the initial stages of the venture, with full materials characterization completed and a thorough geological block model established, but as the project develops ongoing characterization through geotechnical and geochemical testing is absent. Here the mine site has failed to confirm that the anticipated conditions have been met, and as such there is potential that the initially appropriately designed facility cannot be constructed as conditions have changed.

This paper will discuss how the waste rock storage design can be developed from Day -1 of a venture and refined during the life of mine (LOM) to closure. The methodologies presented will be based on established experience in WRD design and construction, with relevant case study examples.

CONCEPTUAL DESIGN DEVELOPMENT

Standard practice allows a WRD to be designed at the start of a project, based on the initial geological block model. Once a site has an understanding of the materials anticipated to be recovered, and their respective volumes, a conceptual landform is proposed for regulatory and stakeholder review. The landform will normally have taken into account various initial laboratory test results, but essentially at this stage of the project any conceptual design can only be considered as good as the data that has been gathered for its development. At this stage no waste has been excavated and therefore the options for landform design are vast.

Any conceptual design where potentially geochemical problematic waste is considered should ensure that firstly sufficient volume of nonreactive waste is available at the appropriate time to construct the waste storage including for encapsulation or for use in a cover system. Secondly, that the nonreactive materials can be appropriately used within a design. For example, should a low permeability layer be constructed an understanding of the appropriate compaction required to achieve target values must be developed, or should erosive materials be known to the site it may be necessary to stabilize outer embankments with coarser grained rip-rap, recognizing this type of material does not readily support vegetation establishment.

Characterization and Availability of Materials

Understanding the materials present at the site is key for any mining project. The emphasis must be from the start on appropriately using the materials for the final WRD landform, in particular where reactive materials may be encountered and correctly placed within the facility.

During initial scoping studies exploration drilling often prevents sufficient sample size for most key geotechnical tests, for example particle size distributions (PSDs). In addition, the small sample collected may not be representative of the overall conditions, and flushing techniques can significantly alter the recovered material from its undisturbed, *in situ* position. Empirical equations can be used to further develop an understanding of the materials, however, these are often not referred to. Focus can be made on separating the anticipated stratigraphy into tens of individual units, some only 30 cm thick, whereas in terms of mining this becomes irrelevant as blasting or machine cutting may encounter several variations at once, and thus subsequent waste rock management and materials placement ignores initial characterization efforts.

In order to appropriately design and subsequently construct and close a WRD any materials characterization program should be completed with the geochemical and geotechnical test schedule focused on any potential issues that the anticipated waste materials may pose to the landform meeting prescribed closure criteria (Jasper *et al*, 2006). For example, if it is known that all waste rock is expected to be benign and geochemically non-reactive, but there is potential for it to be geotechnically unstable and erosive, then laboratory testing should be focused towards PSD analysis, specific gravity and development of erosion parameters such as rill and inter-rill. If materials are to be excavated from the fresh and un-weathered portion of a given stratigraphy geochemical testing should be focused on understanding the potential for acidity, sulfate and/or metals leachate to be generated.

Laboratory testing does not necessarily need to be expensive and timely. There are many low cost but comprehensive tests or procedures than can save time and budgets. Many WRDs have been designed with a limited number of tests completed, but having still developed an extensive

knowledge of the onsite materials. Field testing should also be completed to supplement any laboratory program, they provide great value and can assess any *in situ* conditions quickly and commonly at low costs. They may also present more accuracy when compared to laboratory tests that require the sample to be remolded, and thus representative of the *in situ* conditions. This is of particular relevance with permeability testing: multiple use of *in situ* testing across a range of locations at site allows for the heterogeneity of surface materials to be understood, of great importance if a cover system is required for WRD rehabilitation and subsequent closure, and for development of a revegetation plan. If on site clay materials are to be used as part of a low permeability sealing layer, or to limit atmospheric interactions with waste materials, it is prudent to compare laboratory hydraulic conductivity (K_{sat}) values with those that can actually be achieved on site with the equipment available. Often K_{sat} laboratory values are two orders of magnitude greater than can be achieved at site, if this is not addressed in terms of practicality and feasibility at an early stage then the project may be targeting an impossible design from the offset.

Once the materials available have been characterized it is paramount that their respective volumes and distribution within the material to be mined is determined. If reactive waste requires encapsulation, but the mining schedule has found that the nonreactive materials will all be recovered late in the operation then dump construction must be designed to minimise exposure of the reactive waste to uncontrolled oxidation. This practice will limit potential contamination during operations, in addition to reducing the requirement for material double handling. Understanding the total volume of materials required to be managed onsite allows for an appropriate conceptual landform design to be prepared. The marriage of material properties, respective available volumes and relative timing of materials extraction to the operation are key to appropriately designing a WRD.

Conceptual Design Modelling and Updating a Design

Once a thorough understanding of the materials expected to be encountered at site, and respective volumes, is determined the data should be used to develop a conceptual landform design. The design should be aimed at the final landform at its completion and closure, however, it is also important to it to be developed in 'workable' stages throughout the LOM.

Where initial materials characterization testing has identified potentially problematic materials expected to be encountered during operations it is paramount that they are appropriately considered and thus managed within the landform design. At this point it may be necessary to conduct numerical or analytical modelling to gain a perspective on how the facility may perform over a given timeframe. The use of modelling is a common tool to support a given design, however, it is often used to create the design. For example if a project requires PAF or reactive waste materials to be encapsulated the volume of available benign materials must be determined before any modelling commences. Without a basic understanding of the site conditions modelling simulations may determine that a much greater thickness of benign materials are required than is available, identifying a design which will either never be constructed or will require a separate mineable source of benign materials to what can be provided by the ROM operations. Where climate data is required for use within a model it must be site specific and preferably cover the timeframe that is modelled (O'Kane and Barbour, 2006). Often less than five years of data are compiled and then re-used for years 6-10 and so forth, potentially omitting any above or below average data, of which is key to understanding any WRD's limits in potential performance. If an appropriate range of climate data is not available then assessments relating to the probability of

exceedance must be made. It should be understood, however, that a model will never supply the final design and must only be used as a tool to help inform design decisions. There is a tendency to focus on model outputs and rely on values presented, without revisiting the conceptual design and questioning its feasibility, as previously mentioned.

Once a conceptual design has been approved by all relevant parties it is crucial that it is referred to and updated throughout the LOM. A change within the industry must be made whereby the development of a conceptual design is not just for regulatory approval to commence the operation, but it is something that must be regularly reviewed through the mine life. Should a variation be found (material properties, recoverable volumes and scheduling for example), a change to the WRD design is paramount. Failure to address such ongoing variations or problems may lead to incorrect waste placement, potential delays during operations and additional unnecessary costs.

If initial material characterization was poorly completed and conditions are found to vary during operations, but the conceptual design has not been updated, the relevant regulatory body may require further evidence that a facility can be constructed at site and will meet any prescribed closure criteria. This may also cause delays to the mining schedule and require costly drilling and investigation programs. At this stage a portion of the WRD will have already been completed, reducing the number of options available to the site for design and ultimate successful completion of the project, or requiring such materials to be moved.

DURING OPERATIONS: CONTINUE PLANNING AND CHARACTERIZING

Appropriate waste rock handling during operations is very important. Through the development of a mining schedule the characteristics and volume of materials excavated at any time within the LOM will be known. As such temporary works can be established as required. There may be a restriction on material movement at certain times of the year, for example within tropical regions the assessment of particularly reactive materials should be made and interim procedures proposed to limit rainfall infiltration into exposed reactive waste material during the wet or monsoon season. Materials that are proposed to be used within the outer portions of a landform should be appropriately stockpiled for use at a later date. However, an appropriate material movement register should be established documenting the type of material hauled and the date it occurred. Should operations cease at some point in the future, or the mine changes owners, records would be in place regarding the composition of the stockpiled waste/overburden. This register documents the location of potential rehabilitation materials to be utilized as intended, as well as reactive materials requiring encapsulation and management. It is not uncommon to find during the advanced stage of mine operations that the best materials for closure and rehabilitation of the WRD have been 'lost' as the control on material movement has been poor.

The dumping technique used for material placement must be appropriate to the waste. For example, short tip heads or paddock dumping should be considered for highly reactive materials that have the capability to spontaneously combust. Material segregation has previously been identified as a significant factor in PAF risk management. If preferential pathways exist for oxygen and water to easily move through the WRD it can be expected that oxidation of reactive materials will be accelerated (Pearce, 2014). This has the potential to generate significant issues to the mine site, in terms of personnel safety (from the production of harmful, toxic gasses and spontaneous combustion) and to the environment.

Wherever possible it is advisable to compact each lift as the WRD is progressed. This will assist in managing surface runoff and reducing net percolation. Compaction can be enhanced with the use of finer grained materials such as clayey silts. This process reduces waste rock atmospheric interactions and thus may prevent the generation of acid and metalliferous drainage (AMD) or hazardous gas formation. Compaction can be achieved by use of dedicated equipment or by truck compaction during routine haulage and dumping procedure. When haul trucks are dumping waste at a facility it is advisable to regularly vary the route across the facility that is taken, thus allowing the compaction force to be spread over the materials, rather than concentrating all efforts along the same, repetitive pathway.

It is important that appropriate quality assurance and control (QA/QC) measures are established at the start of any WRD construction project. Over time regulatory requirements are commonly becoming more stringent, and rather than just presenting a landform design for both operations and closure of a facility, organizations are requesting that the methods proposed regarding how such facility will be constructed and how it can be completed are presented. Based on the material characteristics developed QA/QC methods will promote the suitability of a material to its design. There are a vast range of QA/QC actions applicable to many materials and conditions, but very important to site utilizing a compacted clay layer (CCL) is ensuring that the compaction effort for each lift is consistent with the desired optimum water content and density values (as determined through the materials characterization and conceptual design process).

As a mine is progressed it is paramount that ongoing materials characterization is completed to ensure that the facility constructed is as per the designated design, and if this is not possible then the design must be amended to ensure that the designated closure criteria are achieved. Material testing frequency should be conducted at a high level during the initial stages of the mine venture in order to fully understand the strata encountered, and ensure it is as expected. As knowledge of a material is gained, and its characteristics understood, the testing frequency can be decreased. However, the frequency should be increased as materials change composition. Results should feed directly into the materials placement plan and allow for the landform model and design to be updated. There are international standards that discuss the frequency that bulk testing should be completed, for example INAP (2009), these should be best practice and would require consultation and referrence within mining and waste management procedures, as applicable.

CASE STUDY

The following section of this paper discusses relevant case study examples where efforts were made either prior to the excavation of any waste materials, or during the LOM, to appropriately design and construct a WRD that works. In other words, meet the designated closure criteria for the project and achieve regulatory and stakeholder approval.

Poly-Metallic Mine#1 Australia

A WRD landform design was recently developed to include encapsulation of PAF materials. A well-developed geological block model was presented prior to initiation of the mining venture, with comprehensive, and reliable geotechnical and geochemical data. Previously the mine site had been focused on several lithological units, of varying thickness and description. However, in terms of the conceptual landform design only three material types needed classifying: metasediments (heavily weathered sediments and volcanoclastic), dolerite and un-weathered mineralized host

rocks: termed mineralization. Geochemical testing had proven that materials within the weathered zone (upper 100 m deep) comprised entirely NAF waste. Below the zone of total oxidation some PAF material was identified within a transitional zone (active zone of weathering, some 15 m thick) and all fresh materials, unaltered by weathering processes, were PAF. Based on the understood mining schedule, and with reference to the mining equipment known to be utilized, a conceptual WRD design was prepared.

The design was developed based on the PAF waste reactivity and its relative timing in relation to the NAF materials required to encapsulate it and limit the ingress of atmospheric oxygen and incident water.

PAF encapsulation was to be achieved throughout the LOM, even though it would not be encountered until several months into the project. Fortunately, due to the proposed open-pit design PAF waste would be encountered concurrently with NAF materials. The initial design promoted moisture storage within the NAF waste following rainfall events, and its subsequent release to the atmosphere via evapotranspiration during dry periods, limiting rainfall infiltration to the underlying PAF. This moisture 'store-and-release' concept was deemed best suited to the arid to semi-arid climate that the mine site experiences. A second PAF waste management strategy was proposed that included a basal NAF layer to lift the PAF waste from the natural ground surface, thus eliminating the potential for lateral flow through the PAF waste and providing storage for seepage water from the overlying PAF waste (and potential adsorption of AMD products) if the upper NAF material are overwhelmed and seepage into the PAF waste occurs. Furthermore, additional geotechnical stability was provided.

The preferred final design comprised horizontal PAF and NAF layering of specified thicknesses (Figure 1). This option was chosen to be the most appropriate for several reasons, including concurrent placement of NAF and PAF waste at the facility thus preventing double handling or significant temporary works; allowing 'buffer' zones to exist should net percolation occur in extreme rainfall events; and reduction in the potential for differential settlement.

The outer WRD was designed based on the geotechnical properties of the available NAF materials and suitablity to the climate experienced. Perimeter embankments would be of sufficient width that PAF waste was not positioned beneath a sloping section and that PAF waste would not daylight the facility. In addition perimeter embankments utilized appropriate geometries whereby minimal surface erosion would occur and geometries appropriate to the materials and climate at the facility. NAF waste within the outer profile would be homogeneous, thus preventing the development of material segregation and preferential flow path establishment. Appropriate QA/QC measures were proposed in order to achieve the designated facility, in conjunction with an ongoing geotechnical and geochemical laboratory testing program. Finally, a surface water management plan was proposed that allowed individual catchment areas to be developed and minimize the potential for failure of the facility.

The success of this project came from 1) the initial extensive characterization of the materials present and their relative timing and 2) the use of ongoing materials sampling, laboratory testing and characterization to ensure that the facility constructed would perform as per the design.

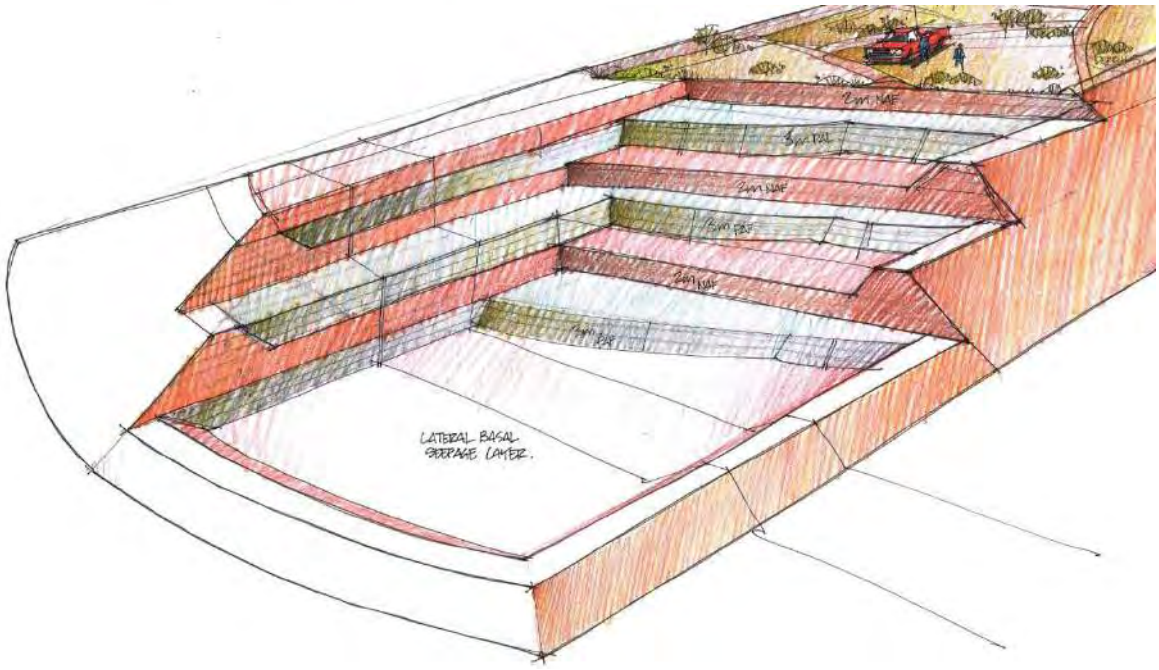

Figure 1 Schematic cross-section through the proposed WRD facility

Poly-Metallic Mine#2 Australia

A design was proposed for a large WRD that utilized NAF waste to encapsulate PAF material. The original geological block model was supported with geochemical data for a substantial (>15 m) unit of NAF waste, overlain by a CCL and finally growth medium. A second CCL was also proposed for between the PAF and NAF materials. As the project progressed it was determined that the waste materials had been incorrectly characterized. As such the design was amended with the NAF unit thickness decreasing. Further studies illustrated that portions of the NAF material were saline and metal leaching, and therefore could not be utilized as previously intended on the facility's outer embankment or plateau, in line with the regulatory requirements of the facility. As such the volume of 'clean' NAF was significantly reduced further and both the landform and cover system design required alteration to minimize any deleterious impact of the mine waste on the receiving environment in the short-term, and to facilitate recovery of the environment disturbed by mining over the long-term. A further complication was that the PAF waste had not been properly analyzed and it has been found to be highly reactive and capable of spontaneous combustion.

With this site efforts had been made to quantify the materials in-pit for WRD construction, however, the reactivity of the PAF material had not be fully understood. In addition, the geochemical characterization of the NAF waste had used the presence of sulfates and pH value as a discriminator for NAF vs. PAF, whereas the presence of salts and heavy metals had been overlooked. Furthermore, when the materials balance was initially amended the WRD construction techniques employed at site were not. As such the material placement measures promoted the materials' reactivity.

CONCLUSION

It is of utmost importance that all materials expected to be excavated are appropriately characterized and their available volume determined. With a thorough understanding of the waste rock both prior to initiation of a venture and confirmed or otherwise during operations, in addition to the climate and environment of a site efforts can be made in developing a conceptual landform design that will meet regulatory closure criteria and satisfy stakeholders. Failure to provide appropriate materials handling and construction techniques to a facility presents huge potential for WRD failure at some point during the LOM, thus leading to environmental issues and large costs in rectifying any damage made during operations.

On-Land or Submarine Tailings Disposal? – Pros and Cons

Bernhard Dold
SUMIRCO (Sustainable Mining Research & Consultancy), Chile

ABSTRACT

Mine tailings management is a major issue for the mining industry and a limiting factor due to competitive land use for example with agriculture or tourism. Most of mine tailings are stored today in constructed tailings impoundments on-land. This practise results in the exposure of sulfide minerals to oxidizing conditions and subsequent in acid mine drainage (AMD) formation in many cases. Due to the environmental and geotechnical stability problems of this tailings disposal practise, the mining industry is searching for alternatively tailings management options. Currently the deep marine tailings disposal is experiencing a revival as such an alternative option. After negative experiences of marine shore or shallow depositions around the world, the deep marine disposal (below the euphotic zone; i.e. < 150 m depth) is seen as a potentially save option in some sectors. The idea to deposit sulfide minerals in a reducing environment to prevent sulfide oxidation and the subsequent element and acid release is sound and appealing. However, the experiences from the past have shown that only the thorough mineralogical and geochemical characterization of the future tailings to be deposited can give the necessary information if the material is suitable for submarine disposal (The tailings can contain more soluble minerals, which are not stable in the marine environment). Then the disposal site has to be evaluated to ensure stable reducing conditions without currents and upwelling. This paper analyzes the pros and cons of each tailings management strategy and highlights the geochemical processes and characterization methodologies, which have to be considered in each case for decision-making.

Keywords: sulfide oxidation, acid mine drainage, prediction, waste management, reductive dissolution,

INTRODUCTION

Final waste management is a critical issue for mining operations, as around the world new legislations are in place for mine closure and environmental protection (e.g. new mine closure law 20.551 in Chile from November 2012). As nowadays metal mining focuses mainly on sulfidic ore bodies, the associated sulfide oxidation and formation of acid mine drainage in mine wastes like tailings are the mayor environmental issued of the on-land deposition of the mine tailings (Dold, 2010, 2014a). Mine tailings disposal is therefore a critical issue for any mine project and must be thoroughly studied before the most suitable solution of each case is found. Main problems associated to the tailings disposal are the geotechnical stability (Azam and Li, 2010; Rico et al., 2008a; Rico et al., 2008b) and the geochemical stability (Dold, 2010, 2014a).

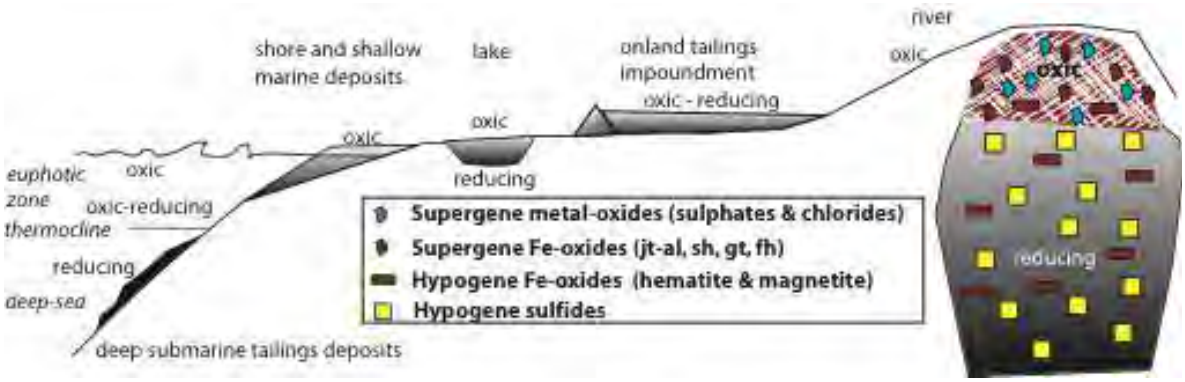

Figure 1: Overview over the different mine tailings disposal options (river, lake, sea and onland disposal (constructed impoundments) and the associated geochemical regimes. On the right the different main mineral assemblages from sulfide to oxide domination in an ore deposit are highlighted.

Historically, mine tailings were dumped first into close-by rivers (Fig. 1), lagoons or lakes (Dold, 2014b; Dold et al., 2009). In some cases the tailings reached the sea and formed so called shore tailings deposits, like at Chañaral/Chile (Bea et al., 2010; Dold, 2006; Korehi et al., 2013), Bahia de Ite/Peru (Diaby and Dold, 2014; Dold et al., 2011) y Bahia Portman/Spain (Benedicto et al., 2008; Martinez-Sanchez et al., 2008; Oyarzun et al., 2013). This practice led to a severe contamination of the associated aqueous systems.

In the years around 1970 at several place around the world, the so called deep submarine disposal of mine tailings started due to the visible problems of marine tailings deposition at the shore line and in the euphotic zone in the Atlas Mine, Filipinas, Island Copper Mine (50 m), Canada, Jordan River Mine, Canada and Black Angel Mine, Greenland. The cases of Island Copper Mine and Black Angel Mine have shown the difficulties of predicting the behavior of the oceanographic system and the importance of mineralogical and geochemical characterization of the tailings before marine deposition. In the latter case, soluble and oxide minerals liberated significant amounts of contaminants into the sea (Perner et al., 2010; Poling and Ellis, 1995), similar to the situation of Ensenada Chapaco (Dold, 2014b), and clearly showed that oxide minerals should not be deposited in a reducing environment.

As this historic overview shows, inappropriate tailings management and a lack of mineralogical, geochemical, and oceanographic characterization of the systems can lead to environmental damage, and has resulted in a shift by the mining industry back to on-land deposition in tailings impoundments.

However, also on-land tailings disposal has many severe problems (e.g. geotechnical and geochemical stability; AMD formation), receiving increasing pressures from society, and therefore, the submarine tailings disposal option is nowadays again being evaluated. This paper shows the factors to be considered for the final decision making for the best tailings disposal option.

METHODOLOGY

In order to be able to predict accurately the environmental long-term behavior of the tailings on-land or submarine, quantitative mineralogy is needed. This give the possibility to predict the behavior of the material in different geochemical conditions and for an accurate prediction of acid mine drainage formation (acid-base accounting). Today advanced technologies are available for automated mineralogical analysis like QEMSCAN® or MLA. If thoroughly calibrated with the ore mineralogy this give an accurate quantification of the complete mineral assemblage, degree of liberation, as well as grain size distributions, important information to increase the efficiency of the extraction process and to predict AMD formation and element release.

However, this methodology does not give detailed information on trace element association to specific minerals or mineral groups. This information is crucial in order to predict if a certain contaminant might be liberated from its host mineral. Therefore, the mineralogical data are combined with high-resolution geochemical data from a seven-step sequential extraction developed for the primary and secondary mineralogy present in typical porphyry copper deposits (Dold, 2003). The leach solutions are then analyzed by inductively coupled plasma–atomic emission spectroscopy. The sequential extractions data can additionally be used to perform a high-resolution ABA (Dold 2010) and should be correlated with the mineralogical data for quality control of the data, and in order to predict AMD formation and element liberation of any mined material. It is important to note that this extraction sequence might have to be adapted to the solubility of the specific minerals (primary and secondary) present in an ore deposit, as this might differ importantly in different ore deposit types.

In order to predict the kinetics of metal release to the environment, so-called kinetic tests are used (Weibel et al., 2011). The tests used in AMD prediction (e.g. ASTM D5744-96) are not suitable for prediction of the behavior of mine tailings in submarine environments, as they expose to an oxic environment. There is currently no kinetic test available to predict the behavior of mine tailings in a reducing environment. Therefore, efforts have to concentrate to develop such a test to simulate the geochemical conditions in the deep-sea environment.

DISCUSSION

Most of the mine tailings are deposited close to the mine site, or at least as close as possible in order to lower costs. However, there are examples were tailings are sent hundred kilometers to a suitable

disposal site. An overview of the principal pros and cons of both deposition strategies are given and then discussed in order to give assessment for decision making.

Pros and Cons of On-Land tailings disposal

Commonly Mentioned Advantages of On-Land tailings disposal are:

- Cheapest option, as lowest transport costs through close-by deposition;
- The economic value contained in the tailings might be exploited in future by new exploitations techniques;
- New dam construction techniques ensure geotechnical stability;
- New tailings impoundments contain an impermeabilization to prevent groundwater contamination and/or to recover water and dissolved metals (e.g. pregnant leach solutions; PLS) from the tailings.
- New tailings deposition techniques like dry stacking use less water and increase the geotechnical stability.

Commonly Mentioned Disadvantages and Risks of On-land tailings deposition are:

- Dam failures due to geotechnical instability (especially in seismic and high rainfall areas and for old tailings impoundments, which were not constructed in an appropriate and safe way);
- Formation of Acid Mine Drainage due to sulfide oxidation;
- Competition with other land-uses like agriculture and tourism;
- Groundwater contamination due to the lack of basal impermeabilization;
- Long-term maintenance and monitoring required
- Low social acceptance

Pros and cons of submarine tailings disposal (STD)

Commonly Mentioned Advantages of STD Are:

- Prevention of acid mine drainage: Reducing environment and lower concentrations of dissolved oxygen limit or prevent sulfide oxidation and any acidity produced through sulfide oxidation will be neutralized by the buffer capacity of marine water;
- Tailings are more geotechnically stable and the possibility of catastrophic failure of tailings dams (on land tailings dam heights may reach several hundred meters), especially in areas with high seismic activity and high rainfall is eliminated;
- Minimal land surface is used. This is a strong argument in Norway where, due to the Fjord topography, on-land space for the tailings deposition is very limited;
- Less long-term maintenance required after deposition compared to on-land disposals.

Commonly Mentioned Disadvantages and Risks of STD Are:

- Smothering benthic organisms and physical and geochemical alteration of bottom habitat;
- Reduced number of species and biodiversity of marine communities;
- Risk of liberation of toxic elements from the tailings to the seawater;
- Bioaccumulation of metals through the food chains and ultimately into fish consumed by Humans, with associated human health risks;
- The water content of the tailings cannot be recovered; this is especially critical in dry climates;
- The deposited tailings cannot be recovered (possible loss of valuable resources);
- Larger footprint on the seabed than on land;
- Potential toxicity of the flotation reagents used on the marine ecosystem;
- Plume sharing and dispersal of the fine particles throughout the sea;
- Relocation of the tailings in different compartments of the marine ecosystem due to upwelling and currents.
- If accidents happen it is nearly impossible to control them in the deep-sea environment.
- Low social acceptance

In the past, many mistake in mine tailings disposal have been done, which led to strong environmental contamination and threat through geotechnical instability. This led to an increasingly low acceptance by the public opinion and therefore difficulties in the permitting process. This is true for the on-land disposal as well as the submarine disposal. The main problems in both cases are the insufficient mineralogical and geochemical characterization of the tailings to be deposited and the characterization of the receiving environment. It is known, that when sulfidic tailings are exposed on-land to oxidizing conditions, acid mine drainage can form. In order to predict accurately if AMD will form, a thorough mineralogical and geochemical study has to be performed. Standard acid-base accounting tests and kinetic testing is not sufficient to address the complexity of the ore mineralogy. Additionally, most of the tailings impoundments do not have an impermeabilization in order to prevent the infiltration of the contaminated solution into the groundwater (Dold, 2014a), and the hydrogeology of the receiving environment is often poorly understood.

If the tailings are deposited into the sea, also a detailed study of the mineralogy and geochemistry of the ore is needed, as well as a detailed knowledge of the sea environment is needed. In this case a special attention has to be given to the oxide minerals (especially Fe-oxides like hematite, magnetite, goethite, ferrihydrite among others), which can contain important amounts of toxic elements (Nystroem and Henriquez, 1994) and might suffer reductive dissolution in the reducing environment of the deep sea (Dold, 2014b). Additionally, the long-term stability of the reducing conditions at the disposal site has to be proven by thorough oceanographic studies. These studies have also to show that at the site, there are no currents and upwelling, which could relocated the material into different geochemical conditions.

In the past on-land tailings disposal was done in very simple forms promoting the oxidation, and thus the AMD formation, mostly with direct contact with water bodies (river, lake, sea, or

groundwater), with the subsequent pollution of those. If on-land tailings disposal is done by best-practice, an impermeabilization and separation from the hydrological system is necessary (Dold, 2008). Also the formation of AMD might be prevented or controlled by different measures, in order to limit the impact on the receiving ecosystem. The geotechnical stability can be increased importantly by the use of state-of–the-art dam construction techniques. If all these factors are considered in the construction of an tailings impoundment on-land, most of the environmental and geotechnical problems from the past can be avoided, and the tailings are in condition for further exploitation with advanced technologies by future generations (Dold, 2008). However, the on-land tailings deposition still has to compete with other land-uses.

In case of submarine tailings disposal, it has to be proven that the material to be deposited is "inert inorganic geological material" following the London Protocol (Dold, 2014b). The objective of submarine tailings disposal is to deposit the sulfide containing minerals into a reducing environment, in order to prevent the sulfide oxidation. However it is often overlooked, that ore deposit often contain not only sulfide minerals, but also oxides like hematite and magnetite or other soluble minerals, which can contain also toxic trace elements. These minerals are not stable under the reducing, alkaline and organic matter rich environment of the deep-sea. Therefore, the mineralogical and geochemical characterization must be very thorough in order to ensure that the material is effectively "inert inorganic geological material".

CONCLUSION

Te above mentioned arguments show that both option have important pros and cons, and it has to be evaluated in each case, which might be the most suitable option. The examples show that only if we count on an accurate quantitative mineralogy and data on the association of trace elements to these minerals, a correct prediction of the behaviour of the material in the different geochemical compartments for the final deposition of the waste material can be given. This is crucial to ensure the long-term geochemical and geotechnical stability of the waste.

Due to the limitation for submarine tailings disposal that only "inert inorganic geological material" can be deposited into the sea, it can be predicted that only few sites might be suitable for this option. Instead, if on-land disposal uses best-practice methods for pollution prevention and geotechnical stability, this option ensures the possibility that future generation might be able to exploit these resources in the future by optimized exploitation techniques.

ABSTRACT

Tailings are the most visible remaining signs of mining activity, that together with mine waste rocks and open pit, are recognized as the "legacy" impacts of mining. In the past, the primary aim was to provide a well-engineered structure into which tailings can be deposited without a great deal of attention given to closure requirements or long term management of tailings storage facilities (TSF). Nowadays, the closure of TSF, must be planned at the beginning of the project so environmental, health and safety impacts do not remain in time after the closure. Not having a closure plan during the design stage may present serious economic consequences for the project, since closure costs without the planning at the end of mine life could threaten the project global economy. This implies that the closure concept must be included in the early phase of the TSF, to guarantee minor impacts in the future and ensure cost-effective closure activities considered in the global budget of the project.

This paper presents a guide to water management in the closure of TSF with focus on physical, hydrological and geochemical stability and its co-relation to improve closure activities for the long term waste and water management. Main impacts on water resources and TSF closure technologies are described like a methodology that needs to be engineered for closure during mine life by civil works and regular monitoring activities, so stability and environmental performance objectives can be achieved.

Successful TSF closure history cases are presented considering application in Chile and Peru, describing their design criteria, learned lessons, advantages/disadvantages, and technology performance under particular Andean region conditions.

Keywords: Contact/non-contact water management, TSF physical/hydrological/geochemical stability, seepage/infiltration control, covers, ARD mitigation

INTRODUCTION

Recently, there has been an increasing awareness for environmental and social sustainability of construction, operation and closure of mining projects. One of the main components that persist after closure is tailings storage facilities (TSFs). Whilst the engineering and geotechnical principles involved in the design of TSFs have been well developed in recent years, many attempts have been made, often on a trial and error basis, to ensure the long-term stability of TSF. Tailings are generally stored on the surface either within retaining structures (slurry or thickened tailings) or in the form of piles (paste or filtered tailings), but can also be stored underground in mined out voids (hydraulic fill or backfill tailings), or below water (lakes and sea) (Vick, 2001). In all cases TSFs host a residue that contain minerals, metallurgical reagents and water that can dissolve and transport contaminants to soil, groundwater and surface water. Also, site conditions may cause hydraulic erosion and soil liquefaction. For this reasons, water management of TSFs is an important issue to maintain physical, geochemical and hydrological stability after closure.

GEOCHEMICAL STABILITY ISSUES

Acid rock drainage (ARD) from mine waste is a worldwide environmental problem that can cause deterioration of downstream groundwater and surface water systems affecting aquatic biota. Weathering of sulphide minerals present in mine waste is responsible for generation of ARD. The quality of ARD is controlled by mineralogical and geochemical reactions in TSFs, and the outcome of these reactions is reflected in seepage waters surfacing through tailings dams, infiltration to soil and to groundwater. However, the design of tailings impoundment and tailings disposal technique ultimately determine whether sulphide minerals are exposed to weathering and whether mine drainage starts to form (Dold, 2014a).

Geochemical Considerations

Geochemical considerations for closure in TSFs depend on tailings disposal method. Most known disposal methods are surface, sub-aqueous and underground tailings disposal. Sub-aqueous (lake or submarine) tailings disposal has the advantage of eliminating air (oxygen) to minimize the oxidation of sulphides and prevent ARD with a low-cost closure and maintenance system. However, this method has been banned and restricted in several countries due to the high risk of environmental contamination. Historically, several cases of sub-aqueous tailings disposal has ended in final liberation of contaminants under reducing conditions, dispersion of chemicals from tailings and sediment contamination after decades of monitoring (Dold, 2014b). This has left impacts on aquatic biodiversity and risk of bioaccumulation of metals through food chains. The feasibility of sub-aquatic tailings disposal is dependent upon specific circumstances, extensive analyses of geochemical characteristics and its response under specific sub-aqueous conditions (Dold, 2014b). Monitoring of water quality, sediment quality and aquatic life is an important tool to control and evaluate sustainable closure.

Underground tailings disposal can prove viable for some of the tailings produced in mine life. In abandoned open pit mines, tailings material can be used to backfill the void, eliminating air (oxygen) and water contact with pit walls and water (groundwater, rainfall) decreasing closure costs associated with the tailings material at the same time as pit remediation. In underground mines tailings material can be used, after geochemical treatment and cement mixer, for structural

purposes on stopes. In this case, monitoring of groundwater and superficial water downstream is an important tool to control and evaluate sustainable closure.

Surface tailings disposal is the most common method, mainly because it is preferable to store tailings on the surface where potential negative impacts can be managed. However, the main problem with surface deposition is that it is very difficult to achieve a sustainable closure solution for surface TSFs since ultimately all materials decompose, erode and are transported to the oceans in geological time scale (Szymanski and Davies, 2004). Also, there is a constant risk of ARD generation by the contact of sulphide tailings with water (groundwater, rainfall) and oxygen (air). In surface tailings disposal, sulphide oxidation with subsequent metal release may occur in the unsaturated border zones close to the embankments (borrow, rockfill or cycloned tailings sand dams) and at the tailings beach surface in active impoundments (Chambers, 2012). Metals released in sulphide oxidation can be retained by secondary precipitates that had formed as a result of oxidation. This mechanism prevents the downward transport of metals in the circum-neutral conditions. However, in acidic conditions, metals are no longer retained in the precipitate and rather dissolved in ARD (Tabra and Lange, 2014). Is relevant to mention that not all metals will precipitate in neutral condition and even neutral drainage may be potentially contaminant.

TSF Site selection - tailings characterization and ARD prediction

Baseline information (seismic, geological, geotechnical, meteorological, hydrological, hydrogeological, biological, soil/sediment quality, flora, fauna, social, and economical) of potential sites for tailings disposal and geochemical characterization of tailings material, are important aspects to consider for the selection of tailings disposal site and disposal method. Land and water uses of populations, flora and animals near and/or downstream tailings disposal site must be considered. Some of these aspects are summarized in the following table.

Table 1 Environmental Aspects for TSF Disposal and Closure Water Management Systems

Environmental Aspects		Tailings disposal	Closure Water Management System
Weather	Rainy (Tropical or Highlands)	Thickened Tailings/sub aquatic disposal	Diversion ditches, spillway, channels, grout curtain, cut off trench, underdrain, drainage system, collection pond, passive or active effluent treatment
	Dry (Desert)	Dewatered tailings/ in pit tailings disposal or co-disposal with waste rock	Diversion ditches, spillway, channels, drainage system, collection pond, passive or active effluent treatment
Geomorphology	Steep terrain	Conventional disposal	Diversion ditches, spillway, channels, grout curtain, cut off trench, underdrain, drainage system, collection pond, passive or active effluent treatment
	Flat terrain	Thickened tailings/Filtered Tailings/ In pit tailings disposal or co-disposal with waste rock	Diversion ditches, spillway, channels, drainage system, collection pond, passive or active effluent treatment
Seismicity	High	Dewatered tailings	Diversion ditches, spillway, channels, drainage system, collection pond, passive or active effluent treatment
		In pit tailings disposal / backfilling mine stopes	Pumping wells, collection ponds, passive or active effluent treatment
	Low	Co-disposal	Diversion ditches, spillway, channels, drainage

Environmental Aspects		Tailings disposal	Closure Water Management System
			system, collection pond, passive or active effluent treatment
		Conventional disposal	Diversion ditches, spillway, channels, grout curtain, cut off trench, underdrain, drainage system, collection pond, passive or active effluent treatment
Hydrology	Rivers, creeks (at the proposed site)	Conventional disposal	Diversion tunnels and coffer dams (derivation of rivers and creeks), diversion ditches, spillway, channels, grout curtain, cut off trench, underdrain, drainage system, collection pond, passive or active effluent treatment
	Lake, sea	sub aquatic disposal	Aquatic flora and fauna monitoring, submarine flow monitoring
Hydrogeology	Unconfined aquifer, discharge zones, geological faults	Thickened tailings/Filtered Tailings	Diversion ditches, spillway, channels, grout curtain, cut off trench, underdrain, drainage system, collection pond, passive or active effluent treatment
	Confined aquifer, no discharge zones	Conventional Tailings / Dewatered tailings	Diversion ditches, spillway, channels, drainage system, collection pond, passive or active effluent treatment

Prevention of ARD

Prevention is the key to avoid negative environmental impacts and costly mining mitigation. ARD prevention may consider at least three basic options: pyrite removal, oxygen exclusion and water control. Pyrite removal from tailings prior disposal is an effective measure to prevent ARD. The residue with high content of pyrite may then be disposed in an anoxic or confined environment. The second option consists to dispose tailings with acid generation potential in an anoxic environment avoiding sulfide reactions, metal leaching and the subsequent migration of weathering products that result from sulfide oxidation. In the closure phase of TSF, this can be achieved by the development of an effective and durable barrier to oxygen, such as water covers, dry covers and/or geosynthetic membranes. Two types of covers are used to isolate wastes and prevent ARD: dry and wet covers techniques.

Dry covers

The dry cover approach aims to reduce the oxygen flux into the tailings, thereby minimizing sulphide oxidation. The amount of acid water formed is also reduced by limiting the water percolation into the tailings. A dry cover usually consists of a combination of drainage layers and sealing clay, inert or non-reactive tailings, geotextile and organic material. Dewatered and reagent-less tailings material is placed on top of the liner to act as an inert protective layer. A gravel and impermeable layer or waste overburden is placed on top of the inert tailings. This cover can be applied in surface and underground tailings disposal. Dry covers behave as a "water stock-release" structure that enhance evapotranspiration and minimize infiltration. The cover thickness will determine its water storage capacity and will be defined as a function of the local rain pattern. About quantitative criteria of water storage and release in dry covers, research should be oriented in that direction, requiring detailed studies and focused on this topic.

The main drawback with the dry cover technique is that it has a relatively high cost (earthworks and soil processing activities) that is difficult to get right.

Wet covers

Water covers are considered to be one of the most effective methods for the mitigation of potentially acid generating tailings. The water cover in man-made lakes and in situ flooded basins is generally shallow (less than 2m) to minimize the size of dams constructed. To limit metal transfer to the water cover, protective layers of sand or organic material are sometimes placed over the tailings to act as a diffusion and mass-flow barrier. A potential problem that should be mitigated is wind-induced mixing and re-suspension. Underwater disposal in natural water bodies is preferred since provides a deep water cover. However, as already mentioned, this method has been banned and restricted in several countries due to the high risk of environmental contamination (Dold, 2014b). A limitation to wet covers may also be the physical stability of TSF, particularly in seismic environments, with risk of water overtopping.

Liners

The use of liners is significantly less common in tailings facilities for mining closure activities. Synthetic materials, such as high density polyethylene (HDPE) are often used with compacted clays to form a composite lining system to prevent polluted seepage through the facility foundation. Liners are commonly used to facilitate the permitting process. This practice has however largely been avoided on cost grounds. New geosynthetic materials such as geosynthetic clay liners (GCL) need more exploration to study their behavior for mining closure activities for long term.

The third option basically consists on the derivation of runoff and collection of contact water, mainly infiltration. These methods are detailed in hydrological stability issues chapter.

Mitigation of ARD and monitoring

If ARD is generated, active and passive technologies are necessary increase pH and remove solutes to accomplish water quality standards for discharge or reutilization. This treatment involves passive and active closure criteria that largely increase closure costs. Improved methods of prevention and control substantially reduce ARD treatment. TSF design must consider the collection of this water, avoiding impacts on soil, groundwater and superficial water. After closure, monitoring of groundwater and superficial water downstream of TSF is an important issue to control possible flows of infiltration during operation and after final closure. However most monitoring plans don't last more than 10 years when the real effects of ARD can be noticed even after hundred years.

Ongoing laboratory testing of tailings and collection of supernatant pond and seepage water samples from TSF during operation and after closure of mine is needed to verify control methods and TSF geochemical stability.

PHYSICAL STABILITY ISSUES

Climate and seismic site conditions need to be considered for the closure of surface tailings disposal, focusing on provide robust structures against the following issues: (i) internal water erosion (piping), (ii) external water erosion (runoff), and (iii) wind erosion.

Erosion

In addition to influencing ecosystems (soil, water bodies, flora and fauna), dust emission can negatively affect human health through particulate matter (PM10) pollution. At TSF closure stage, a cover material is needed to manage runoff erosion and create an appropriate ground surface for project reclamation. Dust emission control play an important role in closure design and a proper implementation will provide the primary control mechanism to meet regulatory air quality requirements. Some other dust control alternatives are: soil cover, top soil/re vegetation cover, phytostabilization, binder material or chemical agglomeration, and wind mitigation civil work structures.

Dam Stability

The design of TSF embankment must consider the damage from repeated occurrences of extreme rainfall and earthquake events as well as progressive processes like internal erosion, which in conjunction degrade dam stability in the long term. For these reasons, a periodic inspection program is needed in the post closure stage (ICOLD, 2011), which includes the following activities:

- Evaluate dam stability, considering gentle slopes and benches.
- Evaluate geotechnical instrumentation (mainly piezometers, accelerometers, and underdrain collection sump).
- Evaluate the compaction of dam crest and slope benches.

However, it is important to consider that the potential for piping, filter clogging or creep deformations over hundreds of years cannot be appreciated by available dam safety evaluation methods (Szymanski, and Davies 2004) and designs need to consider long term civil works at TSFs beyond closure stage.

Geologic Hazards

In the indefinite future TSFs will be subject to the full suite of geomorphic processes operating at their sites. These include landslides and debris flows with river damming, characteristic of the Andes. Like the occurrence of these extreme events, the damaging effect of these processes is only a matter of time, and their recurrence rate is a factor particularly difficult to predict for large-scale geologic phenomena. Even benign processes of alluvial deposition will eventually fill water conveyance facilities unless they are continually cleared of sediment and debris. For these reasons, periodic surveillance programs need to be implemented for post closure stage at TSFs (ICOLD, 2011), to evaluate potential geologic risks and build rock falls and debris flow protection structures.

HYDROLOGICAL STABILITY ISSUES

TSF has to be designed for given annual hydrological conditions or more correctly for a range of conditions in which the storm events are statically included. Decants, pumping systems, spillways, piping, and treatment plants need to be sized for such criteria. However, TSF still has to able to cope with individual extreme runoff events, as they occur when the pond is at its maximum operating level. For closure design (long term) it is necessary to consider events that might come from an extremely heavy rainfall, snowmelt, debris/mud flows, climatic change, or a combination of them.

Freeboard

An adequate approach to closure design is to use two design floods: an environmental design flood (EDF) and a facility design flood (FDF). The EDF is typically from a storm with a finite return period of say 10 to 100 years, or it may be a rainfall/snowmelt event. It is the maximum storm event which still does not result in an unscheduled discharge of water to the environment. The flood from the EDF is retained at TSF, within a freeboard allowance below the invert of an emergency spillway, and managed within the normal operation of TSF basin. For this reason, a maximum operating water level (MOWL) should be specified in conjunction with the EDF. The MOWL should not be exceeded under normal operating conditions. The MOWL should provide for adequate freeboard to store the EDF without discharge over the emergency spillway. However, water storage within the TSF may be contradictory with dry cover integrity and may enhance water infiltration through the tailings deposit. This may result in consequent drainage with high sulfate and/or metal concentrations, for these reasons, is necessary to define dry cover zones (tailings beach against dam), wet cover zones (pond), and a maintenance dry cover program. Physical stability must be the primary objective of long-term closure. No means for controlling ARD can succeed unless the tailings are first made to stay in one place, and anything that violates this provision will necessarily compromise all others.

Spillway

The overtopping of a dam could result in a catastrophic failure, extensive erosion, loss of tailings to the environment, a very large uncontrolled spill of water, and even the complete emptying of the pond. For these reasons, an emergency spillway is a safety measure, which must be included in every TSF for closure, to handle unforeseen events and to protect the environment. Under any circumstance should tailings be allowed to escape from a basin or a dam is allowed to overtop. The FDF must be chosen to ensure that this does not happen. The routed FDF is used to size the emergency spillway. For a tailings basin, it is frequently based on the largest possible storm resulting from the probable maximum precipitation (PMP) which might or might not occur in conjunction with snowmelt. Robust spillways need to be designed and constructed. Floods in excess of the EDF are either allowed to spill unimpeded (very large storms) or to spill slowly with a reduced retention time through the emergency spillway. If spillage cannot be tolerated under any circumstances, then the EDF and the FDF have to be the same.

The following figures show the management of storm flow/freeboard concept and a spillway civil work.

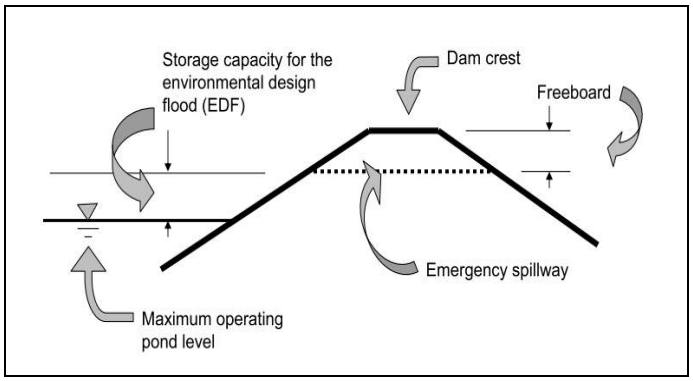

Figure 1 Management of Storm Flows (Golder, 1989)

Figure 2 Spillway and Energy Dissipators

Perimeter Diversion Ditches

Collection and diversion systems for non-contact water (runoff water), consisting of perimeter ditches is required as part of TSF design. For the closure and post-closure phases, it is important to provide lined diversion ditches with long term erosion-resistant materials such as geoweb/concrete solution, GCL liner, or reinforced concrete. Soil excavated ditches without liners are not recommended for TSF closure stage. A periodic inspection program needs to be carrying out for review the integrity of the diversion ditches.

Seepage Collection System – Collection/Polishing Pond

The seepage collection system consists of a cutoff trench and a robust underdrain system. Both systems convey the TSF contact water to collection geosynthetic lined ponds, where water quality is controlled. If the water quality meets the standards, it is possible to discharge it to natural courses. If it is not, water needs to be treated. The installation of downstream monitoring wells is recommended to control periodically the water quality on the TSF on post-closure phase. Polishing ponds or sedimentation ponds are designed to increase the environmental compatibility and quality of effluents from preceding treatments. The water in the reclaim pond is either sent to treatment/polishing ponds for discharge to the environment. Some reclaim water can be sent to evaporation ponds or sprays if the climate is suitable.

Water Storage Dams - Upstream of TSF

An adequate approach for closure design of TSF to control large floods and runoff is to manage water with a high dam storage capacity and a separate water-control dam located upstream of the TSF. Some advantages are: (i) buffering of probable maximum flood (PMF), (ii) controlled diversion, and (iii) promote non contact water.

TSF CLOSURE CASES

El Indio TSFs - Andean Region of South America - Chile

El Indio copper-gold mine is located in the Chilean Andes approximately, 180 km east of La Serena City. The climate is typical of Andes mountain region of dry conditions, with variable winter precipitations (May – September), mainly as snow. On the operation phase the mine had an open

pit and underground activities, with two waste rock dumps, three process/metallurgic plants, and three tailings storage facilities.

The mining company negotiated a voluntary agreement with the Chilean region IV regulatory authorities after 20 years mine lifetime to carry out the closure stage of El Indio Mining project, as there was no legislation yet in place in Chile focused on mine closure. One of the key components of the closure plan was surface water management works developed under the overall objective of "establish a physically and chemically stable drainage system with minimal maintenance and monitoring requirements" (Robledo and Meyer, 2007). As consequence of mining activities, Malo River stream was modified in several sectors with diversion civil works. The main closure activities were: (i) restoration of Malo River drainage system in the process plant area and on TSFs by the construction of engineered lined channels (lined with rockfill and cobblestones), and (ii) abandonment of the existing Malo river diversion system.

Tailings and waste facilities managed in El Indio Mine were: (i) Pastos Largos TSF, (ii) El Indio TSF, (iii) dry tailings modules (filtered tailings), and (iv) sedimentation pond (polishing pond). Specific closure works at the TSFs were considered including surface grading, placement of a cover to prevent hydraulic and wind erosion, and the construction of spillways to manage storm flows. The sedimentation pond is located at Malo River downstream of TSFs stored approximately 66,000 m^3 of sediments (As, Pb, and cyanide among others). Sediments were transported by haul trucks to Pastos Largos TSF for disposal. The pond was removed and the Malo River was restored in its natural stream.

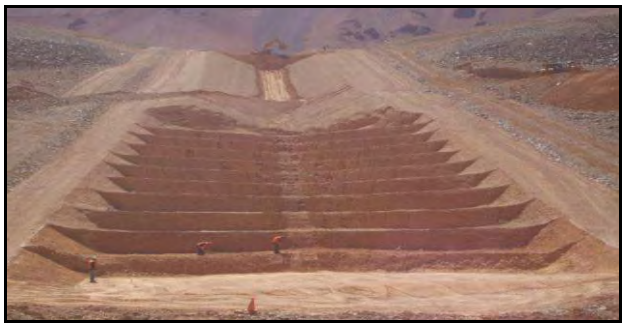

Figure 2 Malo river closure civil works construction (Saez, 2011)

Figure 3 Malo river closure civil works finished

(Saez, 2011)

Figure 4 Filtered TSF – Operating phase (Saez, 2011)

Figure 5 Filtered TSF – Closure phase (Saez, 2011)

Constructed diversion ditches were lined to reduce infiltration of surface water into mine tailings materials and to prevent capture by underground mine workings, with the intent to minimize chemical loading impacts to water. A geosynthetic clay liner (GCL) was selected for lining in most cases. The following pictures show some overall views of closure civil works at El Indio TSFs:

Figure 6 Filtered TSF – Closure construction phase – civil works (Saez, 2011)

Casapalca TSFs – Andean Region of South America - Peru

The Casapalca polymetallic mine is located in Peruvian highlands, approximately 113 km east of Lima city, Peru. The mine is composed by underground activities, and is near to the Rimac river, at an elevation of approximately 4,100 m above sea level. The climate is typical of Peruvian Andes conditions. Annual precipitation is approximately 700 mm with essentially this entire amount falling in the rainy season (November – March). To prevent and reduce the risks for human health and the environment, one of the key components of the closure plan was surface water management works developed under the overall objective of "establish a physically and chemically stable drainage system to Rimac River" (Estrella, 2008). As consequence of mining activities, the stream of the Tacpin creek was modified in several sectors by using a constructed diversion civil works. The main closure activities in the middle part of the Tacpin creek basin were: (i) restoration of Tacpin stream surface drainage channel in the land area and across tailings facilities by construction of engineered lined channels, and (ii) abandonment of the existing Tacpin stream diversion tunnel system.

The tailings waste facilities managed in the Casapalca Mine were: (i) Tablachaca I, and (ii) Tablachaca II. Specific closure works at the TSFs included surface grading and placement of a cover (organic soil layer + clay layer + gravel layer + HDPE layer) to prevent: (i) hydraulic and wind erosion, (ii) oxidation of sulphide tailings, and (iii) physical stabilization of TSF slopes. Hydraulic civil works constructed with reinforced concrete were: (i) diversion ditches to collect no contact water, (ii) diversion tunnel (rock wall reinforced), and (iii) Tacpin stream intake structure to divert runoff to diversion tunnel. Like a post closure activities revegetation was applied, with native plants from the site.

The following pictures show some overall views of closure civil works at Tablachaca TSFs:

Figure 6 Construction of closure civil works (Huaymanta, 2011)

Figure 7 Closure civil works finished (Huaymanta, 2011)

Figure 8 Tablachaca TSF before closure stage (Estrella, 2008)

Figure 9 Tablachaca TSF after closure stage (Estrella, 2008)

Figure 10 Tablachaca TSF closure overview (Estrella, 2008)

In both TSF closure cases the application of the concepts of closure, decommissioning, cover implementation, collection and diversion of non contact water and channeling of water streams are valuable issues. However, it is important to consider that tailings disposal on a riverbed is prone to geological and hydrological hazards on extreme flood events and geodynamic events. It is relevant to consider a periodic OMS program (operation, maintenance and surveillance) and ISR/DSR

programs (Inspection Safety Review/Dam Safety Review) after the closure activities to monitor and control the closure TSF performance at these study cases (ICOLD, 2011).

CONCLUSIONS

The main goal of long-term closure is to achieve "walk-away" conditions that assure physical, hydrological and chemical stability without the need of long-term monitoring and maintenance. This objective depend on the motivation and ability of authorities to deal with mining wastes after decades, and even centuries, avoiding to pass the burdens of today's resource extraction to future generations who will inevitably receive the impacts of these passives (Tabra and Lange, 2014).

One of the main challenges in closure design for TSF is probably their capacity to deal with extreme events (hydrological and seismic). For surface tailings disposal, water management related with high surface water flows should consider the rapid evacuation of water, minimizing erosion and instability, and temporal water storage that requires specific design to minimize infiltration. Civil works and control systems for TSFs must be designed in the early stages of a mining project with conservative criteria and robust structures, thinking about the perpetuity of this component and projecting a periodic schedule of maintenance and restoration in the post-closure stage (Cacciuttolo et al., 2014).

Geochemical stability is a relevant part of a TSF project, particularly if tailings contain acid-generating behavior, because these materials can degrade the strength properties of cycloned tailings sand dams and borrow dams, increasing dam failure risks and generating ARD. In general, mine residues that interact with the environment should be inert to materials and chemicals already in the same ecosystem. If mining wastes are not inert they should be isolated and in a form that is compatible with the adopted waste management technique, the sensitivity of ecosystem and social context.

In recent years, there have been significant advances in physical and hydrological stability of TSFs (investment effort and better decisions on site selection and use of technology for tailings management). However it still remains to devote more time to understand the action of tailings geochemistry and make greater efforts to prevent, control and mitigate ARD on TSF in the long term.

A long-term closure requires going beyond the usual engineering perspective, with an interdisciplinary approach taking in consideration all points of view in important decision making such as site disposal, method of disposal, TSF design, control methods, contingency plans, among others. In most cases, an initial high inversion is more rentable in the long term. Mining, mineral processing and waste management technologies, which offer improved environmental and social performance, and smaller surface footprint, should be preferentially adopted. Also, opportunities for re-use of waste material should be pursued when practicable.

ABSTRACT

Advective gas transport represents an important mechanism controlling internal geochemistry of waste rock dumps (WRDs). Advective transport into WRDs can result in increased contaminants of concern production or create potentially life threatening air quality conditions. Advective transport is a global concern; being the mechanism documented as contributing to the Sullivan Mine fatalities (British Columbia, Canada), and elevated radon emissions from Wismut Uranium mine (Saxony, Germany). Residual pore gas and diffusion across landform outer surfaces post construction contribute less to WRD legacy liability compared to advective transfer. Being advection is a mechanism of substantial liability, can WRDs be constructed economically while managing advective flow?

This paper investigates material controls that manage advective transport during construction. Beyond geochemistry, geotechnical properties are examined in relation to lift heights, material segregation and subsequent advective transfer rates. Waste rock has been characterized for its propensity to segregate based on tip height and dumping methodology, and classified according advective tendencies. Through comprehensive material characterization and scheduling, progressive management of waste material is possible when mine plans and waste rock management plans interface properly. Potential for larger waste rock lifts of reactive material may be possible if waste scheduling highlights that material is of adequate texture to reduce air permeability within larger cells or lifts, for example. Investigation results are compared using Net Present Value (NPV) analyses highlighting value in progressive management of mine wastes in regard to seepage water quality and quantity (and potential for treatment in perpetuity). This paper will present a framework for more comprehensive waste characterization, planning and scheduling, such that WRDs can be constructed economically over the long-term without a strong reliance on developing cover systems as "last minute" mitigation measures. Rather, cover systems be utilized as contributing seepage management mitigation tools, with appropriate WRD construction as the primary contributing management tool.

RELIABLE MINE WATER OPERATION

Mine Water Balance for a Semi-Arid Climate: Overcoming Challenges to Maintain Operations

Scott Davidson and Emily O'Hara
New Gold Inc, Canada

ABSTRACT

Development of a mine water balance model (WBM) is an essential part of early permitting work and operational planning. New Afton is situated in a semi-arid climate, where its WBM predicted a zero-discharge and net loss facility. Challenges when situated in a semi-arid environment, include significant losses at various stages of the mining cycle and the requirement to supplement the process with freshwater. Water management onsite is essential for all mining operations, and minimizing water losses is essential for arid and semi-arid climates. Freshwater use is highly material to local communities of interest, in particular our First Nations partners. Another challenge that needed to be overcome was that New Afton's water license allows for 139m³/h of freshwater to be pumped from Kamloops Lake, although it had initially applied for 290 m3/hr.

Prior to full operation, two significant water losses were not completely understood. These included void loss in the Tailings Storage Facility (TSF) and ventilation losses from underground. Void losses account for on average 137m³/h when operating at 12,000 tonnes per day. This value was unable to be determined with accuracy until tailings had been produced from the mill, after operation had commenced. Ventilation losses were not expected to be significant, and thus weren't considered when the initial WBM was developed. Due to the extremely dry climate in Kamloops, ventilation losses were first monitored in 2013. Throughout the year, dry air that is pumped underground is vented as warm humid air due to equipment use and water sprays for dust control. Water losses through ventilation on average were found to range from 10 to 18 m³/h. Quantification of these losses was critical to being able to determine actual operation freshwater demands and allow New Afton to amend its permit.

Keywords: Mine, water, arid, climate

INTRODUCTION

New Afton is in its third year of operation, with commercial production reached in June 2012. The scheduled throughput for the mill was 11,000 tons per day, however, this throughput was exceeded early during commercial production. The mine currently operates at a rate of approximately 14,000 tons per day, with opportunity for increased throughput. It is currently licensed to withdraw 139m³/h, or 1,218,000m³ annually from Kamloops Lake.

Located in a semi-arid climate with on average 278mm of precipitation annually, water management is an essential part of New Afton's operating considerations. Water use at the mine site is a significant area of concern for local First Nations and the general community. Managing water quality is also of a very high interest. New Afton minimizes its water use through the following management strategies:

- Recycling of process water in the mill facilities
- Using chemical dust suppressant for dust control
- Recycling all water drawn from underground dewatering
- Maintaining a "zero discharge" water balance.

As part of permit applications prior to operation, New Afton completed a water balance model depicting pre-construction, construction, early operation, full operation and closure. Based on these water balance models, it was estimated that approximately 290m³/h of makeup water from Kamloops Lake would be required, to account for contingencies and increases in production. However, as part of regulatory applications, it was also mentioned that 139m³/h was required for base case, and thus this was the awarded withdrawal rate granted by the government. Following commencement of operations it was realized that the water balance developed for the permitting contained two significant omissions and that the permitted withdrawal rate was insufficient for continuous uninterrupted operations. In November 2013, an application was submitted to increase the licensed water withdrawal rate from 139m³/h to 212m³/h to ensure the operation has sufficient water for continuous operations.

METHODOLOGY

Following the commencement of operations, and as part of its Mines Act permit, New Afton was required to develop an operational water balance for the site. During the development of the operational water balance it was quickly noticed that tailings void losses had not been included along with ventilation system losses. The development of the operational water balance was conducted by BGC Engineering Inc. (BGC) and was based on a combination of process design details and operational data. In July 2013, BGC provided the following water balance based on actual inputs and estimated monthly averages from the first year of operations.

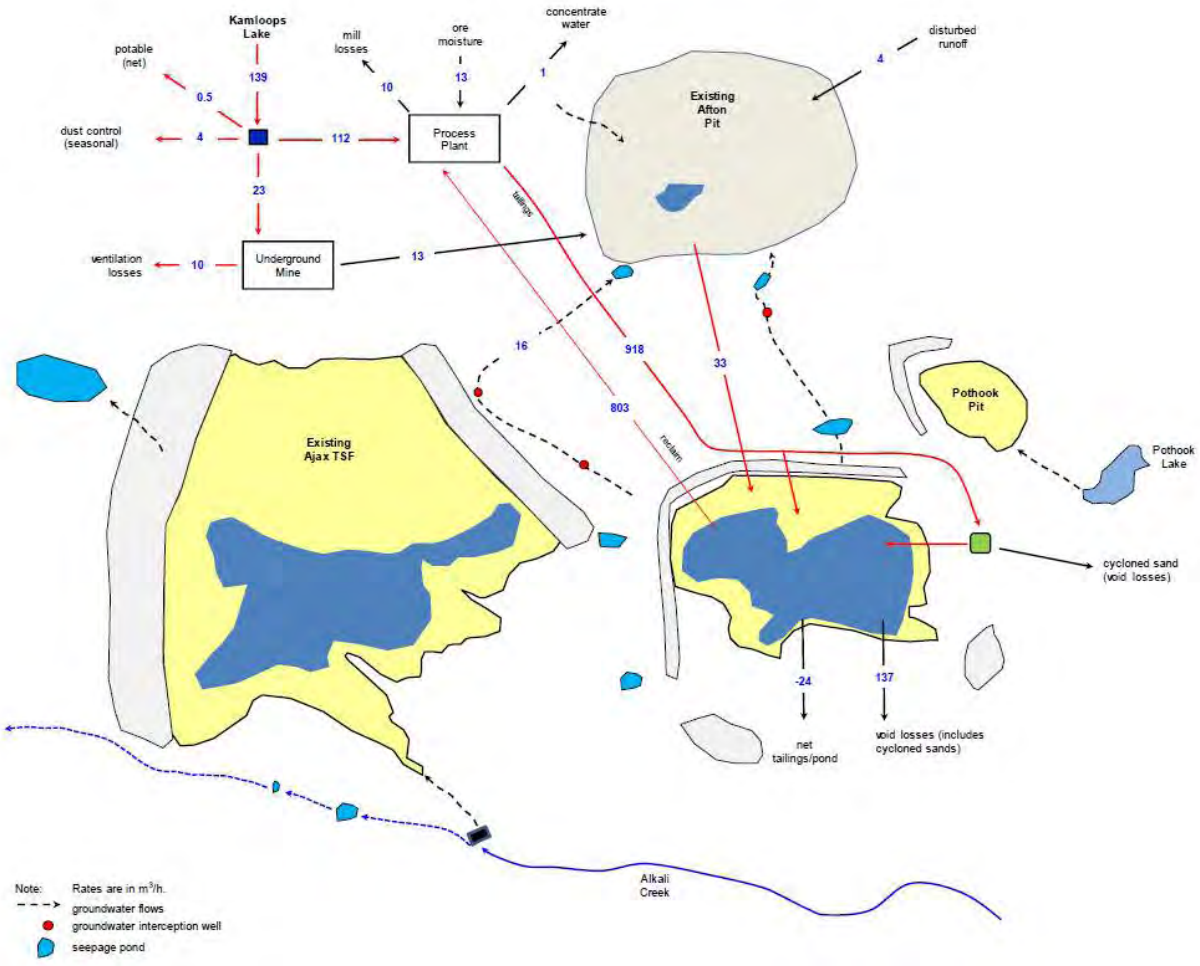

Figure 1 New Afton Average Annual Flows Life-of-Mine (BGC, 2013)

Tailings Void Losses

Tailings void losses is the volume of water that is lost in tailings voids during placement of tailings into the storage facility. Void losses are calculated through the following formula, which is derived from the dry unit weight equation (Budhu, 2007) (Nomenclature for all formulas can be found at the end of this publication):

$$void\ loss = \left(\frac{1}{\rho_s} - \frac{1}{SG}\right) \cdot tailings\ tonnage$$

The current assumption is that the final settled dry density of the tailings will be 1.47t/m³, however it is expected that realized final dry densities may range between 1.4t/m³ and 1.60t/m³ (BGC, 2013).

The settled dry density will vary throughout the life of the project due to ongoing consolidation, so estimating an average for the sake of developing a water balance needs to take this into consideration. Table 1 demonstrates the variation in void losses over the given range of settled dry densities at a production rate of 12 000 tonnes per day. It can be seen from this table that a relatively small change in the settled dry density of the tailings has a substantial impact on the volume of water being lost.

Table 1 Void Losses for Various Settled Dry Densities (BGC, 2013)

Settled Dry Density (t/m^3)	Void Loss (m^3/h)
1.40	176
1.47	159
1.55	141
1.60	131

Bathymetric surveys are carried out annually throughout the life of mine in order to provide data on the existing field settled dry densities and are used to update the water balance model. The surveys are conducted using a boat equipped with a GPS system and a sonar unit. The 2013 bathymetric survey resulted in an estimated settled dry density of 1.47 t/m^3 which matched the water balance value of 1.47 t/m^3.

Ventilation Losses

Ventilation losses were not calculated during the permitting process, as this was not expected to be a significant pathway for water loss. Operations personnel realized though that the ventilation system in the summer months was pushing warm to hot dry air underground while in the winter months the air was cold and dry. Exhaust from the underground was found to be warm humid air throughout the year. Table 2 demonstrates the monthly averages for temperature and relative humidity at the ventilation intake, exhaust and the Kamloops Airport weather station.

Table 2 Ventilation System Temperature and Relative Humidity

	Average Monthly Results				
	1981-2010	2013-2014			
Month	**Kamloops Airport Temp (°C)**	**Intake Temp (°C)**	**Intake RH (%)**	**Exhaust Temp (°C)**	**Exhaust RH (%)**
January	-2.8	-2.7	90.0	13.3	80.4
February	0.1	-6.8	72.3	12.5	76.8
March	5.2	2.9	64.8	12.9	78.7

October	8.5	-	-	-	-
November	2.1	-2.0	90.2	13.6	77.6
December	-2.7	-5.7	88.5	12.8	76.6

Ventilation losses are estimated through the monitoring of relative humidity and temperature at intake fans, exhaust fans and the portal. These readings are recorded hourly on a data logger and retrieved monthly. The water holding capacity for air is estimated based on the August-Roche-Magnus formula (Lawrence, 2005) as shown below:

$$e_s(T) = 6.1094e^{\left(\frac{17.625T}{T+243.04}\right)}$$

For this estimation, it is assumed that there is constant standard atmospheric pressure.

Figure 2 shows the calculated water losses that occurred throughout the monitoring period in 2014. This includes water loss from the ventilation fans only, with another 2m³/h approximately lost from the mine portal. Table 3 contains a monthly summary of the average calculated water losses from the ventilation system.

Water Requirements

Fresh water is required throughout site for showers and bathrooms, underground dust suppression and mill operations. The semi-arid climate at New Afton requires the application of significant dust control measures. Often this would be the continual application of water to roads and bare surfaces, however New Afton has implemented the following controls to assist in the reduction of surface dust:

- Recycled asphalt application on high traffic areas
- Progressive reclamation to provide vegetative cover to bare surfaces
- Application of flocculant to exposed tailings sands during snow free period
- Application of Magnesium Chloride to roadways during dusty months.

The majority of makeup water is provided to the mill process, with on average $112m^3/h$ being used. Current testing is being completed to determine the effect of dissolved metals and salinity on gold and copper recovery, which could put further demands on the freshwater requirements within the mill.

The current major shortfall for water requirements is the ability to maintain a large enough pond volume on the Tailings Storage Facility (TSF). A sufficient volume of water within the pond is required in order to ensure sufficient settling time for fine particulate prior to being recycled back into the processing plant. Based on operating experience at New Afton, the minimum required tailings pond operating volume is approximately 1 Mm^3 at a throughput of 14,000 tpd. The original estimated minimum tailings pond volume for the design throughput of 11,000 tpd was 500,000 m^3, however, it was found even at volumes above this that there was insufficient settling time within the pond.

Figure 3 shows the estimated New Afton tailings pond free water volumes for different throughputs, based on the inclusion of measured ventilation system and tailings void losses. The figure shows the steep decline in free water within the tailings pond based on throughput.

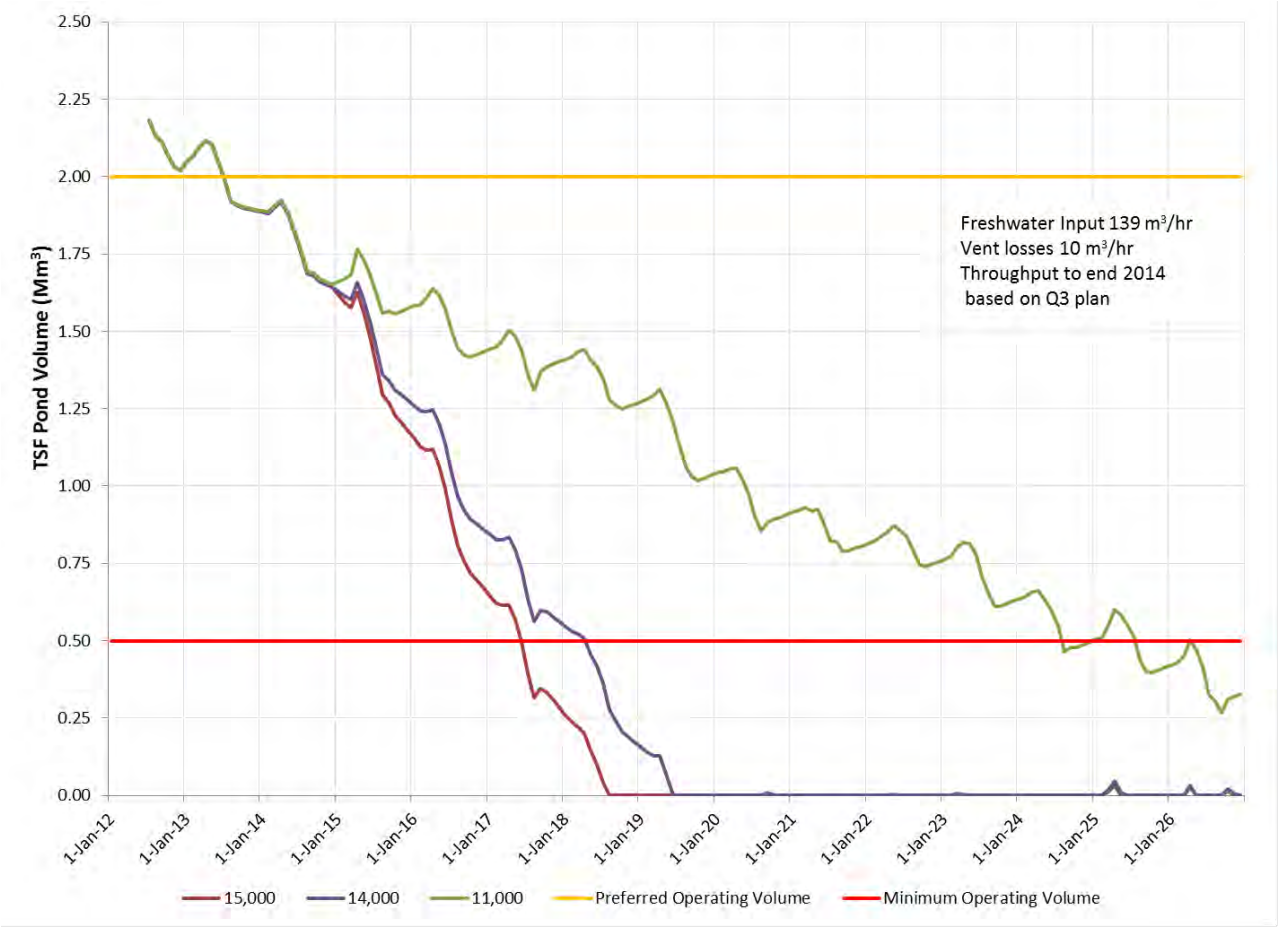

Figure 3 Estimated Tailings Pond Free Water Volume Based on Throughput

CONCLUSION

The reliability of water balances for mines operating in a semi-arid climate is critical to ensure uninterrupted operations. Water balances modelled prior to operation are often based on a variety of factors that can easily have significantly different results once operation commences. This can be due to a variety of reasons, and doesn't always imply that errors were made in the assumptions during the development of these models. As water balance models are an integral part of all levels of mine permitting, it is essential to have a level of confidence and that sufficient resources are made available to best develop this model. Errors or omissions in a water balance may have significant impacts on mine operations over the life of mine.

In the case for New Afton, insufficient care was taken to ensure all reports and applications had a single freshwater requirement and thus, the water volume allocated only accounted for the minimum requirements for an 11,000 tons per day operation, with no level of contingency. The omission of ventilation system losses and water contained within the tailings pores significantly

affect the estimated free water balance for the mine. New Afton has continued to increase its throughput above the original mine plan resulting in an additional shortfall of water volume. The mine has applied to increase its licensed water allocation, however this is an ongoing project that faces many delays through the regulatory process.

Use of Cemented Paste Backfill Based on Arsenic – Rich Tailings from Cyanidation

Roger Hamberg, Christian Maurice and Lena Alakangas
Department of Civil, Environmental and Natural Resources Engineering, Division of Geosciences and Environmental Engineering, Luleå University of Technology, Sweden

ABSTRACT

Gold is extracted by cyanide leaching from inclusions in arsenopyrite from a mine in the north of Sweden. The major ore mineral assemblage consists of pyrrhotite and arsenopyrite-loellingite. Effluents from the gold extraction are treated with $Fe_2(SO_4)_3$, with the aim to form stable As-bearing Fe-precipitates (FEP). The use of cemented paste backfill (CPB) is one alternative suggested for management of tailings. In CPB, tailings are commonly mixed with water (typically 25%) and low proportions (3-7 %) of binders and backfilled into underground excavated areas. Tailings containing As (1000 ppm) mainly as As-bearing FEP:s were mixed with low proportions (1-3 %) of biofuel fly ash(BFA), ordinary cement (CE) and water for the formation of a monolithic CPB-mass. Two mixtures were blended; CE with 1 wt. % of cement and CE-FA consisting 2 wt. % of CE and 1 wt. % of BFA. Unmodified tailings and CPB-monoliths were submitted to a tank leaching test (TLT) for comparison of the leaching behavior of As in the tailings and CPB-masses respectively. Results from the TLT showed that the inclusion of As-rich tailings into a cementitious matrix increased leaching of As. In CPB-mixtures, small (> 1%) proportions of As desorbed from FEP:s and were subsequently incorporated into less acid-tolerant species (i.e. Ca-arsenates and As bonded to cementitious phases). CE was least effective in As-immobilization; the As-release was related to pH and the dissolution of Ca-arsenates. In CE-FA, As-release followed the behavior of Si suggesting the incorporation of As with Calcium-Silicate-Hydrates (C-S-H) in the cementitious matrix. Unmodified tailings generated an acidic environment in which As-bearing FEP: s was stable. As-leaching increased in CPB-mixtures on a short-term basis, but buffering minerals in CPB-mixtures could decrease the oxidation rate of pyrrhotite, which in turn, stabilizes pH and the As-bearing FEP: s.

Keywords: Arsenic, Cemented Paste Backfill, Cyanidation

INTRODUCTION

Gold ores and concentrates containing arsenic minerals (i.e. arsenopyrite) are often refractory in nature, meaning the minerals need to be dissolved in order to release the associated gold. Arsenopyrite usually co-exists with other sulphide minerals such as pyrrhotite and pyrite. Arsenic does not form stable complexes with cyanide, but it is very soluble during cyanidation. Consequently; the slurry produced in this process must be treated to immobilize As before discharge into tailings facilities. Cemented paste backfill (CPB) is a method where tailings are converted into a monolithic mass by the addition of low proportions (3-7 %) of binders. CPB focuses on the minimization and/or enhancement of the quality of percolating water. CPB offers moreover a geotechnical support to underground mine cavities increasing operational benefits for the mining industry (Coussy *et al*., 2011). CPB is also used for backfilling of non-load bearing constructions or tailings dams where strength of the CPB-material is of less concern, but aims for the prevention of metal release and reduction of Acid mine drainage (AMD) remains. Immobilization of As in CPB-materials have been attributed to the formation of stable As-precipitates, the entrapment of As in the cementitious matrix by sorption onto calcium-silicate-hydrates (C-S-H) or substitution within the crystal lattice of secondary cementitious minerals (Coussy *et al*., 2011). The most common binder material used in CPB is cement. As amounts of tailings often exceed millions of tonnes, the cost of cement becomes substantial and many studies have been done to promote the usage of alternate materials in CPB. Granulated blast furnace slag (GBFS) and biofuel fly ash (BFA) have successfully been used for partial replacement of cement in CPB due to their pozzolanic and alkaline properties (Kim & Jung, 2011; Coussy *et al*., 2011). GBFS and BFA could neutralize acidity arising from sulphide-rich tailings and prevent trace element spread (Coussy *et al*., 2011). However, Bertrand (1998) showed that low proportions (0.9-6.8 %) of slag and cement could be insufficient to mitigate Acid Mine Drainage (AMD)-production long-term. It is believed that alkaline materials (fly ashes, slags) increases the mobility of As, but some contradictory results have shown a reduced mobility by the possible formation of stable Ca-As complexes (Hartley *et al*., 2004; Randall, 2012).

Cyanidation tailings slurries from As-enriched sulphide ores are often treated with lime, H_2O_2 and O_2 and $Fe_2(SO_4)_3$ to co-precipitate As (V) with Fe forming stable As-bearing Fe-precipitates (FEP) and to increase the pH to prevent generation of AMD. Within these treatment processes, precipitates with varying Fe/As-ratios could form. As-bearing FEPs with a Fe/As < 4 are assumed to be stable under oxidized conditions when pH 4-7 (Riveros et al., 2001). The pH stability range of As-bearing FEPs is broadened with increasing Fe/As ratios and precipitates with Fe/As ratios $\geqslant 8$ are stable over a wide pH range (3-8).Raising pH to alkaline levels may increase the risk for destabilization of As-bearing FEP. Previously conducted studies (Benzaazoua *et al*., 2004, Coussy *et al*., 2011; Randall, 2012; Coussy *et al*., 2012) have focused on the stability of arsenopyrite, scorodite or spiked As in natural or synthetic CPB. The stability of As-bearing FEP:s in CPB-materials has gained less attention. The purpose of this study was therefore to investigate the behavior of As in a CPB-material using the tank leaching test (TLT).

MATERIALS AND METHODS

Tailings were collected from a gold mine in the north of Sweden. The major sulfide minerals are pyrrhotite(6.5 wt. %)and arsenopyrite-loellingite(0.2 wt. %). The gold occurred primarily as inclusions in arsenopyrite (Sciuba, 2013). Tailings were treated with $Fe_2(SO_4)_3$, H_2O_2, $CuSO_4$ and

lime in order to form stable As-bearing FEP:s, and detoxify residual cyanides. Samples were collected at depths of 0-30 cm from ten different locations on the tailings dam and mixed to form a bulk sample of approx. 15 kg. Two types of binders were tested for the preparation of various paste mixtures: Portland cement (Ordinary Portland Cement also named CE) and biofuel fly ash (FA) provided from a biofuel incineration plant located in Lycksele, Sweden. Main elements and total contents of As and S in tailings, CE and CE-FA are presented in table 1.

Table 1 Main elements, total content of S and As in tailings, CE and CE-FA (n = 3, ± SD)

Speciation of As and S in tailings was assessed using the modified sequential extraction scheme described by Dold (2003) and suggested that a majority (95 %) of As in the tailings of Svartliden was associated with the Fe (III)oxy-hydroxides-fraction (Table. 2). The majority of S was associated with the water-soluble fraction and the primary sulphides fraction.

Table 2 Speciation of As and S in tailings from Svartliden, extraction scheme adopted from Dold (2003) (values in % of total content).

Fraction	Water soluble	Exchangeable	Fe(III) oxy-hydroxides	Fe(III) – oxides	Secondary sulphides	Primary sulphides	Residual
As	0.00	0.81	94.6	1.81	0.02	2.75	0.03
S	35.0	10.8	6.99	5.36	4.41	37.5	0.00

Preparation of the CPB-material

Tailings were mixed with the binders, and distilled water was slowly added to reach a solid percentage about 73-74 %. A water content of 26-27% in the CPB-mixtures is required for paste transportation through a pipe network. CPB-mixtures of CE, FA, water and tailings were poured into plastic bottles with a diameter of 5 cm and a height of 10 cm. A small hole was drilled in the bottom of each bottle before filling for the drainage of excess water. After filling, the bottles were sealed and cured for 28 days in 22°C in a moist environment. Two mixtures were prepared: CE, with the addition of 1 wt % ordinary portland cement (OPC) and CE-FA, with an addition of 2 wt % OPC and 1 wt % biofuel fly ash. Proportions of binders and tailings were adjusted to achieve required hardened strength characteristics of 200 kPa with a minimal addition of binders. Tests of unconfined compressive strength (UCS, curing time of 28 days) on the CPB-materials showed that the mechanical strength of CE and CE-FA were 207 kPa and 179 kPa respectively.

Tank leaching test (TLT)

The Dutch standard (EA NEN 7375:2004) was implemented. TLT consists of the leaching of a monolithic block. CPB-samples were taken out of the bottles after 28 days of curing and rectified into regular cylinders. CPB-monoliths were applied on plastic supports at 2 cm from the bottom of the tanks. Distilled water was thereafter filled to reach a level that ensured a 2 cm water head surrounding the CPB-sample and a liquid/solid (L/S) ratio fixed to 10cm^3 of solution/cm^2 of exposed solid for all samples. A reference sample consisting solely of tailings was used for the comparison of cemented and unmodified tailings. Tailings (reference) were placed in paper filter bags (1μm) recessed in nylon filters. Nylon filters were then hung up in the lids of the tanks. Duplicates were realized for each CPB-sample, a total amount of 6 samples were leached at the same conditions. Leachate was removed and replaced after 6h, 1day, 2.25 days, 4 days, 9 days, 16 days, 36 days and 64 days. Leachate was stirred manually before collection and analysis. The same volume of leachate was used for each renewal. Leachates were filtered through a 0.45-μm membrane filter followed by measurement of pH, Eh and conductivity and analyzed for total content. The mass transfer of As in tailings and CPB-materials was calculated according to (EA NEN 7375:2004):

$$M_{ti} = (C_i \times V_i) / A \qquad \text{(eq. 1)}$$

M_{ti} (in mg/m^2) is the calculated as mass of As released during a leaching period, i, C_i (mg/l) is the As concentration in the period i, V_i (L) is the leachate volume in period i and A is the specimen surface area exposed to the leachate (m^2). The apparent diffusion coefficient of As was determined using the logarithm of cumulative M_t until the i-th period, plotted vs. the logarithm of time. Modelling was conducted using PHREEQC, adapting the database developed by Blanc et al., (2014). Element concentrations from the leachate in the TLT were used for the identification of arsenic species.

Sample analysis

Concentrations of 31 elements were determined for solid samples of tailings, cement and biofuel fly ash with triplicate samples. The modified EPA method 200.7 (ICP-AES) and 200.8 (ICP-SMS) (US EPA, 1991) were used and performed by an accredited laboratory (ALS Scandinavia, Luleå, Sweden). Water samples from the TLT were analyzed by an accredited laboratory (ALS Scandinavia, Luleå, Sweden) to determine their elemental composition. Elements (As, Cd, Cr, Cu, Mn, Ni, P, Pb and Zn) were determined by ICP-SFMS while Al, Ca, Fe, K, Mg, Na and S were determined by ICP-AES. ICP-SFMS and ICP-AES analyses were performed using modified versions of EPA methods 200.8 and 200.7 (US EPA, 1991), respectively.

RESULTS

In TLT, the highest As concentrations released during a leachate renewal cycle were 41.3 mg/m^2 observed for CE, 13.7 mg/m^2 for CE-FA and 1.6 mg/m^2 for tailings. The cumulative release of As is most pronounced in CE (101.5 mg/m^2), and least in tailings (5.3 mg/m^2). Leaching of As from tailings descends troughout the test but has an increasing trend in both CPB-mixtures (CE and CE-FA). The release of Fe was more than a 100-fold larger in tailings compared to that in the CPB-materials. The evolution of Si and As were closely related in CE-FA but showed less or no correlation in CE and tailings (Fig.1).

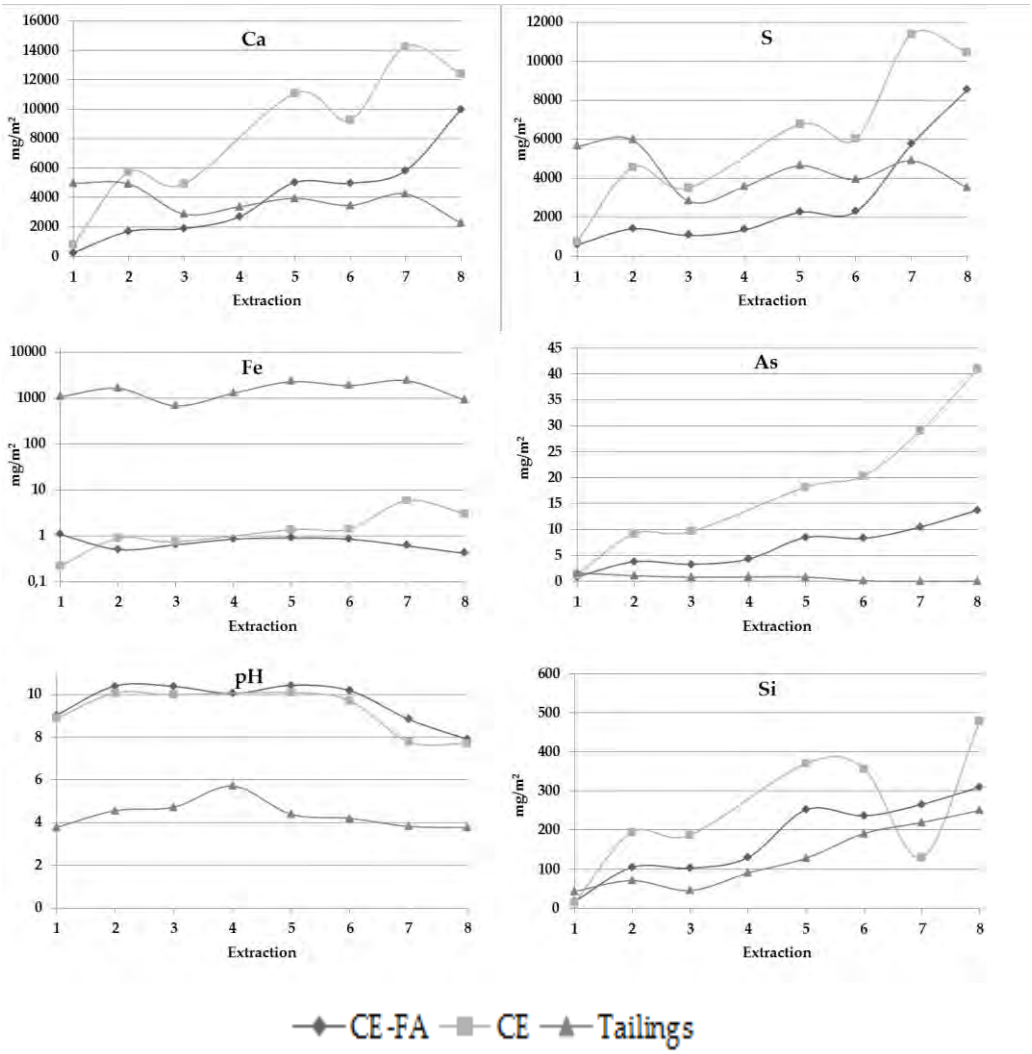

Figure 1 Evolution of pH, S, Ca, Fe, As and Si in tailings, CE and CE-FA during TLT.

For As dissolving from the surface and for the short initial release of surface-deposited As (surface wash-off), the graph slopes (r_c) are expected to be <0.4. In the case of a diffusion control mechanism, this plot is expected to be a straight line with a slope of 0.4–0.6 (EA NEN 7375:2004).

Table 3 Mass transfer mechanisms in tailings and CPB-materials during TLT

Mix	Cumulative As mg/m²	r_c	Mechanism
Tailings	5.5 ± 0.7	0.21 ± 0.09	Wash-off
CE	98 ± 4	0.62 ± 0.01	Diffusion
CE-FA	53 ± 0	0.46 ± 0.13	Diffusion

According to calculations based on the standard of (EA NEN 7375:2004), the mechanisms for As-leaching was a wash-off-effect in tailings and an effect of diffusion in the CPB-materials (Table. 3).

DISCUSSION

The cumulative release of As was highest in CE (98 ± 4 mg/m^2), followed by CE-FA (53 ± 0 mg/m^2) and comparatively less in tailings (5.5 ± 0.7 mg/m^2). Oxidized conditions prevailed in CE, CE-FA and tailings throughout the test and became more oxidizing with time.

As-leaching in tailings during TLT

The As-release was low in tailings during TLT and pH varied from 3.8-5.7. Previously conducted sequential extraction tests suggest that the majority of As was associated with FEP (Table. 2). Calculations in accordance to the TLT-standard suggested that leaching of As in tailings was predominately a wash-off-effect (Voglar and Leštan, 2013). In alkaline conditions during cyanidation, As-sulfides are oxidized to arsenite and arsenate in the presence of oxygen. The proportion of each species is dependent on solution composition, redox potential and pH. Release of As was initially higher from the tailings than from the CPB-materials. This could be due to the presence of As (III) in tailings pore water that was suggested by modeling. The presence of As (III) could be due to insufficient pre-oxidation of As (III) to As (V) during treatment processes.

FEP:s could become unstable at pH < 4, releasing adsorbed As into solution. The As-release was descending from the 2nd extraction in the TLT when pH was 5.7 -3.8 (Fig. 1). In the middle of the TLT-test, a reddish crust appeared on the tailings surface. This crust was assumed to be a Fe-precipitate that might decrease the permeability and weathering ability. The newly formed crust of Fe-precipitates could provide additional surfaces amenable for As-adsorption obstructing further As-release. The ability of FEP for adsorbing As (V) could be reduced due to competition of sorption surfaces by high concentrations of SO_4^{2-} in the leachate (Frau et al., 2010). The negative effect of SO_4^{2-} on the adsorption of As onto FEP could potentially be counteracted by the co-adsorption of Ca^{2+}, which may function as a multi-absorbent for As at pH values of 4-6 (Jia and Demopoulos, 2005).

As-leaching in CPB-materials (CE and CE-FA) during TLT

Initially, the cementation has decreased leaching of Ca, S, Fe, As and Si. According to modeling, As-release in the CPB-materials was governed by As (V) and Ca-arsenates. Initial release of As (III) in tailings could have been hindered by the addition of binder materials such as cement and fly ash which promotes the oxidation of As (III) to As (V) (Moon *et al*., 2008). Calculations in accordance to the TLT-standard suggested that leaching of As in CPB-materials is predominately an effect of diffusion (Table 3). A physical entrapment of As into the cementitious matrix could hinder the effect of As-diffusion in the CPB-materials. The hydration of pozzolanic additives under alkaline conditions forms secondary growths of calcium silicate hydrates (C-S-H). These C-S-H-products serve to improve the microstructure of CPB, leading to lower porosity and permeability mainly due to mineral precipitation (Benzaazoua *et al*. 1999; Hassani *et al*. 2001). The permeability of a CPB-material could increase due to a phenomenon called sulfate attack where sulfates react with Ca-ions forming swelling secondary phases such as gypsum. The volume of C-S-H: s could also be far in excess of the available pore volume and cause internal stress and subsequent micro-cracks increasing permeability in the CPB-material (Fall & Benzaazoua, 2005).

For CE-FA-samples, As release follows the behavior of Si. Arsenic may then have been incorporated into the matrix of (C-S-H) as suggested in Coussy *et al*., (2011). In CE-FA where pH varies from 10.5 to 8.0, all hydrated cement phases were assumed to have been dissolved (Ayora *et al*., 1998). The content of soluble S-species in tailings (approx. 11,000 ppm, Table. 2) increases the risk for a sulfate

attack to occur within the CPB-material (Fall & Benzaazoua, 2005). However, CE-FA includes BFA and Hassani *et al*. (2001) suggested that mixtures of fly ashes and cement in CPB-materials are more resistant to sulfate attack than cement alone.

The mechanisms of As-release in CE differed from the mixture of CE-FA. The As-release in CE was less correlated to the behavior of Si and increased more strongly as pH decreased from 10 to 8. The point of zero charge (PZC) for As-bearing FEP: s occurs at a pH≈8.3. Alkaline conditions (pH: 7.7-10.4) in CE suggested that As has been desorbed from FEP: s and re-precipitated as Ca-arsenates. In alkaline conditions observed in the CPB-materials, As (V)-species of $HAsO_4^{2-}$ and AsO_4^{3-} are the most probable As-species (Smedley & Kinniburgh, 2002). These anions could react with calcium ions in the pore water forming Ca-arsenates according to reactions 1 and 2 (Ahn *et al*., 2003):

$$HAsO_4^{2-} + Ca^{2+} + nH_2O \rightarrow CaHAsO_4 \cdot nH_2O \quad (1)$$

$$2AsO_4^{3-} + 3Ca^{2+} + nH_2O \rightarrow Ca_3(AsO_4)_2 \cdot nH_2O \quad (2)$$

Ca-arsenates formed in pH > 10, are highly soluble at lower pH (Benzaazoua *et al*., 2004). The presence of Ca-ions in the pore water could however increase the surface charge density of the FEP: s increasing their capacity for As (V)-adsorption. This effect is most evident at pH: s of 8-10 (Wilkie & Hering, 1996). The addition of binders lowered Fe-leaching, alkaline environments could enhance the precipitation of FEP: s forming crusts on the sulfide surfaces. These crusts form rapidly under alkaline conditions, creating a thin permeable coating obstructing the minerals' further oxidation (Belzile *et al*., 2004, Asta *et al*., 2013).

Leaching of As in the CPB-mixtures was most prominent when pH fell from 10 to 8 in the end of the TLT. This is probably due to a physio-chemical effect where cementitious phases sensitive to a pH-decrease have dissolved enabling more water to percolate through the monolith. More arsenic was released from CE. Increasing the binder-proportion will not necessary increase the strength of the material, but more swelling minerals could form and decrease the permeability.

Future aspects concerning the use of CPB on As-rich tailings from cyanidation

Most of the As in the tailings were present as As-bearing FEP: s which constituted approximately 95 % of the total As. Arsenic in these precipitates is sensitive to reductive, extreme acidic or alkaline environments. Arsenic dissolutions under reductive environment may contribute to the As release into solution when the management of tailings are not adequately designed. Although, results from the tailings TLT showed that As–bearing FEPs may be stable under acidic and oxidizing conditions common to the tailings piles, more extensive pyrrhotite oxidation generating extreme acidic conditions may increase As-leaching on a long term basis.

Results from TLT suggested that the addition of binders may increase As-leaching on a short term basis. However, the addition of binders increased the tailings' acid-neutralizing capacity and introduced more Ca-ions and Fe precipitates into the tailings matrix, both of which may facilitate the immobilization of As and reduce the potential for sulfide oxidation. Another positive effect originating from the formation of a monolithic mass is that the high degree of saturation in the material reduces the intrusion of oxygen and water percolation. Pyrrhotite oxidation is not obstructed, but in alkaline conditions, Fe may precipitate on the surfaces of sulfide grains retarding its further oxidation. The addition of binders may, therefore, have a positive effect on the stability of As-bearing FEP: s on a long term basis.

CONCLUSIONS

The inclusion of As-rich tailings into a cementitious matrix increased leaching of As. Alkaline conditions in CE and CE-FA during TLT caused a small proportion of As to desorb from As-bearing FEP: s. Desorbed As could then have been incorporated into the cementitious matrix and/or re-precipitated as Ca-arsenates. Leaching of As in CE-FA followed the behavior of Si, which implies that the dissolution of cementitious phases governed the As-release. The mechanism of As-leaching in CE differed from that in CE-FA. Leaching of As in CE increased more strongly as pH decreased from 10 to 8, suggesting the formation of Ca-arsenates. As-bearing FEP: s was stable in tailings where pH was 3.8-5.7, leaching of As was low and descended during TLT. The addition of binders could have a positive effect of As-leaching long-term due to increased acid-neutralizing capacity and higher proportions of FEP: s. This, in turn, could facilitate As-adsorption and decrease the sulfide oxidation capacity.

From Salt Balance to Contaminant Flux: Managing Water Quality Risk Using a Systems Approach

Terry Harck
Solution[H+], South Africa

ABSTRACT

We used a salt balance to describe contaminant transfer within a mine water system. The system included mine workings, mineral processing plants, water storages (both clean and dirty), and tailings storage facilities as components. Analysis of modelling results identified sub-systems associated with potential water quality risks. In particular, approximately 6 000 tonnes of dissolved salts associated with the tailings component could not be accounted for. Under the prevailing regulatory regime, this could be a significant water quality risk. However, the fragmented monitoring network and poorly characterised hydrogeology was not able to resolve the magnitude of the risk.

The cost of developing a tailings source term was significantly less than the cost of upgrading the groundwater monitoring network. Therefore, the tailings sub-system was characterised in detail. This involved collecting tailings process water and drain samples. We also collected tailings samples from various depths in the facility. Geochemical and hydraulic analysis of the tailings allowed an indicative source term to be developed. This quantified the contaminant flux through the tailings during deposition and after closure.

During the operational phase approximately 1 000 tonnes per year of dissolved salts actually leaves the tailings as seepage through the footprint. The residual salt mass leaves the tailings at the rate of approximately 250 tonnes per year once the tailings have desaturated.

The improved resolution of the tailings sub-system indicated that the tailings are a sink for dissolved salts in the mine water system. The fine particle size and low permeability of the tailings under compaction, is a natural mitigation that limits the rate of salt release. Therefore, the magnitude of the water quality risk was found to be moderate

Keywords: Salt balance, source term, tailings, water balance, drainage

INTRODUCTION

Two of the most important and fundamental tools of mine water management are water and salt balances (DWAF, 2006). Water distribution systems on mines are developed ad hoc in response to demand. Therefore, they include inherent inefficiencies, which lead to excessive water consumption and often unnecessary increases in dissolved solids. The goal of water and salt balances is to improve efficiency and water quality. However, the uncoordinated and independently led aspects of a mine water system overlap in a formidable way. As Ramo and St Clair (1998) put it: "it is like knitting with a tangled ball of yarn. It must be untangled before we try again to make the sweater".

The systems approach is a means of applying common sense (Ramo and St Clair, 1998). It is a tool for solving challenges in all spheres of human endeavour. Of course, the solutions typically involve interaction of previously self-directed groups of people and unprecedented flow of resources and information. Naturally, the solution is a considerable change from the present and past way of doing things.

A multi-disciplinary team has been assisting a South African platinum mining company in developing, refining and applying a detailed water balance. The team developed a water balance for a mine water system consisting of dozens of mine shafts and associated underground workings, multiple water storages (both clean and dirty), several mineral processing plants and associated tailings storage facilities (TSFs). The mining operation is located in the western limb of the Bushveld Igneous Complex. The team has "untangled the yarn" and assisted the mining company in "knitting a new sweater" out of their water distribution system. This paper describes one aspect of the work conducted. Specifically, it addresses the question of salt movement at TSFs.

METHODOLOGY

An annual water balance was developed for the operation by considering measured and estimated/calculated inflows and outflows from defined water management units (WMUs) according to the methodology of DWAF (2006). Each WMU is an individual sub-system of the larger mine water distribution system. To determine salt loads in circuit, chloride concentrations were obtained from four sources:

- The environmental monitoring programme, consisting of a database containing analytical results of samples collected from May 1995 to July 2012;
- Drinking water and service water quality analyses from March 2012 and June 2012;
- Tap water analyses from sampling conducted in May and June 2012; and
- Analyses from sampling conducted in June 2012.

Calculation of unmeasured chloride loads was conducted by determining the difference between input and output loads for each water management unit according to the methodology of DWAF (2006). Assuming that inputs equal outputs yielded the unmeasured chloride load by difference. Clearly, this is only valid for a chemical component that behaves conservatively within the mine water system.

Due to lack of data, seepage and interstitial water storage in TSFs were combined into one flow in the water balance. The salt mass balance calculated using water quality data and water balance flows revealed that the input salt load to most of the TSF sub-systems was greater than the output

load. To maintain salt mass balance a new output was added representing the salt load presumed to be lost in seepage (Figure 1).

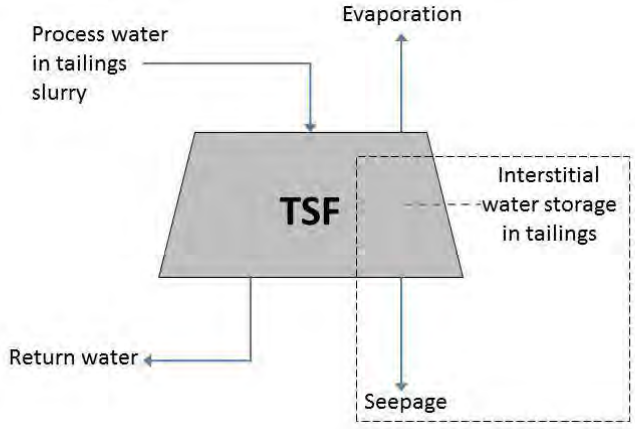

Figure 1 Schematic of the TSF water balance sub-system

The "seepage and interstitial" flow component was found to account for nearly half of chloride mass lost in the TSF sub-system (Table 1). However, the chloride mass of the seepage component could not be resolved from the available data. This was a question of considerable significance to the mining company. South African legislation makes it illegal to contaminate local water resources. Seepage from the TSFs could affect downstream water resources and potentially incur an environmental liability.

Table 1 Summary of water balance and calculated chloride mass balance for a selected TSF

Inputs	**Flow (m^3/a)**	**Cl mass (t/a)**	**Outputs**	**Flow (m^3/a)**	**Cl mass (t/a)**	**% diff**
Tailings slurry water from processing plants	3 670 038	1 703	Seepage, evaporation, interstitial losses	1 835 019	795	
			Return water	1 959 557	909	
Subtotals	**3 670 038**			**3 794 576**		**3.3**
		1 703			**1 704**	**0.1**

At the time, the mine was upgrading a fragmented water monitoring network and developing a more complete understanding of the local hydrogeology. Therefore, environmental monitoring data were unable to confirm the presence of a contaminant plume from the TSF, let alone its significance. Rather than incur the cost of additional monitoring wells, the mining company decided to establish a source term to resolve the seepage component of chloride losses from the TSF.

A source term describes the flux of contaminant mass emitted from a source. It is required for groundwater contaminant transport modelling and consists of a numerical description of the mass of contaminant emitted per unit time. The following tasks were conducted:

- Collect samples – augered from tailings, water samples
- Analyse samples – geotechnical characteristics, geochemical characteristics
- Develop source term from geochemical modelling of seepage quality coupled with estimates of seepage volume from the tailings

Sampling

Tailings samples were collected from auger holes bored into 12 locations on the top surface of the TSF using a portable, hydraulically-powered auger. Tailings samples were collected at 1.5 m intervals from each hole. Mixtures of tailings and distilled water at a ratio of 1:2 were made for each sample in the field and pH and EC measured using a calibrated Hanna HI98130 handheld meter. Twelve samples for laboratory analysis were selected based on the pH/EC profile results.

Water samples were collected from TSF drains 18, 32 and 54 on the perimeter of the TSF.

A drum was filled with slurry from a discharge point. The suspended tailings were allowed to settle and a sample of the tailings supernatant water was obtained. All water samples and the tailings supernatant were filtered by syringing the water through 0.45 μm polycarbonate membrane cartridges. A separate sub-sample for metals analysis was preserved with 2 mL of laboratory-grade nitric acid. All water samples were kept at 4°C from sampling to delivery at the laboratory. Samples were delivered to the laboratory the same day as collected.

Analysis

The analytical programme was conducted by a South African National Accreditation System (SANAS) certified laboratory.

Sixteen water samples were analysed including:

- Tailings drain samples (3)
- Tailings supernatant sample (1)
- Tailings sample leachates (12) obtained according to the modified ASTM D3987 method using deionised water at a liquid:solid ratio of 4:1.

All water samples were analysed for the following:

- Physico-chemical parameters (pH, Conductivity, Total dissolved solids (TDS), Alkalinity titration)
- Major anions (F, Cl, SO_4, NO_3)
- Cations (Na, K, Ca, Mg, Al, Fe, Mn, Cu, Pb, Zn, Cr, and others)

Twelve samples of tailings were analysed for the following:

- Mineral identification (by x-ray diffraction (XRD) or microscope petrography)
- Whole element analysis (by acid digestion and chemical analysis of the digest)
- Particle size distribution
- Saturated hydraulic conductivity
- Moisture content

Due to technical difficulties, unsaturated hydraulic conductivity was not measured. Generally, these results would inform numerical modelling of the long-term post-closure moisture content and seepage rate from the TSF. However, numerical seepage modelling was excluded from the scope of work due to time constraints.

Methodology

The analytical results were used to estimate tailings seepage quality during the operational phase of the TSF and post-closure. Interstitial water quality in the tailings during the operational phase, and hence seepage quality was estimated from the drain water quality. The post-closure seepage quality was estimated from the tailings leachates. PHREEQC (Parkhurst and Appelo 1999) was used to correct for dilution using the measured moisture content and mineralogy as inputs. Post-closure seepage rate were estimated from the saturated hydraulic conductivity results on the tailings samples.

RESULTS AND DISCUSSION

Water at Drain 18 appeared to be affected by local reducing conditions and is not considered to indicate the general quality of interstitial water in the tailings seepage (Table 2).

Table 2 Summary of water analysis results for the selected TSF

Parameter	DRAIN 18	DRAIN 54	DRAIN 32	SUPERNATANT

Hg	0.0002	<0.0001	<0.0001	<0.0001

Chloride concentration in TSF seepage was estimated to be 433 mg/L based on the salt balance. This contrasts with the median chloride concentration of 506 mg/L in water from Drain 54 and Drain 32 (Table 2) and the chloride concentration of 352 mg/L in tailings supernatant. Equilibrium geochemical modelling of the water qualities indicates:

- Tailings supernatant is in equilibrium with calcium carbonate and aluminium hydroxide while being supersaturated with iron hydroxide.

- Water in contact with the tailings (Drain 54, Drain 32) becomes supersaturated with calcium carbonate, presumably from an increase in carbon dioxide partial pressure at depth in the tailings.
- Drain water is more concentrated than tailings supernatant and suggests a water loss of between 20% and 40% between the penstock pool and the drains.

Major ion proportions indicate that the supernatant and drain samples are compositionally similar (Figure 2). However, the compositions of the tailings leachates are significantly different (Figure 2 and Table 3).

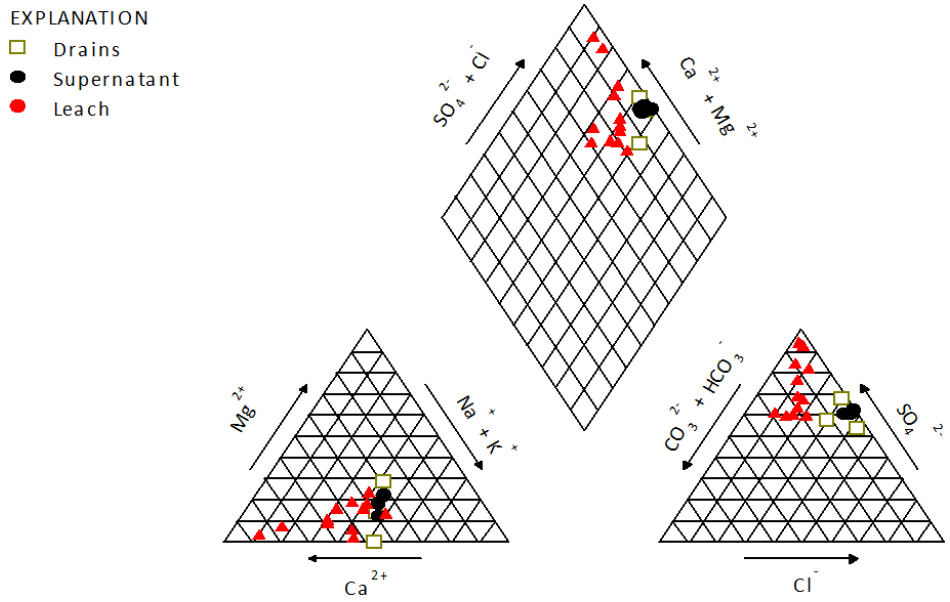

Figure 2 Piper diagram illustrating major ion composition of tailings leachates and water

Table 3 Summary of tailings leachate composition for the selected TSF

Plagioclase, pyroxene, chromite are present in all samples which is consistent with the mineralogy of the platinum ore. Amphibole is also associated with the ore and is present in all but two samples.

Particle size distributions indicate that the tailings particles are in the range 0.001 mm to 0.85 mm (Figure 3). This classes the particles as silt or fine sand. The distribution for all samples is generally similar.

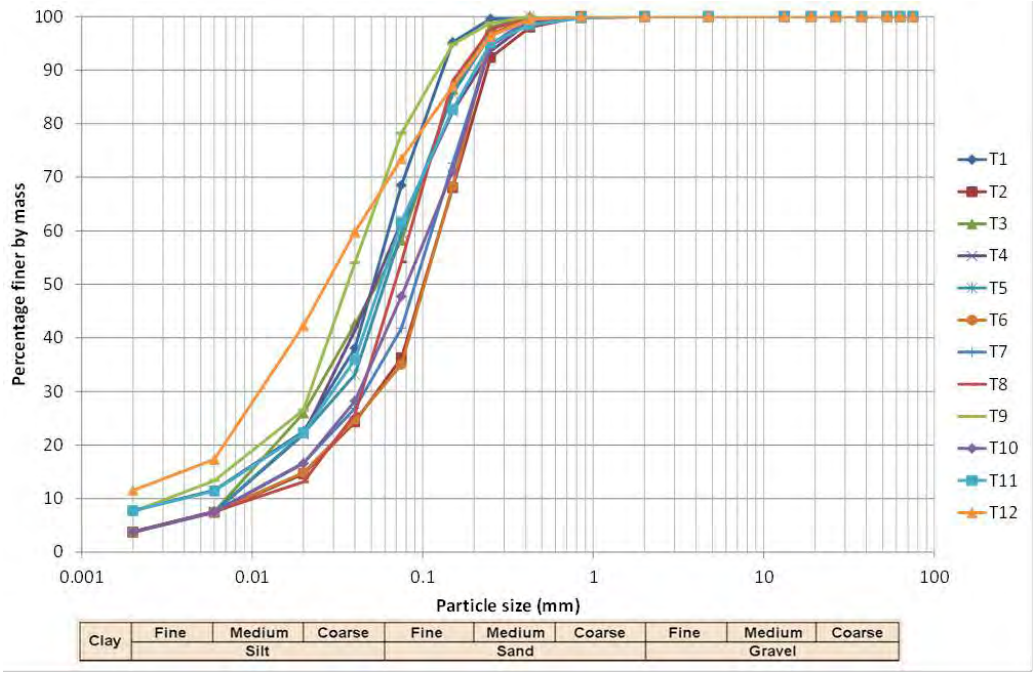

Figure 3 Tailings grain size

Saturated hydraulic conductivity of the tailings samples was directly measured by the laboratory at confining pressures of 50 kPa, 100 kPa, and 200 kPa. The median values were 1.15×10^{-7}, 5.85×10^{-8}, and 1.85×10^{-8} m/s respectively, showing a trend of decreasing hydraulic conductivity with increasing confining pressure. Median moisture content of the tailings samples was found to be 10%.

The TSF water balance indicates that seepage and interstitial losses in the tailings amount to 1 835 019 m^3 per year on average. Over a TSF footprint area of 119 ha this volume suggests that the effective hydraulic conductivity of the tailings is 5×10^{-8} m/s. This is consistent with the 10^{-8} to 10^{-7} m/s range in hydraulic conductivity expected in silt-sized material and is generally in agreement with the physical characterisation of the tailings conducted in this study.

Estimated confining pressure at the base of a 30 m column of saturated tailings ranges from 191 kPa to 272 Kpa with a median of 238 kPa. This is greater than the 200 kPa applied in the laboratory. Considering the trend of decreasing hydraulic conductivity with increasing confining pressure, a hydraulic conductivity of the order of 10^{-8} m/s or lower may prevail at the base of the tailings. Applied over the tailings footprint, this yields an annual seepage volume of 375 278 m^3.

After closure and draining of excess water, the tailings would eventually achieve equilibrium between the rate of rainfall recharge and moisture loss. Unsaturated conditions would prevail in the tailings and the actual rate of seepage through the footprint will be a function of tailings moisture content and the unsaturated hydraulic conductivity. As a rule of thumb, unsaturated hydraulic conductivity is one or more orders of magnitude less than saturated hydraulic conductivity. Therefore, for the selected TSF, unsaturated hydraulic conductivity would be at most 10^{-9} m/s. This yields an estimated post-closure seepage rate of less than about 37 528 m^3/year.

The TSF drain water is an indicator of seepage quality during the operational phase of tailings deposition. The median chloride concentration of samples DRAIN32 and DRAIN54 is 506 mg/L.

The leach tests on tailings samples indicate the results of interaction between the tailings and water. Therefore, they are a starting point for assessing the results of rainfall infiltrating the tailings after closure. However, the liquid to solid ratio in the TSF after closure is likely to be considerably lower than the 4:1 ratio used in the leach tests. Based on the laboratory moisture results, a liquid to solid ratio of 1:10 appears more likely.

The geochemical modelling code PHREEQC (Parkhurst and Appelo 1999) was used to simulate the removal of water from the test leachates in contact with the minerals gibbsite, barite, calcite, chromite and hematite (**¡Error! No se encuentra el origen de la referencia.**). A CO_2 partial pressure of 10^{-2} atm was applied to simulate conditions deep in the tailings.

Table 4 Summary of modelled post-closure seepage quality for the selected TSF

Graphical representation of the time varying seepage rate and seepage quality (as chloride concentration) from the TSF footprint is shown in Figure 4. The product of these two quantities yields the mass of chloride entering the groundwater system beneath the tailings. The duration of

the operational phase has been assumed to be 20 years, followed by approximately 20 years of dewatering.

Based on the outcome of this assessment, the chloride mass entering the groundwater is 190 tonnes/year during the operational phase. This decreases to 20 tonnes/year after closure (Figure 4). This contrasts with the combined seepage and interstitial estimates of 795 tonnes per year from the salt balance.

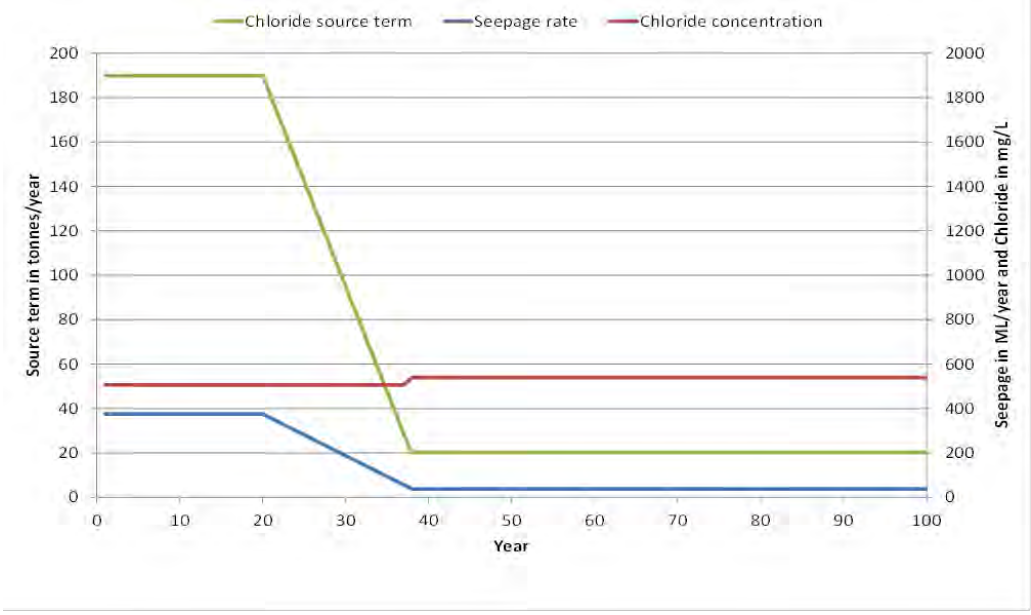

Figure 4 Source term for the selected TSF

CONCLUSION

Physical characterisation of tailings material from the selected TSF has allowed seepage through the TSF footprint to be estimated. This was calculated as 37 528 m^3/year during the operational phase, decreasing to 3 753 m^3/year after the tailings have desaturated post-closure.

Tailings seepage quality during post-closure can be geochemically modelled from drain water quality and leach test results. Considering the mineral assemblage in the tailings and the tailings moisture content, chloride concentrations vary from 506 mg/L during the operational phase to 540 mg/L after closure.

The source term combining the seepage rate and seepage quality indicates that the tailings are a sink for dissolved salts. During the operational phase 5 960 tonnes per year of dissolved solids are placed on the selected TSF. However, 1 117 tonnes per year actually leaves the tailings as seepage through the footprint. The residual salt mass leaves the tailings at the rate of approximately 262 tonnes per year once the tailings have desaturated. The fine particle size and low permeability of the tailings under compaction, is a natural mitigation which limits the rate of salt release.

Closer analysis of the TSF sub-system resolved water balance outputs from the mine water distribution system.

Innovative Mine Waste Management Planning at a Site with Multiple Waste Streams

Brent Johnson, Gary Parkison and William Cincilla
Hatch Consulting, USA

ABSTRACT

The Metates Project will exploit a large-scale, low-grade gold-silver-zinc deposit located in west-central Mexico in the states of Durango and Sinaloa. A total of 2.3 billion tonnes of ore and waste rock will be excavated at the mine site in Durango (the Metates site) over a mine life of 25 years. The ore will be crushed and sulfides floated, resulting in a concentrate that gets pumped about 120 km to the Ranchito site for additional processing. The concentrate will be pressure oxidized (POX) then cyanide leached to extract the gold and silver. The acidic solution generated in the POX circuit will be neutralized using limestone and lime, resulting in extractable zinc and a significant amount of residue. This process results in significant amounts of four primary waste streams: waste rock and flotation tailings at the Metates site and neutralization residue and cyanide tailings at the Ranchito site. An evaluation of these waste streams was conducted to develop environmentally sound and practical management strategies.

One testing program involved characterizing individual and blended neutralization residue and cyanide tailings. Testing included elemental analysis, acid-base accounting, net acid generation, rinse testing, mineralogy, and humidity cell testing. Additional testing was conducted on various engineered blends to optimize the pH to minimize metals and other constituent leaching from the blended waste material and to evaluate geotechnical stability of the blends.

Results indicate that a blend of neutralization residue, cyanide tailings, and limestone can be designed that has less leaching potential than either of the individual end-member waste materials. The blended residue also has the required characteristics to be geotechnically stable in a dry stack configuration, thereby reducing disturbance and aerial distribution of the waste material.

The resulting operational and closure waste management strategies are more protective of the environment and lower cost than conventional waste facilities for each waste material.

Keywords: closure, metals-leaching, tailings, treatment, blending

INTRODUCTION

The Metates Project is located in northwestern Mexico in the northwestern portion of Durango State, some 160 km northwest of the city of Durango and 175 km north of the coastal resort city of Mazatlan. The Project includes mining of an open pit for 19 years with an additional 6 years of processing, for a total operating mine life of 25 years. Ore will be milled and undergo flotation to produce a bulk sulfide concentrate. The concentrate will be transported via slurry pipeline to the processing site (Ranchito – Figure 1) where the sulfides will be oxidized in a pressure oxidation (POX) circuit prior to cyanidation to recover the gold and silver.

Four primary mine waste streams will be generated; waste rock and flotation tailings at the Metates site, and cyanide tailings (CNT) and neutralization residue (NR) at the Ranchito site. The flotation tailings and waste rock will be co-disposed in a single facility; with the flotation tailings being placed daily in layers, over exposed waste rock to limit oxidation of the waste rock during operations. At the Ranchito site, the two waste streams are to be blended together and placed as a paste in a tailings facility, taking advantage of the neutralizing capacity of the CNT to achieve an optimal paste pH such that metals (and other constituent) mobility is optimized. The blend will also take advantage of the geotechnical character of the NR to minimize infiltration and impacts to the environment.

This paper presents laboratory testing results from the CNT and NR materials which were conducted to identify management options including material blending opportunities.

METHODOLOGY

CNT and NR materials have been generated as part of ore processing development at various phases of feasibility to maximize recovery and reduce processing costs. As of September, 2014, two sets of materials have been generated, and a third set is proposed for early 2015. Results are presented for the first set of materials and some preliminary results for set 2.

The goal of the program is to develop a strategy to manage these waste streams to minimize the potential impacts to the environment while keeping operational costs low, and to design a system that will evolve seamlessly into a robust closure plan and design. Design objectives include:

- Using only a single facility for both waste streams
- Minimizing acid rock drainage and metals leaching
- Minimizing the footprint and disturbance
- Maximizing clean runoff and minimizing contact water quantity
- Minimizing infiltration of precipitation
- Maintaining the ability to execute concurrent reclamation
- Minimizing cost of construction, operations, maintenance, treatment, and closure.

Waste streams were evaluated separately and as a blended product to identify potential opportunities for improving the environmental and geotechnical behavior of the ultimate, placed material and to optimize the placement methodology. The waste material testing included:

- Acid base accounting (ABA) (ASTM D2492-02) (Sobek, 1978).
- Multi-element analysis (MEA) - EPA Method 3050 aqua regia digestion (USEPA, 1992a), and finish method 6010B (USEPA, 1994)

- Rinse testing including synthetic precipitation leaching procedure (SPLP - EPA Method 1312, USEPA, 1996), and shake flask extractions (SFE – ASTM D3987 – 85) and toxicity characteristic leaching procedure (TCLP – EPA Method 1311, USEPA, 1992b)
- Humidity cell tests (HCTs) - ASTM D5744-07 (2007)
- Lime titration
- Mineralogy

A CNT/NR blended tailings sample was titrated with lime (CaO) to raise the pH of the material in steps and develop a dosing curve for the material. A set of 11 samples was then generated at 0.2 pH shifts and sent for additional SPLP testing to evaluate the effect of material paste pH on constituent mobility. The resulting SPLP pH values suggested kinetic/aging effects. Based on this information, an additional blend was generated and analyzed at regular time intervals for mineralogy.

An additional blend of CNT and NR was generated and allowed to rest. A sub-sample of the blend was collected at selected time intervals and analyzed by x-ray diffraction (XRD) to determine the changes in mineralogy that occurs in the sample through time.

RESULTS AND DISCUSSION

Acid Base Accounting

The CNT have 5.5 percent total sulfur, of which 1.63 percent is sulfide. The paste pH value was 9.5. No NAG pH was tested on this sample. The neutralization potential (NP) to acid potential (AP) ratio (NPR) and the net neutralization potential (NNP) are reported well above the potentially acid generating (PAG) cutoffs suggesting the sample is non-PAG. HCT results indicate a pH of 7.44 after 28 weeks with measureable alkalinity (approximately 11 mg/L). 1,040 mg/L sulfate was being produced on the last week of the HCT.

The NR has 13.99 percent total sulfur, but the amount of sulfide sulfur is low at 0.35 percent. The paste pH is 7.9, but despite the low sulfide sulfur, both the NPR and NNP suggest the material may be PAG due to a low NP. Humidity cell data, however, indicate a steady pH of about 7.5 after 28 weeks and consistent production of alkalinity between 15 and 20 mg/L, indicating this sample is non-PAG.

Multi-element Analysis

Not surprisingly, the CNT are the most highly enriched with respect to metals (and other constituents). The CNT are, relative to crustal abundances, elevated in Mo, Pb, Cu, Ca, Cd, Bi, and As. Values of As, Sb, Bi and Pb are three orders of magnitude higher than average crustal values. These materials are depleted in Al, Mg, Na, K and Mn (up to two orders of magnitude compared to crustal values).

The NR is elevated in Cd, S, Ca, and Zn relative to the upper crustal values. Concentrations of As, Cd and S are over three orders of magnitude higher than crustal abundances. They are depleted in P, Na, Al, and K.

Rinse Testing

Results of the SFE tests are summarized in Table 1 and show the CNT, NR, and blended material rinsate chemistries (one test each). Data indicate that the major chemistries of the CNT and NR are very similar and that the blended material rinsate major ion concentrations are typically very similar to the end members; however, the metals and other ion concentrations tended to shift to be either greater or less than the range defined by the end member concentrations rather than in between. The orange cells in Table 1 are those constituent concentrations in the blend that are outside the range and higher, while the blue shaded cells represent those in the blend that are outside the range and lower.

The resulting blend pH is between the two end members, but the effect of this pH change is to shift constituents' solubility. This results in changes in constituent mobility with a relatively small change in the pH; some increasing, while others decreasing. Of those constituents with significant change, with a Mexican water quality standard, all decreased in the blend rinsate relative to the end members except for Cd.

Humidity Cell Tests

The NR HCT had an elevated first flush of sulfate from about 3,300 mg/L to just under 2,000 mg/L, at which point the sulfate concentration stabilized for about 8 weeks (Figure 1). Sulfate then declined to under 1,000 mg/L for about 6 weeks then rose and stabilized at 1,500 mg/L for the remainder of the test; likely in equilibrium with gypsum in the sample. The pH remained very stable, between 7 and 8 for the entirety of the test. Alkalinity was also stable at around 20 mg/L. No net acidity was generated during the test.

The HCT leachate for CNT indicated a relatively high initial sulfate concentration (8,160 mg/L), followed by a steady decline, asymptotically approaching 1,000 mg/L (Figure 2). The pH was in the 9 to 10 range during the first 12 weeks of the test and then declined to between 7.5 and 9 in the second half of the test. The alkalinity started at just above 200 mg/L and declined to stabilize between 10 and 20 mg/L through the test. No net acidity was generated.

Titrations and Mineralogy

Figure 3 shows the original titration results for the blended material from the bench measurements (bench paste pH). The titration curve shows a regular and linear trend. However when the subsequent individual samples were generated and sent for SPLP testing, the resulting pH values were much lower than the original pH values and much less linear.

Table 1 - SFE results summary

(orange shading indicates an increase in concentration relative to the end members; blue indicates a decrease)

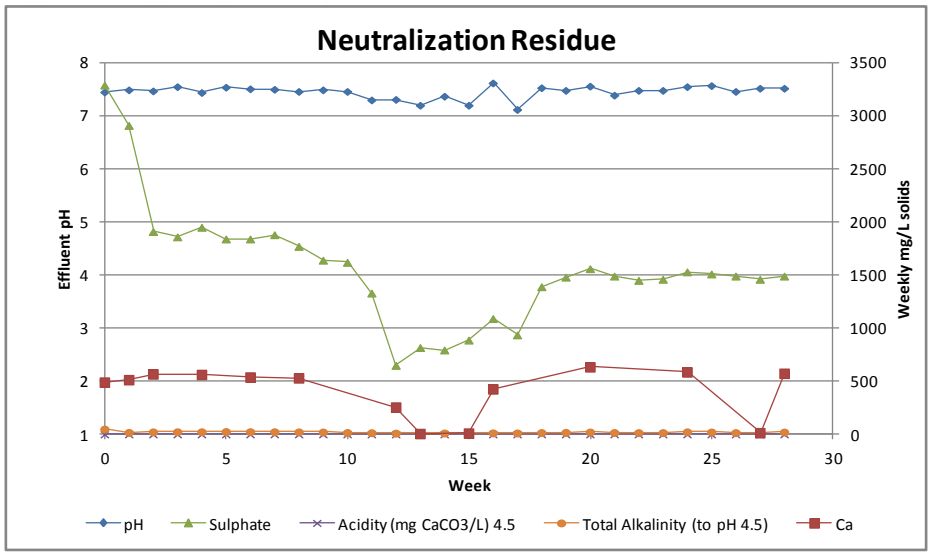

Figure 1 - NR HCT Results

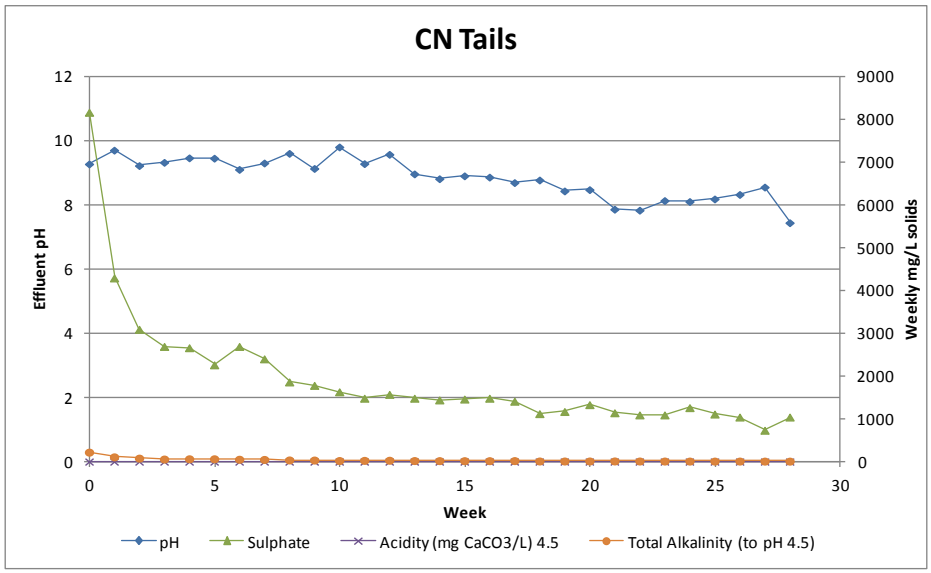

Figure 2 - CNT HCT Results

The difference noted between the bench titration and the SPLP suggests that the samples evolved chemically through time and consumed alkalinity, lowering the pH. Figures 4 and 5 show the major and trace analyte concentrations. Major ions were generally constant over the range of pH values tested in the SPLP except for aluminum concentration, which increased with increasing pH, and iron, which varied between 0.04 mg/L and 0.18 mg/L. Trace analytes were also largely below detection and somewhat insensitive to the relatively small change in pH tested by the SPLP. Arsenic increased slightly from 0.0046 mg/L to 0.0076 mg/L, likely reflecting the weaker sorption at higher pH values. Antimony and thallium decreased slightly with increasing pH.

The chemical changes suggested from the titration data were investigated further by aging a blended CNT/NR sample and analyzing samples' mineralogy at increments. Figure 6 shows the mineralogical composition through time. The results indicate that the majority of the material is gypsum, with lesser amounts of amorphous phases and silicates (predominantly mica and quartz). The quantity of amorphous material decreases from about 27 percent to about 10 percent over the course of 10 days, with a corresponding increase in gypsum content.

The geotechnical characteristics of the blended material that had been aged for only 12 days suggested significantly increased strength (compressive strength increased from 10 kPA to 440 kPa) and low hydraulic conductivity ($1x10^{-7}$ cm/s) is achieved.

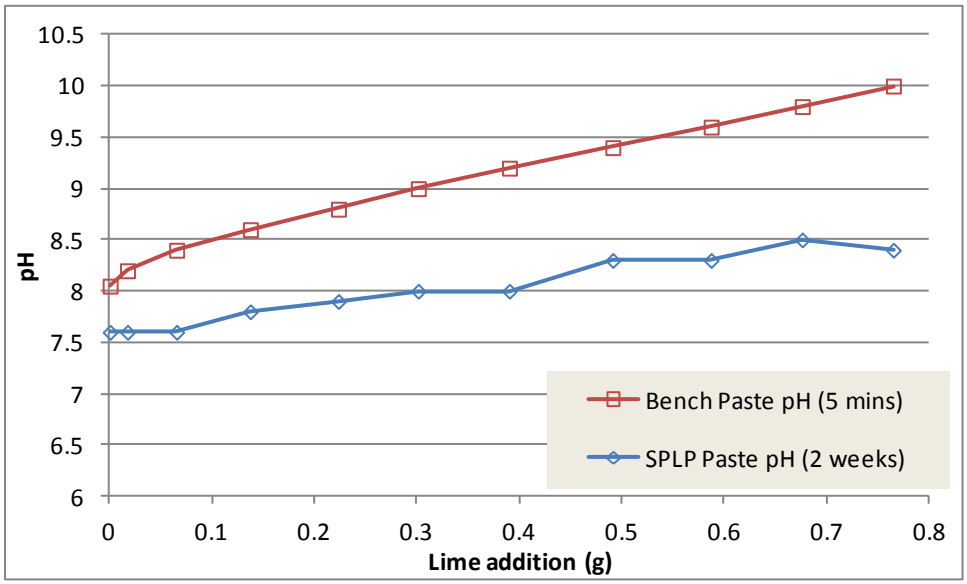

Figure 3 - Lime titration results

DISCUSSION AND IMPLICATIONS FOR MATERIAL MANAGEMENT

NR is a relatively inert material consisting predominantly of gypsum from the neutralization of sulfuric acid by lime in the process.

- NR is considered PAG by ABA because the net neutralization potential is -5.7 and NPR is 0.5, however sulfide sulfur is only 0.35 percent of the total 13.99 percent total sulfur so acid production is expected to be low or unlikely. Paste pH is 7.9.
- HCT data show that the final pH of the NR is 7.52 after 28 weeks with no acid generation. Elevated amounts of sulfate were generated, but this is likely due to the high gypsum content of the material.
- Multi-element analyses by aqua regia show this material is elevated in 9 metals over crustal abundances (at least four times crustal abundance) including sulfur.
- Rinsate chemistry has a circumneutral pH, and is a calcium-sulfate type with generally low-to moderate metal and metalloid concentrations.

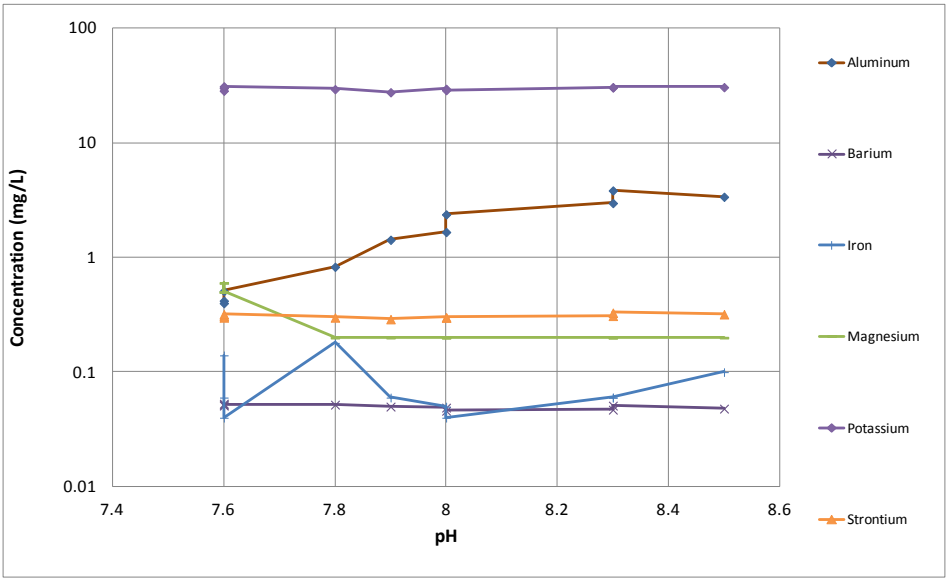

Figure 4 – Major analyte concentrations in SPLP extract

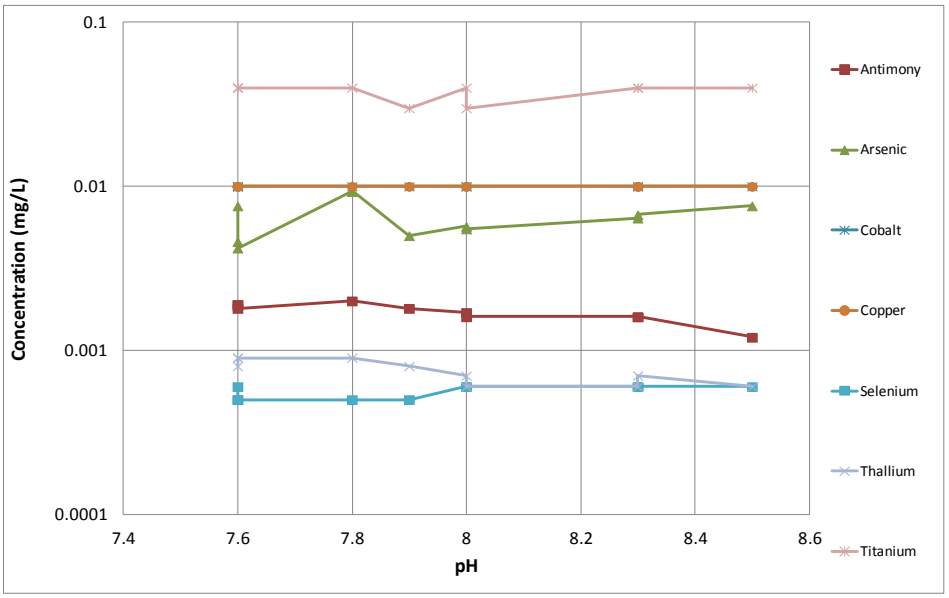

Figure 5 – Minor and trace analyte concentrations in SPLP extract

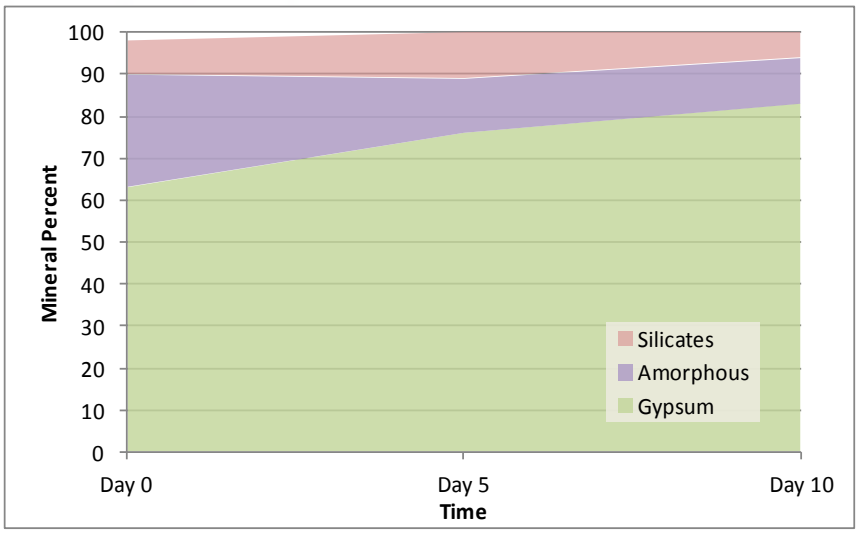

Figure 6 - Evolution of mineralogy through time of NCT/NR blend

CNT are generally alkaline due to the lime addition during the process, with some elevated metal and metalloid concentrations in leach and rinse testing. CNT have the following characteristics:

- CNT are considered non-PAG by ABA testing because NNP is 48.2 and NPR is 1.9. Paste pH is 9.5.
- While total sulfur is 5.5 percent and sulfide sulfur is 1.63 percent, the material does not exhibit acid production in HCT. Final pH was 7.44 after 28 weeks.
- Multi-element analysis indicates this material is elevated in 9 metals over crustal abundances (at least three times crustal abundance) including sulfur.
- Rinsate has an elevated pH (9.7) but a similar major ion chemistry as the CNT with a calcium-sulfate water type.

The CNT/NR blended material is geochemically stable with a circumneutral pH and low metal/metalloid leaching potential:

- Blended material had an NNP of 20.5 and an NPR of 3.2 which would categorize this material as non-PAG. Paste pH was 8.3.
- Total sulfur was 11.26 but the sulfide sulfur was 0.29. Because of this, acid generation is very low or negligible.
- Multi-element analyses by aqua regia show this material is elevated in 11 metals over crustal abundances (at least four times crustal abundance) including sulfur.
- Rinsate has an elevated pH (9.1) and was a calcium sulfate water type but constituent concentrations tended to shift (either up or down) compared to the CNT and NR.

Rinsate constituents from the CNT/NR blend generally show non-linear relationship (i.e., concentrations are not showing conservative behavior). For example, iron concentration declined to 0.032 mg/L from 0.21 and 0.25 mg/L (NR and CNT, respectively). Speciation modeling using PHREEQC (Parkhurst, 1995) indicates that all three waters are supersaturated with respect to various iron oxy-hydroxide phases (e.g., goethite), but that the blend was less supersaturated. This

suggests that iron oxy-hydroxide precipitation occurred in the blended material, providing sorption substrate for various other metals/metalloids in the process. Modeling results also suggests that the rinsate waters were kinetically unstable (relatively labile phases were indicated as being supersaturated) indicating that additional aging of the samples could result in significant mineralogical maturation and environmental behavior. These processes will continue to be investigated in ongoing studies.

Overall, data suggest the blended CNT/NR material will be a physically and chemically stable product that will be suitable for long-term storage. The blended material has physical and chemical properties that have environmental and geotechnical benefits which outperforms either end-member material. The material matures quickly resulting in a high-strength, low permeability material that is easily handled as a dry-stacked material, resulting in more streamlined operational management and lower risk environmentally both during operations and closure. Material can be blended at the run-of-mine production rates and placed in a single facility, with the high gypsum content acting to encapsulate and reduce metals mobility in the material. No acid generation and only minor metals leaching is expected from the material. Some elevated sulfate concentrations may require limited water management but will generally be suitable for reclamation using standard best engineering and closure practices.

Groundwater in the Chilean North: A Brief Synopsis

Sven Renner[1] and Igor Aguirre[2]

1. *Federal Institute for Geosciences and Natural Resources, Germany*
2. *Senior Consultant on Geothermal and Groundwater Resources, Chile*

ABSTRACT

This paper synthesises information on the groundwater resources in the northern part of Chilean mainland, scattered to date.

The climate in the Chile increases in aridity towards the north and becomes extremely arid in coastal areas. North of 27ºS, precipitation ranges from less than 1 mm/y at the coast and in the Central Depression to 350 mm in the Andes. The lower, extremely arid parts make up the Atacama Desert.

This paper focuses on groundwater resources in the Chilean North, where water is scarce and a growing mining and agro industrial activity puts an increasing pressure on the resources. Ground water resources are found mainly in sedimentary basins. The geological evolution of the basins is always associated to the overarching process of the Andes Range uplift. There is however a great variety of different geological settings that produces different types of groundwater basins, with different dimensions and recharge mechanisms.

In order to give a general view on the hydrogeology of the Chilean North it was necessary to strongly simplify the often complex natural situations and to classify the groundwater basins. The main criterion for the classification was the geological setting as it controls much of the geographic location, hydraulic characteristics, size and geometry of the basins. Three types of groundwater basins are discussed in the paper. These basins host the biggest portion of the groundwater resources in the North. There is a brief description of the geology and groundwater characteristics for each.

Keywords: Hydrogeology, Chile, Groundwater, Resources, Management

INTRODUCTION

Chile's mainland stretches from 18°S to 56°S, approximately 4200 km along the west side of the Andes. The physical geography is characterized by a general subdivision of the country from West to East into a Coastal Area that quickly rises into the Coastal Mountain Range; farther to the East follows the Central Depression that separates the Coastal Mountain Range from the much larger Andes Mountain Range with volcanoes above 6000 m altitude (Fig. 1). This general pattern however varies, as the coastal range submerges into the Pacific Ocean in the northern and southern ends of the country.

The climate towards the North becomes arid to extremely arid. North of 27°S, precipitation ranges from less than 1 mm/y at the coast and in the Central Depression to 350 mm in the Andes. The lower, extremely arid parts make up the Atacama Desert. This paper focuses on groundwater resources in the north of the Chilean mainland, where water is scarce and a growing mining and agro industrial activity puts an

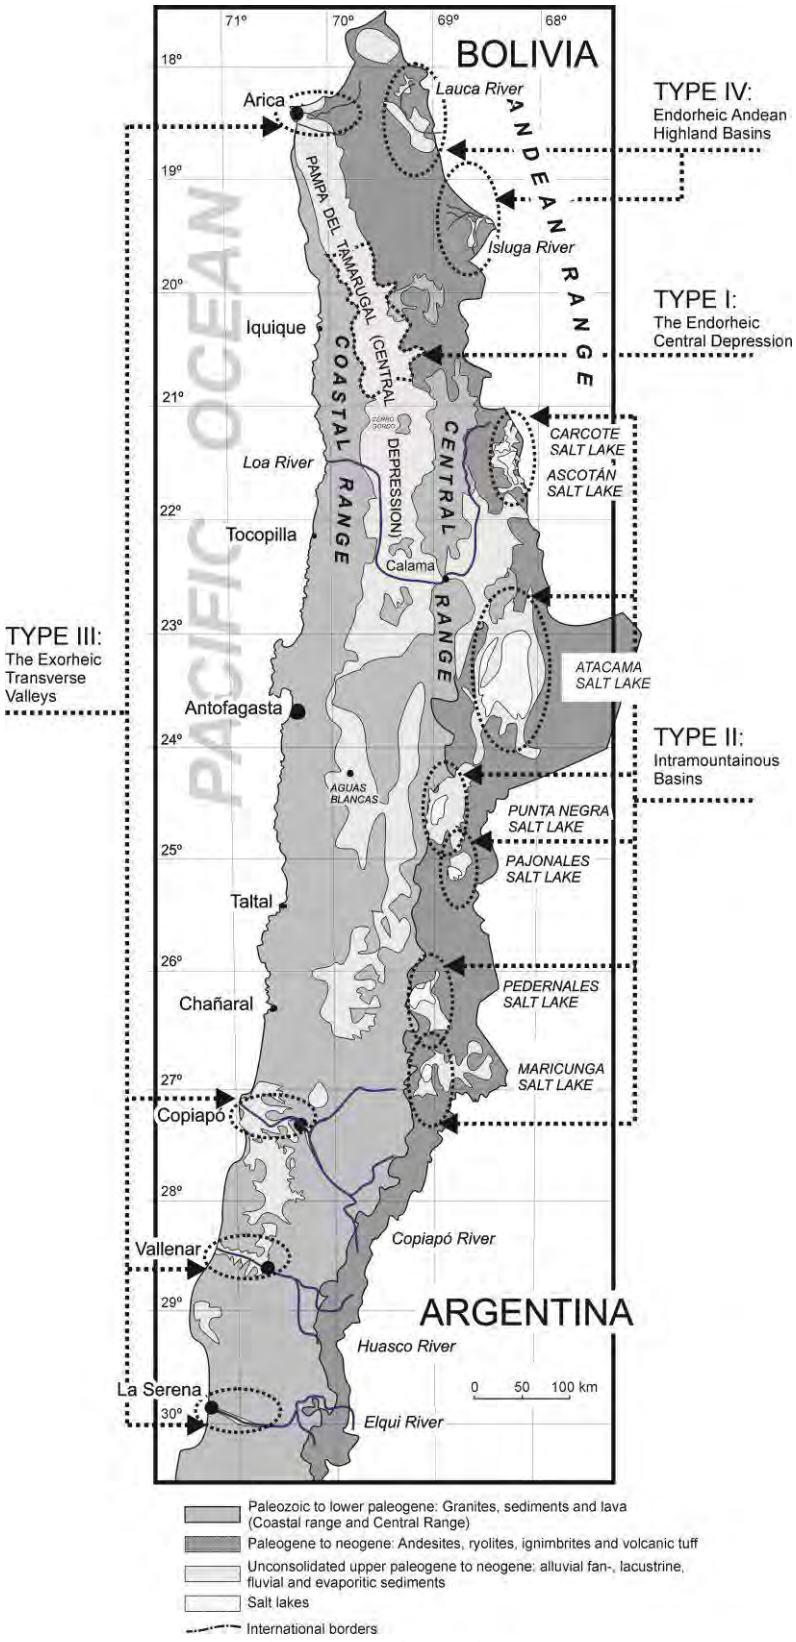

Figure 1 Groundwater basin types in northern Chile I through III as referred to in this paper. Type I is characterized by a clear division between coastal range, central depression and Andes Range. South of Cerro Gordo, the Andes Range splits into several horst and graben structures and develops a series of intramountainous basins (Type II) , where salt lakes can be found, like the *Atacama*, *Punta Negra*, *Ascotán* and *Carcote*. Type III is the E-W pointing river valley aquifer that drains into the Pacific Ocean.

increasing pressure on the resources. For the purpose of this paper, the Chilean North is defined as the part of the country located north of the capital. Groundwater is found mainly in sedimentary basins, the richest of them being located within the central depression. The geological evolution of the basins is always associated to the overarching process of the Andes Range uplift. There is however a great variety of different geological settings that produce different types of groundwater basins with changing geological and tectonic settings, dimensions and recharge mechanisms.

In order to give this brief overview on the hydrogeology of the Chilean North it was necessary to strongly simplify the often complex natural situations, highlight certain general patterns and omit other, less representative ones and to exclude areas that do not host major groundwater resources. It was further necessary to classify the groundwater basins. The main criterion for the classification was the geological setting as it controls much of the geographic location, hydrologic characteristics, size and geometry of the basins.

Three types of groundwater basins are discussed in the paper. They host the largest portion of the groundwater resources in the North (there are, however, other types of minor importance, like the endorheic highland basins in the far north, which are not considered in this paper). There is a brief description of the geology and groundwater characteristics for each.

THE GROUNDWATER BASIN TYPES OF THE CHILEAN NORTH

According to current knowledge, all major groundwater resources in the Chilean north are located in sedimentary basins. Sedimentation is occasionally interbedded with layers of ignimbrite or volcanic tuff. Aquifers of lesser importance are found in valley sediments of little extension and fractured rocks. The classification of groundwater basins in the Chilean North was based on structural and to lesser degree hydrographic criteria: Type I, The Endorheic Central Depression is a large sedimentary basin between the coastal mountain range and the Andes, roughly between 19°30´S and 21°S, known as the Pampa del Tamarugal, Type II, Intramountainous Basins: South of 21°S, the western flank of the Andes Range breaks up in a series of horst and graben structures that give way to the development of sedimentary basins of varying size, and Type III, Exorheic Transverse Valleys: This type includes river valleys with varying sedimentary deposits, which generally drain high Andean areas and flow from East to West. They occur in the extreme North of the territory.

TYPE I, THE ENDORHEIC CENTRAL DEPRESSION (PAMPA DEL TAMARUGAL)

Between 19°30'S and 21°S the Coastal Range rises parallel to the Andean Range and reaches 3000 m altitude, producing an Endorheic Central Depression (ECD) with a groundwater reservoir of unique importance (Fig. 1). North of it the Coastal Range dips below the Andean piedmont sediments and ignimbrites and allows the Andean Rivers to reach the Pacific Ocean. To the South, the ECD ends at the *Cerro Gordo* (Fig. 1), where the impermeable basement crops out.

The ECD in this area is named Pampa del *Tamarugal*, the *Tamarugo* Flatlands, after the prevailing vegetation of the area. It is a neogene and paleogene fluvial and alluvial basin, filled with sediment previously eroded in the Andes. The average altitude of the plane is 1200 m a.s.l.. The surface of the ECD is about 4000 km^2. (Fig. 2). Precipitation and direct groundwater recharge in the Pampa area is almost nil. Potential evaporation lies between 2000 and 2500 mm/a (Rojas & Dassargues, 2007).

Geology

Massive sedimentation into the ECD starts in the early to middle Oligocene (García, 2001) or early Miocene (Vogel et al., 1980). At the bottom lies the Azapa Formation, generally fluviatile in the east and clay rich, of lacustrian origin in the west (Karzulovic, 1979). During the Pliocene, volcanic activity in the Andes of northern Chile increases. Above the Azapa Formation lies the 60 to 200 m thick sequence of the Altos de Pica Formation, in which ignimbrites, rhyolites and volcanic tuff are frequently to be found between the terrestrial layers. Brüggen (1950) refers to it as *formación liparítica*.

Above the Altos de Pica Formation lies the Diablo-Formation, composed of up to 110 m of gravel, conglomerate, silt and clay. This formation, between parallels 19°45´S and the South end of the *Pampa del Tamarugal*, is in part overlaid by the Huaylas Formation series of ryolites and terrestrial sediments (Tobar et al. 1968, Vogel, 1972, Salas et al., 1966). In the ECD, the neogene sediments can be up to 450 m thick; together with the paleogene layers, the total thickness of the basin filling can reach 900 m.

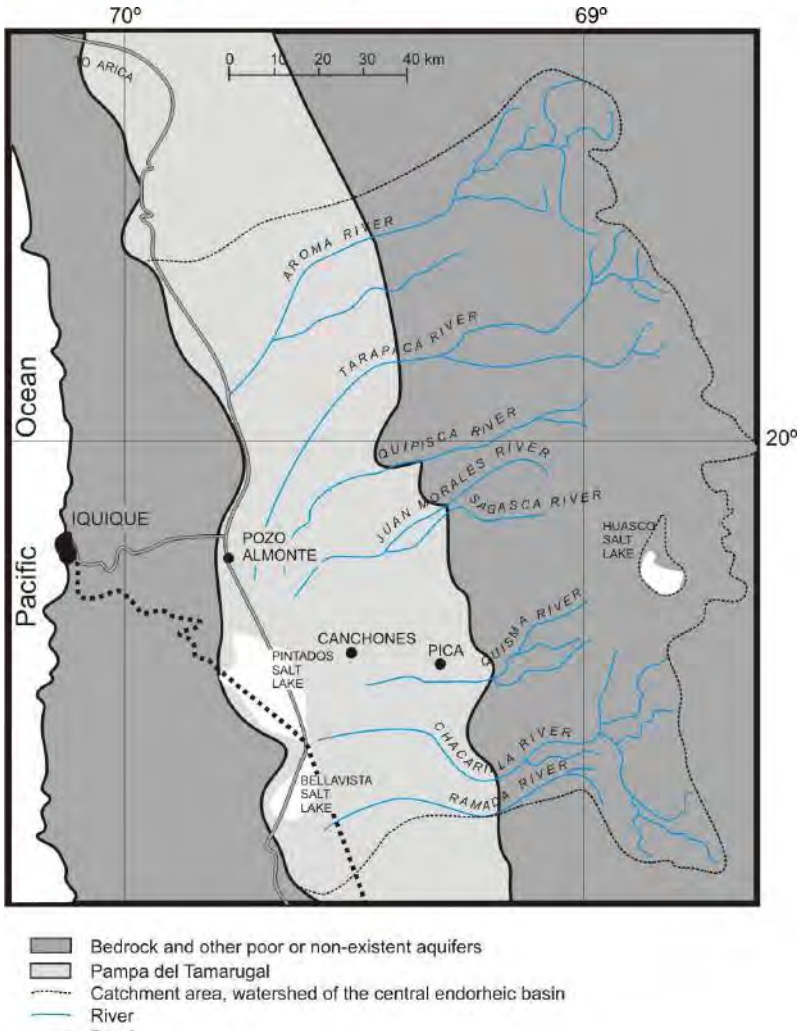

Figure 2 Catchment area and orography of the Basin Type I, the *Endorheic Central Depression – ECD – located in the Pampa del Tamarugal*.

Hydraulics, recharge and discharge

The pre-paleogene sedimentary, volcanic and metamorphic formations build the impermeable basement of the basin. The conglomerates and sandy layers of the upper 120 m of the Altos de Pica Formation provide the most important aquifers (Karzulovic, 1979). This formation is a series of layers that starts at the bottom with a generally thick layer of low permeability conglomerates, followed by volcanic tuff. They are covered by permeable sands and conglomerates, a layer of rhyolite and finally thick deposits of gravel and sand. As the volcanic layers thin out towards the West, sedimentary formations thicken. Their fluvial origin accounts for lateral and vertical hydraulic heterogeneities.

In the ECD, several rivers that come down from the Andes die in the alluvial fans of the Pampa. The most important are from North to South: *Aroma*, *Tarapacá*, *Quipisca*, *Sagasca / Juan de Morales*, *Quisma* and *Chacarilla* (Fig. 2). Their flow direction is generally North-East – South-West. Only the *Aroma* and *Tarapacá* are perennial. The rest is intermittent and infiltrates in the upper part of their hydrographic basin. Flow rates show a strong increase due to summer precipitation in the highlands.

Natural groundwater flows from North-East to South-West and into the *Bellavista Salt Lake* (Fig. 2), its natural point of discharge by evaporation. Groundwater depth decreases towards the point of discharge.

The upper aquifers (down to 20 m below surface) are generally unconfined or leaky. Lower aquifers are mostly confined. Billinghurst (1893) describes an artesian well near Pica in an aquifer 124 m below surface. Water levels however will most likely have dropped in the meantime due to intense water extraction from numerous wells in the basin.

Wells registered at the *Dirección General de Aguas* (DGA, 1988) show transmissivities between $6 \cdot 10^{-4}$ m^2/s and $1.5 \cdot 10^{-2}$ m^2/s with an almost normal distribution and a median of approximately $5 \cdot 10^{-3}$ m^2/s. This matches the average transmissivity of $5 \cdot 10^{-3}$ m^2/s, provided by Fritz et al. (1981).

A clear spatial zoning of hydraulic characteristics is not possible with the information at hand. Vertical permeability is generally low due to the numerous interbedded clay layers and the productivity of the aquifers usually decreases with depth. The deeper lying Paleogene aquifers have generally unfavorable hydraulic characteristics and are not used. Parts of these layered aquifers appear to have no present recharge but host water from humid periods in the Holocene (Fritz, 1981; Aravena, 1995). There is however a present recharge that has its origin in the higher Andes where precipitation is more abundant.

The infiltration of rivers flowing down from the Andes is by far the most important recharge mechanism in the ECD. Infiltration occurs mainly in the upper areas of the alluvial fans and ignimbrite outcrops on the West flank of the Andes (Karzulovic, 1979), which especially between 2500 and 3500 m a.s.l. are fractured by insolation weathering (at Canchones, temperature variations of up to 40°C within 10 hours have been recorded).

References for average groundwater recharge in the ECD vary between 500 l/s (Karzulovic, 1979) and 1000 l/s (DGA, 1988). Rojas & Dassargues (2007) calibrate their numerical flow model with the DGA (1995) calculations for the recharge rate of 975 l/s. The importance of storm runoff for ground water recharge has been a discussed subject. Houston (2001) claims strong influence of infiltrating flash floods after summer precipitations in the highlands and calculates its contribution in Quebrada de Chacarilla alone at over 200 l/s as an average over the year, which would considerably increase the estimates provided by DGA and Karzulovic. Peña et al. (1989) however, gave storm runoff much less importance based on isotope hydrochemistry in the Salar de Llamara, south of the Salar de Bellavista.

The ECD has its natural point of discharge in the *Bellavista* and *Pintados* salt lakes (Grilli et al. 1989, Falcón, 1966, Fig. 2), at the southern end of the basin, where the evaporation in 1980 was calculated at around 286 l/s (DGA, 1988). Since then, the increasing drawdown of the water levels must have diminished evaporation significantly. This assumption is confirmed by Rojas (2005), who calculates evaporation in the salt lake area at around 275 l/s in 1993 with a decreasing tendency.

To this, discharge through evapotranspiration of the *Tamarugo* trees must be added. Merino (1995) calculates this at around 1100 l/s for the whole basin. This value matches approximately the Rojas & Dassargues calculation (2007), which, based on the JICA (1993) and DGA (1988) studies, assume an increase of the evapotranspiration from 210 to 904 l/s between the years 1960 and 1993 due to forestation campaigns. Rojas & Dassargues (2007) suggest an additional discharge of 164 to 365 l/s of out-flowing groundwater at the southern edge of the basin, thus assuming this basin not to be completely endorheic.

In any event, groundwater pumping accounts for the highest withdrawal rates in the ECD. The utilization of the groundwater resources at an industrial scale started with the production of nitrate during the second half of the 19th century. The present pumping rate in the ECD is around 1,500 l/s, 700 of which are for drinking water and taken from the *Canchones* (Fig. 2) and El Carmelo deep wells. The use of groundwater for drinking purposes began in the 60´s. Today the total drinking water supply of Iquique (aprox. 250,000 inh.), *Pica*, *Pozo Almonte* and *Huara* is provided by the *Pampa del Tamarugal* groundwater.

The present groundwater extraction from the ECD aquifers plus the natural discharge of the system, according to all reports clearly exceeds recharge rates, even if there is an additional recharge from higher Andes regions via fractured base rock into the basin as suggested by Margaritz et al. (1990). Since the 60´s, the groundwater levels have fallen in almost all the DGA observation wells between 2 and 4 m (Rojas, 2005). According to Rojas & Dassargues (2007), by 2050, assuming an increasing pumping rate of 20%, water levels will have dropped another 2 m in average.

TYPE II, INTRAMOUNTAINOUS BASINS

South of the Cerro Gordo, the Central Depression continues (Fig. 1, Fig. 3), but not as an endorheic basin. Its ground water resources are generally poor and restricted to small areas, as described by Henríquez (1972) for the Pampa Unión area and Falcón & Henríquez (1968) for the *Baquedano* area, with high concentrations of TDS (Henríquez, 1977). The general lack of groundwater in the *Pampa del Tamarugal* south of the Loa River is due to a change in the geological setting: From the 21°S southwards. The Andes break up into numerous North – South oriented horst-and-graben structures, forming a chain of depressions: the *intramountainous basins* (Fig. 3). They trap water coming down from the Andes. Between the *Pampa del Tamarugal* and these basins rises a large horst structure called *Central Range* (*Cordón Intermedio* / *Cordillera Media*, Fig. 1), that hosts some of the worldwide most important copper deposits: *Chuquicamata*, *El Abra*, and further South *Escondida*.

The Atacama Salt Lake represents the biggest of these intramountainous basins. Combined with the Calama basin, it hosts around 90% of the groundwater resources of the Tarapacá region (Harza, 1978) with its capital Antofagasta (Fig. 3). The Calama tectonic basin as described by May (2005) is subdivided into the hydrographic units of the Middle and Upper Loa Basins plus the San Pedro and Salado basins, both tributaries to the Middle Loa basin (Fig. 3). The intramountainous basins further comprise the *Ascotán* and *Carcote* Salt Lake Basins in the North (21°30´S), the Punta Negra Salt Lake and Agua Verde Salt Lake Basins in the South, roughly at 25°S. This tectonic pattern continues to the South with the salt lakes of *Pajonales*, *Aguilar*, *Pedernales* and *Maricunga* at 27°S as described by Aguirre (2003), Iriarte et al. (1998) and Iriarte (1999). All but the Loa Basins and its tributaries are endorheic (Fig. 3).

Geology

The horst structure of the *Central Range* is called *Sierra de Domeyko* in the South and *Sierra Limón Verde* in the North (Fig. 3). The range is basically composed of low permeability Jurassic and Cretaceous folded granites and sediments (Zeil, 1964).

The neogene sedimentation processes in the intramountainous basins are equivalent to those described for the *endorheic Basin* of the Pampa del Tamarugal. Sedimentation occurs mainly from the Volcanic Andean range in the East and produces a generally several hundred meter thick sequence of paleogene and neogene alluvial fan deposits, fluvial, and in their western part often lacustrine or evaporitic sediments, interstratified occasionally with less permeable layers of ignimbrites and volcanic ash (Bravo, 1975). The main patterns of the intramountainous basins are therefore similar, consisting of large alluvial fans on one side (mostly in the east) and a gentle slope in the bottom area that ends in a salt pan.

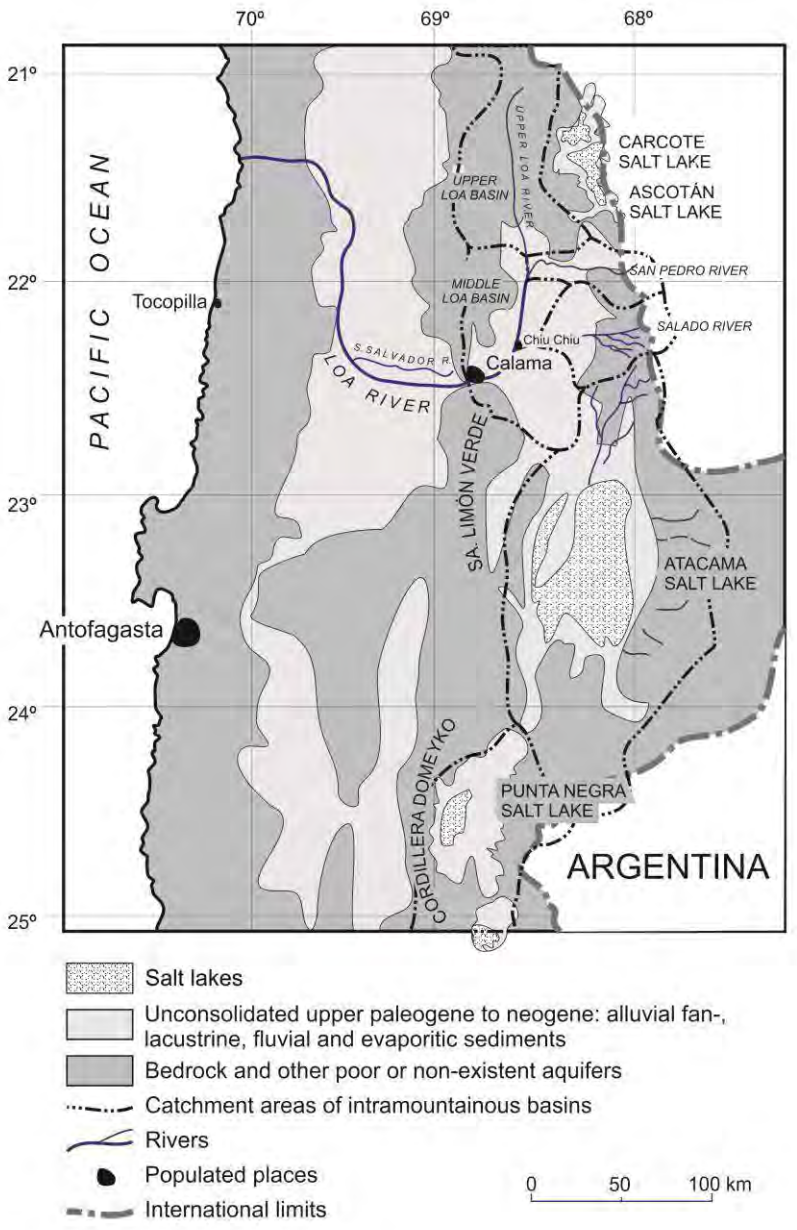

Figure 3 The intramountainous basins and their catchment areas. These depressions form a chain east of the Pampa del Tamarugal and trap the water coming down from the Andes.

Only the middle Loa Basin (Fig. 3) differs from this pattern and comprises aquifers in the 120 m thick Calama Formation and overlying Loa Formation, composed at the bottom of conglomerates and breccia and farther up of an unusual, 50 to 100 m thick series of lacustrine limestones. Naranjo & Paskoff, 1981, place the beginning of the Calama Formation in the Lower Miocene, while Marinovic & Lahsen (1984) place it in the Middle Miocene. This is contradicted by May et al. (2005), assuming the beginning of the Calama Formation during the lower Eocene. Both formations are overlain by the Pliocene Chiu-Chiu Formation. East of *Chiu Chiu*, the limestone shows evidence of karstification with a lake in a typical, large scale doline: The *Laguna Chiu Chiu* or *Inca Colla* (Hauser, 1999).

Hydraulics, recharge and discharge

Precipitation in the intramountainous basins depends largely on their geographical elevation and is generally higher than in the *Pampa del Tamarugal*. It reaches 25 mm/a at the *Salar the Atacama* (2300 m a.s.l.), 50 mm/y at the *Vega del Turi* (*Salado Basin* at 3000 to 3300 m a.s.l.), 40 mm/y at the *Ojos de*

San Pedro (3800 m) and 120 mm at the *Ascotán Salt Lake* (3700 m a.s.l.). Potential evaporation for all areas ranges between 1750 and 3500 mm/a (Harza, 1978).

Only in a few areas, such as *Aguas Blancas* (Fig. 1), South-East of Antofagasta, fresh water can be found (Henríquez, 1970). This is recharged by precipitation in the highest areas of the Central Mountain Range, at almost 5000 m, west of the *Punta Negra Salt Lake* (Fig. 3).

The general groundwater flow direction in the intramountainous basins is East-West, controlled by groundwater recharge from the Andes. Exceptions are found in the *Salar de Ascotán*, where a significant recharge occurs from the eastern flank of the *Aucanquilcha Volcano* (aprox. 6200 m a.s.l.), and in the *Atacama Salt Lake Basin*, where 80% of the recharge is provided by rivers that flow into the basin at its north-eastern end. Flow direction here is therefore predominantly NE-SW (Harza, 1978).

All basins host productive aquifers within the unconsolidated layers of neogene sand and gravel. Groundwater is found generally within an unconfined upper aquifer and a lower confined one, separated by one or several layers of ignimbrite or volcanic ash. Artesian fresh water springs were observed in the *Atacama Salt Lake*, in *Tebenquiche*, close to *San Pedro de Atacama* and *Tilopozo*, at the southern end of the salt lake by Galli (1955). Due to the tectonic setting and volcano activity thermal springs are frequent.

Groundwater depth generally decreases towards the salt pan. Transmissivity has been determined by Harza (1978) in all basins shown in Fig. 3 and ranges between $5 \cdot 10^{-2}$ and $7 \cdot 10^{-3}$ m^2/s. Specific yield ranges between 0.15 and 0.2.Depth of the unconsolidated, mostly saturated sediments reach 120 m in the Salado Basin, 350 m in the San Pedro Basin, 250 m in the Loa Basin, 160 m in the Ascotán / Carcote area and more than 400 m in the Salar de Punta Negra Basin (Harza, 1978).

The intramountainous basins are generally endorheic. Only the Loa basins and sub-basins differ, feeding the Loa River, the most important surface water of the Chilean North with a catchment area of around 34,000 km^2 (Fig. 3, Brinck, 1975). At the western edge of the Middle Loa Basin, where the impermeable bedrock crops out, ground water rises to the surface and forms the *Calama wetlands* (*bofedales*).

As a consequence of its geological features, the Middle Loa basin hosts two aquifers, the upper in the carbonate Loa formation and the lower in the granular Calama formation. The Loa Aquifer is fractured and unconfined. The lower aquifer is partly confined by a 30 to 120 m thick layer of clay (Hauser, 1999).

Groundwater recharge of the intramountainous basins is provided mostly by precipitation in the higher altitudes of the volcanic range of the Andes, where it reaches 300 mm/a. Water is led into the basins by mostly intermittent mountain rivers and creeks (during the rainy season between January and April) and subsequent base flow. Recharge rates are estimated by Harza (1978) in the various basins and yield at *Ascotán Salt Lake* (480 l/s), *San Pedro Basin* (700 l/s), *Rio Salado Basin* (1000 l/s), *Atacama Salt Lake Basin* (1600 l/s), *Punta Negra Salt Lake Basin* (800 l/s).

Groundwater recharge in the middle *Loa Basin* occurs through the inflowing rivers *Salado*, *San Pedro* and, first of all, *Loa* (Fig. 3), which gathers precipitation water from the *Miño Volcano* (5600 m a.s.l.). Precipitation in the basin itself is approximately 4 mm/a.

Groundwater discharge in the intramountainous basins occurs through evaporation at open water tables of wetlands and salt lakes, generally found at the western side of the basins (Fig. 3). Only the middle and upper Loa Basin have an important surface water discharge that drains the basin together with the evapotranspiration at the wetlands in *Chiu Chiu* and *Calama*.

The *Salado Basin* discharges through springs (*Baños del Turi* – 145 l/s) that flow into the Salado river (450 l/s) and evapotranspiration at the adjacent wetlands and salt lake (*Vega del Turi*). Harza´s (1978) estimation for the latter is of 400 l/s.

TYPE III, EXORHEIC TRANSVERSE VALLEYS

It was mentioned before, that the predominant geomorphological feature of the Chilean territory is the subdivision from West to East into a Coastal Mountain Range, the Central Depression and the Andes Mountain Range. This set of features, however, is discontinued in some areas and replaced by transverse valleys. In these areas, rivers run east-west in narrow valleys through the Andes and open up when approaching the pacific coast. Transverse Valleys can be found between 27°S and 33°S (from North to South: *Copiapó*, *Huasco*, *Los Choros*, *Elqui*, *Limarí*, *Choapa*, *Quilimarí*, *Petorca*, *La Ligua*, *Aconcagua*). It is only North of Santiago that the Coastal Range and the Central Depression reappears. Here it hosts the most fertile soils of the Chilean mainland. Another set of transverse Valleys are to be found in the northernmost part of the country, between 18°15´S and 18°40´S. It comprises the two major rivers *Lluta* and *San José* (called *Azapa* in its lower course) and their tributaries.

In what follows, the *Copiapó River* is picked out and described as a representative example for the Transverse Valleys between 27°S and 33°S. It appears to be representative not only in hydrogeological terms, but also with regard to its development as an important agricultural area, the mining industry that competes with it for water and the ever higher constraints of available water resources.

The Copiapó Valley

The *Copiapó River* begins with the confluence of its main tributaries, the *Río Jorquera* and the *Río Pulido*, with respective catchment areas of aprox. 4200 and 2000 km². From this point to the ocean, the river has a length of aproximately 162 km and drains a catchment area that extends over 18.400 km². Farther downstream, close to the village of La Junta, the *Copiapó River* is joined by the *Manflas River*. These are virtually the only superficial water courses. Approximately two thirds of the total catchment area does not feature superficial drainage (Fig. 4), except for occasional storm runoff.

Geology

The *Copiapó River* runs through a set of basement formations that contain folded sediment rocks, volcanic and volcanoclastic rocks, with a generally N-S oriented axial plane and varying slopes towards E and W. They constitue the base and the flanks of the river bed and are described in literature as *formación La Ternera*, *formación Lautaro*, *formación Punta del Cobre*, *formación Abundancia* and *Nantoco*, *formación Pabellón* and *Totoralillo*, *lavas and breccias of the Sierra La Indiana*, *formación Bandurrias*, *formación Cerrillos*, *Quebrada La Higuera*, *Lavas of the Sierra La Dichosa*, *Upper Cretacous Subvolcanic intrusives*, *Cretacous Granitoides* and *Paleocene intrusives*. These units are generally impermeable. Although some of them appear to be fractured, their hydraulic permeability and storage capacities are nil (Aguirre, 1999, y Troncoso, 2012).

River sediments are scarce above the confluence with the Manflas river (close to the Lautaro dam), at aprox. 1200m a.s.l. Downstream the confluence, quarternary fluvial and fluvioalluvial sands and gravel make up for thick and continuous confined and unconfined multilayered porous aquifers. Zones of lesser hydraulic permeability are found in old fluvial or fluvioalluvial mudflow sediments (Aguirre, 1999).

Hydraulics, recharge and discharge

In the findings and maps of Aguirre (1999) and Troncoso (2012) on the hydrogeology between the *Lautaro Dam* and *Piedra Colgada*, aprox. 10 km downstream of the city of Copiapó, hydrogeological units are grouped into four categories according to their relevance as a groundwater resource: high yielding, medium and low yield and those of nil relevance.

Aquifers that are relevant for groundwater storage and flow tend to be unconfined, but show local signs of confinement, especially between *Cerrillos* and *Valle Fértil*, as well as downstream the *Lautaro Dam*, between *San Antonio* and *Los Loros*. Between *Los Loros* and *Paipote*, wells yield between 1 and 150 l/s and groundwater levels vary between artesian and 135 m depth (Fig. 4) (Aguirre, 1999, Troncoso, 2012).

High yielding aquifers include those in fluvial deposits, especially fluvial deposits of present time river beds and some fluvial deposits that show interstratification with fluviolacustrine deposits (Fig. 4). These strata types are often interconnected and produce aquifer systems with relatively high storage coefficients and transmissivity values. Medium and low yield aquifers in the *Copiapó River Valley* are typically layers that contain a large interstitial fine sediment fraction, low porosity, low permeability and a certain degree of cementation. These layers generally receive their recharge through vertical infiltration during the meager rainfall events. They represent a relatively small share of the valley formations and can be found in some fluvioalluvial sediment bodies, mud flow deposits, ancient river terraces. There are, however, also high permeability layers like dunes and dejection cones, located at the flanks of the river bed, that produce low yields due to meager to nil vertical recharge.

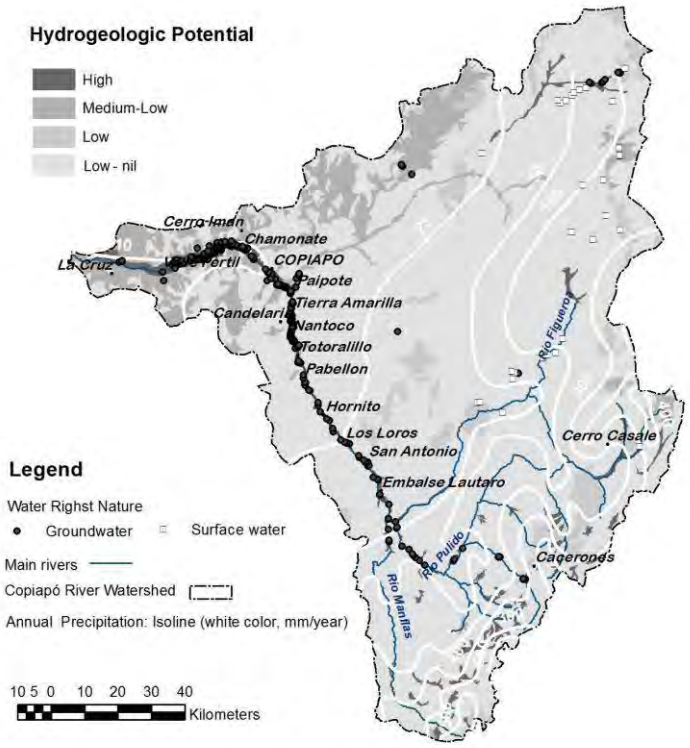

Figure 4 Hydrography of the Copiapó Valley (after Aguirre, 1999, SERNAGEOMIN, 2012, Hidromas, 2013)

The *Copiapó Valley* sediments are bedded in a basement of predominantly impermeable rocks with no relevant groundwater ocurrence. Exceptions can be found in fractured rock formations with locally interconnected flow paths but with a generally very limited recharge. A considerable number of intrusive rocks in the valley area form downright geological barriers, as for instance in La Puerta and Piedra Colgada (Fig. 4).

Hydrogeological properties (such as permeability, transmissivity, storage and specific yield) have been described extensively by DGA (1987), Aguirre (1999), SERNAGEOMIN-BGR (1999), SERNAGEOMIN (2012), DGA-DICTUC (2010) and HIDROMAS (2013).

Transmissivity of the valley sediments vary between $1 \cdot 10^{-3}$ and $2 \cdot 10^{-1}$ m^2/s. Highest values ($2 \cdot 10^{-1}$ m^2/s) can be found upriver, close to the *Lautaro Dam* and midway to Copiapó at *El Yeso* and *Totoralillo*. Lowest transmissivity values were measured in *Villa María*, *Hornitos*, *La Puerta* and *Los Loros* (Fig. 4). (DGA 1987a). Intermediate values of $5 \cdot 10^{-3}$ m^2/s are typically found where *Pulido River* joins the *Ramadillas River*. High variations are found close to *Iglesia Colorada* with values that range between $5 \cdot 10^{-3}$ and $4 \cdot 10^{-2}$ m^2/s.

Hydraulic permeabilities of the Copiapó River Valley aquifers typically range between $2 \cdot 10^{-4}$ and $2 \cdot 10^{-3}$ m/s, the lower end of this scale is often found perched aquifers. However, clay and silt-layers, located on the borders of the river bed and deposited mainly during occasional flooding, have permeability values as low as $1 \cdot 10^{-5}$ and $1 \cdot 10^{-6}$ m/s (SERNAGEOMIN-BGR, 1999).

There is only little information on storage coefficients. Data are provided by DGA (1987) indicate values between 0.016 and 0.11. Other studies (DGA, 1995) calculate averages of 0.05, 0.10 and 0.15 depending on the area. For resource estimation purposes, SERNAGEOMIN-BGR (1999) and DGA (1995 and 2003) assumed a storage coefficient of 0.1. Transmissivity values range between $1 \cdot 10^{-2}$ and $2 \cdot 10^{-1}$ m^2/s (DGA, 1987b, 1995).

Aquifer thickness varies strongly along the valley. Drillings proved maximum thickness of at least 180 m. However, geophysical campaigns (Aguirre, 1999 and SERNAGEOMIN, 2012) show fluctuating thicknesses between 100 and 200 m with local peaks of 250 and 300 m. These are supposed to be related to tectonic depressions produced by faults (Fig. 4) within the basement.

Recharge of the *Copiapó River* valley aquifers is produced by vertical infiltration of rainwater (especially in the higher catchment areas in years of high precipitation) and irrigation. In urban areas, losses of the potable water supply system as well as sewage play a major role. Discharge is dominated by groundwater pumping (in wells). A few points of natural spring discharge are left (such as *Los Loros-La Puerta*).

In general terms, there has been a continuous and marked overexploitation of groundwater resources in the aquifers of the Copiapó valley due to extraction rates that exceed recharge rates by far. The success of Chilean table grapes on the international market as of the 80's, led to a remarkable extension of Agricultural surfaces in the valley. Today, the valley is characterized my monoculture and irrigated surfaces are no longer restricted to the floodplain of the river but climb up the flanks.

In addition to this, mining industry and potable water supply of urban areas added another large portion to the demand. According to DGA-DICTUC (2010), natural and artificial recharge adds up to 3.6 m^3/s while estimated consumption is put at 5 m^3/s and therefore produces a deficit of aprox. 40%. These numbers are confirmed by the numerical modeling carried out by HIDROMAS (2013) that considers the time span between 1993 and 2012. The main conclusions are that the upper catchment system (down to *La Puerta* – Fig. 4) features a water surplus. Evidence is given by a large number of natural springs (e.d. in the vicinity of *Los Loros*). By way of contrast, the aquifers downstream of *La Puerta* suffer from a marked and continuous deficit of approximately 1.3 m^3/s, equivalent to 50% of the average recharge volume. This mismatch produces sustained and accelerating groundwater level drawdown since the 90's in several areas of the lower valley, especially between *Mal Paso* and the city of *Copiapó*.

Building Better Waste Landforms for Reactive Waste: A New Level of Waste Assessment and Construction

Peter Scott, Ian Taylor, Paul Weber, Steven Pearce, Bonnie Dobchuk and André Kemp
O'Kane Consultants, Australia

ABSTRACT

Comprehensive waste characterisation and scheduling enables mines to design and construct waste landforms to manage acid and metalliferous drainage (AMD). Characterisation of wastes not only identifies problematic waste streams but also wastes with useful physical and geochemical properties that can be used to mitigate or neutralise AMD. However, optimising the placement of these beneficial materials whilst mirroring the mine schedule and avoiding double-handling requires planning from the outset.

Surface cover systems are often used in isolation at closure to manage water and oxygen ingress into waste rock storage facilities. Their effectiveness is generally limited by the type and availability of materials at that time, that is, there may be insufficient material, it may be degraded or otherwise lacking in its capacity to perform as wanted. Furthermore, the reliance on retro-active works may be complicated by competing demands for useful waste material and cost.

This paper outlines a holistic approach to designing and constructing mineral waste rock landforms based on a comprehensive understanding of the waste geochemical properties and schedule and integration with an appropriate landform design and cover system. The physical and geochemical properties of the waste, and interrelationships of key properties, including reactivity, hydraulic conductivity, moisture-holding capacity, erosion resistance is discussed. Consideration is given to construction and placement of wastes including tipping heights, selective placement of reactive waste, compacted intermediate low-permeability layers and surface water management.

The scope of this paper extends to the benefits of numerical modelling to provide a comprehensive understanding of materials placement and optimisation to reduce the reliance on only the final cover systems to manage net percolation and AMD generation. Specifically the ability to manage water seepage, oxygen ingress, acid generation rates and long-term surface erosion are fundamental.

Keywords: waste rock, geochemistry, landform, cover system, characterisation

INTRODUCTION

A continuing challenge to managing modern open-cast mining of deposits hosted in rocks that contain metal sulfides is the successful and "correct" disposal of reactive sulfidic and metalliferous waste rock within a landform that is geotechnical and geochemical stable, that is non-polluting and non-erodng. Waste rock containing metal sulfides when exposed to oxidising condtions will start to react and dissociate into more readily soluble and potentially deleteirous products (acidity, sulfate and metals) that may be released from their confining rock mass by meteoric waters, and are referred herein as reactive waste. Managing reactive waste rock during mining relies on a comprehensive understanding of the chemical and physical properties of the waste and an informed landform design. Only through better knowledge of materials characteristics and using this knowledge to effectively place mined waste in waste storage landform, considered in the context of the climate and environmental setting, can these objectives be reliably met. The presence of reactive waste necessitates a set of management procedures be developed to ensure effective waste rock landform design to minimise impacts of acid and metalliferous drainage (AMD). These procedures include those listed below and discussed in this paper:

- Construction of a geological model of the waste, based on the drillhole database;
- Waste chemical and physical properties characterisation using Static testing methods for waste rock, soil and subsoil;
- Block modelling of waste rock and merging with the ore resource model, to create the life of mine (LOM) waste mining schedule;
- Design and construction of waste landform for containment and management of reactive waste, including final batter design, and final cover system design, and erosion management;
- Design of water management for waste landform;
- Validating the waste model using in-pit geological mapping;
- Selective handling and placement of waste in designated areas of the waste rock landform;
- Validating placement of waste within the waste rock landform;
- Monitoring for success of placement using piezometers within the waste rock landform, and downstream of this facility;
- Regular technical reviews monthly (internal), three to six monthly (external);
- Implementing these procedures for Life of Mine.

MINE WASTE PROPERTIES

Geological model

The geological model of the potential waste associated the economic deposit is built from the exploration drillhole database of logged geological properties compiled during the exploration and resource evaluation phase. The drillhole database is the main source of geological information pertaining to the deposit and the potential waste, in the early stages of the project and will continue to be so through the life of the mine provided it is regularly updated with new data. A well-structured and comprehensive database makes it possible to define the range of waste rock types and their geological properties prior to undertaking the acid-base accounting testwork. The drill hole logging data that can be used to develop the sampling and to further classify waste include:

- Ore-waste boundaries;
- Lithology - major and minor (host rocks, cover rocks, construction material, soil, alluvium);
- Structural features - faults, shears, veins, fractures;
- Logged sulfide minerals quantity;
- Sulfide and carbonate mineralogy;
- Sulfide and carbonate texture and morphology;
- Spatial relationship of sulfides with acid consuming minerals in the host rocks;
- Depth of oxidation to include base of total oxidation (BOTO) and base of partial oxidation (BOPO);
- Depth of water table;
- Defining the transition waste areas to identify areas of partially oxidized PAF waste and flag these areas to be included in the waste model as reactive waste.

The drillhole database containing logged geological information is used to construct the 3D geological model. Using the geological model drill sections are constructed at regular grid spacing (e.g. 50 m or less for smaller deposits) through the proposed pit area and are used to derive the sampling plan. Each section has the drillhole trace and geological units plotted as well as logged data such as presence of sulfides, oxidation depths, structural data (faults and shears), ore and waste boundaries etc.

Sampling plan

All waste holes should be analysed for total sulfur, ideally at 1 m or 2 m interval widths up to a maximum interval width of 5 m and analysed for total sulfur. Total sulfur should also be analysed for each sample, waste as well as ore, collected for the exploration and resource drilling programs to build up the sulfur database for constructing the waste model.

Additionally representative samples of all lithological units related to the mine development need analysing. The sampling should cover all the areas of the mine plan, at least for the proposed Pit "Shell". This approach should aim to identify the geological units likely to provide an AMD problem, are acid neutralising, non-polluting waste, metal and sulfate saline leachate generating waste, as well as timing, destination and placement of the waste rock. The number and type of samples to be tested and evaluated is site specific and should reflect the complexity of the geology and the problem being addressed. Sampling interval widths should be a minimum of 1–2 m.

Samples of potential waste rock and ore selected in the sampling plan should be analysed for following chemical properties:

- total sulfur (LECO and portable XRF(field)) as a minimum, and ideally sulfate sulfur, and sulfide sulfur (CRS) to estimate maximum potential acidity (MPA);
- the drill holes sampled for the full pit profile (from surface to footwall to the ore) should be analysed for total sulfur as a minimum; these samples will provide the basis for construction of the waste block model;
- acid neutralising capacity (ANC); where
- net acid generation (NAG), including NAG pH;
- rinse pH, and field peroxide oxidation test;
- total and leachable metal concentrations; and
- overburden of subsoil and topsoil tested for soil nutrients, exchangeable cations, sodicity, salinity, and acidity.

Samples are typically classified as PAF (potentially acid forming), NAF (non-acid forming) based on the ABA results (Sobek *et al.*, 1978; Coastech, 1989; INAP, 2009), NAG (Miller *et al.*, 1997) and ANC:MPA or net potential ratio (NPR).

The development and understanding of physical material properties to be used within a landform construction are equally critical to its success as its chemical properties. Key physical properties to be derived and fully understood include:

- Characterizing the texture of the material, easily completed through particle size distribution (PSDs).
- Atterberg limits: important to understand the activity of a clay (potential to shrink/swell) and organic content.
- If clays are to be compacted to form a low permeability layer (CCL) it is critical that an understanding of the compaction effort, optimum moisture content and density required, through compaction testing (e.g. Standard Proctor).
- Target sampling and drilling is important to understand variation in material properties for different material types
- Erosion tests (slake durability, Emerson crumb, rill and inter-rill development);
- Moisture Retention Curves (MRCs) used to predict the soil/rocky mulch water storage, water supply to the plants (field capacity) and material aggregate stability
- Field and lab-based permeability tests (falling head, gain K_{sat}).

Assessment of waste rock properties doesn't end at the pre-mining stage but continues through the life of the mine to closure and decommissioning of the waste rock landform. The geological model and the waste block model must be regularly reviewed, reconciled and updated by in-pit mapping, sampling and testing of the in situ waste rock throughout the life of the mine. In-pit validation of waste by Mine Geologist involves:

- Checking the boundaries of the waste rock domains against exposed geology in the pit floor on the current mining bench; the pit geologist should utilise the geological information in the pit walls as well as the pit floor.
- Undertaking/supervising the waste validation sampling plan
- Checking domain classification is correct.
- Correcting the boundaries and classification, before and after blasting;
- Supervising/undertaking field testing of waste using field oxidation pH and rinse pH tests (Ahern *et al.* 2004) and sulfur by portable XRF.

A typical waste rock classification is summarised in Table 1.

WASTE BLOCK MODEL

Waste blocks commonly are larger in size (e.g. 20×20×5 m) external to the ore blocks, which may be 2.5×5.0×5.0 m in dimension. Block sizes used are governed by the geology of the ore and waste and the mining plan (Scott and Eastwood, 1998). The block model for waste is distinctively different from the sectional geological model used to identify waste types present and to design the sampling program. Block modelling for waste like ore resource modelling is used to calculate material volumes and hence tonnages. The block model calculates the volumes by defining and connecting adjacent cells with similar properties. The spatial properties of these cells are defined by x, y and z co-ordinates relative to a fixed reference point. Unlike the ore resource model, the amount of ana-

Table 1: Possible waste classes for sulfidic waste

Waste Type	Waste Class	Description
1	NAF	Non-reactive Waste comprising 100% NAF and negligible metals and is defined NAF non-metalliferous waste;
2	SD	Reactive Waste comprising rock material with excess acid neutralising capacity that will generate neutral to alkaline drainage with elevated sulfate and is defined as NAF sulfate saline (SD) waste;
3	MNAF	Reactive Waste comprising rock material with excess acid neutralising capacity and elevated metal concentration that will generate neutral to alkaline drainage with elevated sulfate and metals in leachate and is defined as mineralised NAF;
4	PAF	Reactive Waste that has limited acid neutralising capacity and elevated sulfide concentration and will generate acidic drainage with metals and sulfate and is classified as PAF waste.

lytical data concentration acquired from drilling for waste volume definition is commonly low. For some projects a large database for total sulfur has been compiled as part of the ore/waste definition and can be used to build the waste block model. For some project the deficiencies of analytical data in the waste database can be largely overcome through increasing the data density by integrating the acid base accounting (ABA) testwork with the drillhole database-derived geological model. This enables the testwork to be more effectively directed. It facilitates extrapolation of testwork data through association of test samples with like geology. It is advisable to keep the geological parameters simple, e.g. total pyrite, total carbonate, lithology, weathering, and fracture density etc. When interpolating static testwork data, it is important to use primary data such as ANC, MPA or sulfur values rather than ratios such as NPR or NAG.

Mine schedule

The waste schedule aims to identify waste units and their relative quantities to make use of their properties in different parts of the overall landform, including waste types suited for:

- NAF waste for basal layers and encapsulation of reactive waste, where exposure to oxygen, wind and water should be limited.
- Cover systems materials generally comprising inert material with properties that control the ingress of meteoric water into the landforms.
- The surface of landform embankments, comprising blockier units that resist erosion and or benign.
- Benign blocky material (rip-rap) waste for construction of drainage features, such as underdrainage, interflow drainage, drainage to intercept geological fracture flows (e.g. for in-pit or hillside landforms), diversion drains from upstream catchments, plateau catchment drains is required.
- Reduced permeability layers, typically comprising finer grained material, such as clays and oxide waste that can be suitably compacted.
- Use of natural alkalinity to neutralise acid salts: waste with excess ANC can be used in up gradient locations and in preferential flow areas to counter AMD.

- Growth medium to support vegetation, typically comprising stripped material from the landform (and pit) footprint, which generally is more suitable for revegetation.
- Layers forming capillary breaks, to limit the upward migration of salts.

WASTE LANDFORM CONSTRUCTION

Design and placement

The placement of PAF waste in the waste landform affects its reactivity by exposure to oxygen and seepage pathways. Consequently, the risk of gas production, AMD generation and the propensity for reactive material to self-heat and combust can be controlled via engineered placement.

In the waste rock landform and reactive waste and NAF are dumped separately, with the reactive waste encapsulated by the NAF waste. NAF waste is paddock dumped and then worked with a dozer to form the flattened and compacted base layer of the landform. Reactive Waste is placed in the middle each lift of the landform by paddock dumping and flattening with a dozer to reduce preferential pathways for air entry and net percolation. Finally, an outer NAF layer is constructed on each dump lift to complete the encapsulation. Compaction of materials occurs as dumping progresses, minimising infiltration of water into the dump. The tops of each lift are compacted and graded to slope away from the crest to manage runoff.

The key processes affecting pyrite oxidation are water seepage through the dump, thermal conductive heat transport and airflow through the dump mass. Numerical modelling and assessment at various mine sites has found that waste material texture and placement methodology is highly influential for both seepage rates and air flow rates (O'Kane *et al.*, 2012).

Most slopes in nature are characterized by a variety of shapes including convex and concave forms interspersed with ridges (spur ends) and swales (hollows), Carson and Kirkby (1972). Waste rock landform batter slopes should ensure geotechnical and erosional stability, aided by the coarse-texture and minimum length of slopes left at the angle of repose. Hence, low height slopes should be left at the angle of repose, and high slopes should retain the angle of repose for the upper part, retain intermediate benches or fill them, with the lower bench only pushed out to half the angle of repose (18° or 1 in 3). Reprofiled waste rock slopes should mimic natural concave slopes, which are stable geotechnically and erosionally (Ayres, 2006).

Erosion

Landform stability is related to erosion potential, and its assessment is a vital component of the landform design process. The greatest risk of failure of final rehabilitated mined landscapes is associated with gully erosion and failure of the re-established surface water drainage courses to adequately convey surface water flows McKenna and Dawson (1997). Erodibility and infiltration parameters are used to assess erosion potential for various batter slope options and overall landform shapes. Factors that should be considered include:

- selecting the least erodible materials for use in high erosion risk areas;
- modifying the erodibility of highly erodible materials, often through addition of rock or tree debris;
- batter gradient, slope length, and shape (linear, concave);
- additional inputs or design changes if required to manage risk of tunnel erosion;

- impact of increasing surface contact cover (rock, standing vegetation, tree debris etc.) and whether additional resources will be needed to stabilize batter slopes;
- impact of allowing flow from the landform top to discharge onto batters;
- impacts of concentrating flows (berms, rock drains); and
- Water infiltration and gas influx into the reactive mine wastes.

The Watershed Erosion Prevention Project (WEPP) modelling can be used to develop the indicative geometry of the variable concave landform at specific locations along the width of the landform and compares erosion along a series of transects that represent different longitudinal profiles (perpendicular to embankment contours) of a designed landform. In WEPP numerous slope configurations can be modelled and compared to develop a set of profiles that erode quite consistently along the modelled profile length. The slope configurations can then combined to form a 3D surface and modelled in SIBERIA to provide a quantitative assessment of erosion. The site survey can be interrogated using AutoCAD Civil 3D and together used to validate model predictions. The modelling is used to inform the engineering design.

Cover systems

The mine's primary strategy to manage reactive waste is to reduce the deep percolation of surface water through the waste material and thereby prevent AMD. This includes cover systems that limit advective gas transport into the waste pile and limit the flow of water (Cash *et al.*, 2014; Wilson *et al.*, 2014). Increasingly store and release covers are being provided to waste rock landforms as part of the closure design with the purpose of controlling percolation of rainfall runoff through these facilities. The focus in successful design is on the specification of the cover with respect to percolation performance and erosional stability facilitated by understanding cover material properties.

Construction of a cover system over reactive waste rock is a technique used at numerous mine sites around the world to control AMD over the long term. A cover for a waste landform located in a semi-humid or humid climate would typically include a reduced permeability layer of compacted fine-textured material (RPL) to reduce the ingress of atmospheric oxygen and net percolation of meteoric waters to the underlying waste material. A cover system with a RPL also requires an overlying layer to protect the integrity of the barrier layer and provide a medium for the growth of vegetation. This layer, referred to as the growth medium layer, also helps to reduce the percolation of meteoric waters to the underlying waste through storage and subsequent release of moisture to the atmosphere as a result of evapotranspiration. Where the site is subject to intense rain events there may be a need to install a drainage layer above the RPL and below the cover system to remove excess infiltration of meteoric water via interflow processes (O'Kane, 2012).

Over compaction of the growth medium layer, particularly in the root zone, should be avoided during construction. Soil compaction restricts root growth and reduces the available water holding capacity of the growth medium. Daniels & Amos (1981) found compaction was the major soil factor limiting long-term revegetation success at a re-claimed mine site in Virginia. Compaction between 80% and 85% of the standard Proctor maximum dry density provides many of the stabilizing benefits of soil compaction without jeopardizing the viability of vegetation development and growth (Gray, 2002).

WATER MANAGEMENT

The waste rock landforms must be able to provide drainage of surface water without significant erosion, limit net percolation of meteoric water to contained reactive waste rock and must retain sufficient moisture to support vegetation within the cover system. Options available in the landform design for managing meteoric water entering the landform catchment to minimise erosion and interaction with placed reactive waste rock include:

- Diverting clean water around the waste rock landform; limit run-on from external catchment to the landform;
- Diverting mine-affected water to holding dams for treatment prior to release or completed pits;
- Avoid shedding runoff from waste rock landform tops over slope crests which will result in erosion of the slopes; slope final and intermediate landform plateaus away from the slope crest and install crest bunding;
- Wherever possible divert runoff from waste rock landform tops to intercept natural gullies;
- Construct a cover system to handle incidental rainfall through increased storage capacity (e.g. store and release system);
- Construct cover system to handle excess water through providing drainage beneath the cover system (interflow) to reduce velocity and remove water excess to cover system capacity;
- Where reactive waste needs to be contained and managed the cover system must be designed to limit net percolation through the entire waste landform and may require a low permeability layer beneath the cover to assist in limiting net percolation;
- Avoid where possible contour banks and downslope drains as long term water management structures as they are prone to overtopping and piping; install these structures as temporary measures only (Williams *et al.*, 2012);
- Where possible avoid placement of reactive waste beneath final batter slope unless it can be adequately sealed to minimise interaction of reactive waste rock with meteoric water and discharge to receiving environment;
- Limit exposure of reactive waste to meteoric water during and post waste rock landform construction;
- Utilize compaction of intermediate waste rock landform surfaces to limit rainfall infiltration during landform construction; and
- Use cross-bunding and paddock dumping as part of the final cover system on the waste rock landform top surfaces to compartmentalise the landform catchment and contain incident rainfall, to encourage infiltration and reduce surface runoff.

MONITORING

The landform performance monitoring herein is referred to as initial (over a period of 1 – 2 years) and short-term (variable time frame) performance observation, investigation, and recording. The components of performance monitoring include erosion stability, vegetation establishment, weed and grazing control, and contaminant seepage rate from the wastes. The initial performance monitoring will provide inputs to the early remedial actions if the deficiency is identified in design and construction processes. During the short-term performance monitoring, the vegetation community develops and a range of soil processes continue to establish. As a result, landform stability should improve in response to the rehabilitated site evolution, and the contaminant leaching rate becomes

stable and acceptable to the receiving environment. At the end of the short-term performance monitoring, the landform should complete the transition from "newly rehabilitated land" to "established rehabilitated land".

Monitor key processes such as:

- Net percolation
- Heat transfer
- Vadose zone gas composition
- Oxygen migration
- Salt uptake
- Soil water characteristic curves

Cover system performance monitoring involving instrumentation includes:

- Meteorology
- Actual evapotranspiration (eddy covariance)
- Surface runoff
- Net percolation (lysimeter)
- Interflow or lateral sub-surface drainage
- Soil moisture
- Temperature
- Gas flux

CONCLUSION

The understanding of unsaturated zone hydrology and geochemistry is of key importance when considering the design of landforms containing mineral waste(s). Limited knowledge of waste material properties can lead to poorly designed and constructed landforms have the potential to cause unwanted environmental impacts, such as AMD, saline drainage, erosion, along with the inability to meet closure objectives and the desired final land use(s). Good environmental outcomes over long time scales is more likely with a thorough understanding of the waste materials properties, combined with early planning and design informed by in-situ data collection.

Plugin Arcgis – FEFLOW – Case Study

Katty Barzola, Ezio Crestaz and Robin Dufour
DHI Peru

ABSTRACT

Numerical FEFLOW groundwater flow models are designed, evaluated and finalized according to the specific purpose of a study. Often following completion of a model it is necessary to make small changes to the model as new data is collected, and observe the effects these changes have. This would normally require a FEFLOW specialist. Arcgis-FEFLOW is a tool that has been developed with the purpose of allowing people with knowledge of Arcgis to make small changes to a completed flow model and assess the results including the automatic update of the figures for the report.
A simplified FEFLOW model developed to evaluate potential effects of a proposed mine expansion on the groundwater system was used to demonstrate a practical application of Arcgis-FEFLOW. The results of this model were presented in August of 2013, one year later this model required an update of water level information, pumping well rates and new values for recharge (boundary conditions). The results of the update were related to fluxes, flow direction water levels. These results were compared with the original for different scenarios created in FEFLOW. This process of edits and assessment was then re-created in Arcgis using the pluggin Arcgis-FEFLOW.
The advantage of this tool is that it is accessible by people who do not necessarily have years of experience in numerical modeling but are familiar with ArcGis and also allows the direct use of data from a database.
The main disadvantages of this plugin are the limited 3D visualization, which is standard when working directly in FEFLOW, also it is not recommended to try to perform a calibration with the Arcgis-FEFLOW plugin as it is not designed for this purpose.

Mine Water Disaster Issues of Carboniferous and Permian Coalfields at Eastern China and Their Technical Countermeasures- A Case Study on Wanbei Mining Areas

YuhuaWu, Zhongwen Duan , BenkuiSun and Rongjie Hu
Wanbei Coal-Electricity Group, China

ABSTRACT

The coal bed of Eastern China coalfields is mainly composed of Carboniferous and Permian coal measures strata, where mining safety is threatened by a variety of water disasters especially at the Wanbei mining areas. In this study, we first introduce the main mine water disasters in the East China Coalfields such as Cenozoic loose stratum “bottom containing” water inrush, sandstone fracture water inrush, Carbonic and Ordovician limestone Karst water inrushes, Column collapse water inrush, water related environmental pollution and resource loss, and the like. We then expatiate on 1) several measures for water disasters prevention and control with Wanbei Coal-Electricity Group as an example, including in-advance rigorous problem explorations, and mine water inrush mechanisms and related forecast and early-warning technology, as well as key technologies, 2) eight-in-one water disaster prevention and control work system, 3) "water-control and green mining" concepts, and 4) the prospective of future development.

Keywords: East China; Wanbei Coal Mines; Mine water issues; Technical countermeasures

INTRODUCTION

The coal beds of coal mines in Eastern China are mainly composed of Carboniferous and Permian coal measures strata bounded by the Cenozoic loose layer at the top and Middle Ordovician carbonate rocks at the bottom. Because the former often contain multiple sand aquifers and the latter is the most water-rich regional aquifer, they are the main water sources causing mine water disasters. During the past two decades, water inrushes occurred in more than 220 mines in China, causing more than 8,000 deaths, and economic losses of more than 30 billion RMB[1]. These incidents occurred particularly in mines of the Carboniferous and Permian coalfields in Eastern China.

The Wanbei coal mining area is complicated because of geological, tectonic and hydrogeologic factors. It belongs to the Xuhuai region, Luxi subzone, Huabei stratigraphic zone and has bedrock covered by the Cenozoic loose layer and stratigraphic structure composed, in geologic time sequence, of Cambrian, Ordovician, Carboniferous, Permian, Tertiary and Quaternary rocks. The tectonics of the coal-mining area is well developed with a total of more than 50 faults with falls ≥100 m [2]. Most water inrushes are sourced directly from the roof and floor, with fracture water as the main source. Some floor inrushes from Karst water sources also occur to a lesser extent. In addition, the mining area has other features that present a potential water filling risk, such as water-conducting karst collapse columns, aquifers at the bottom of loose layers in the limestones of the Taiyuan group at coal bed's floor, and at sandstone fractures of the coal bed's roof and floor [3]. In the history of mining, all types of typical and representative water disasters and severe water disasters have occurred in this area.

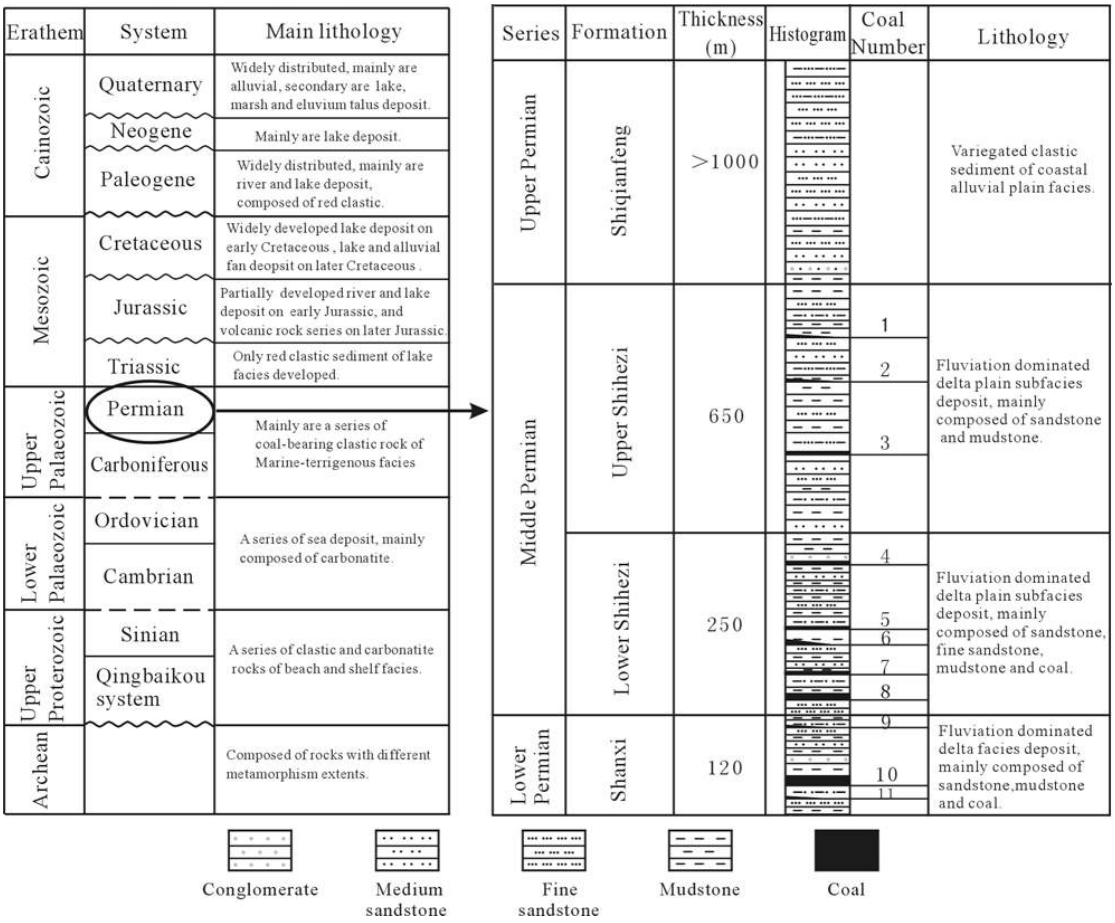

Figure 1 Stratigraphic integrated histogram

MAIN MINE WATER ISSUES IN WANBEI MINING AREA

The main mine water issues in Wanbei mining area include: 1) great threats to the mining faces positioned at shallow depth, caused by the well-developed Quaternary water-bearing strata located on the bottom of the Cenozoic loose layer and water-rich "ancient gullies" in some areas; 2) threats from abundant fracture water to the coal bed roof sandstones (faults), especially at new coal mine zones and faces; 3) threats from the confined aquifer to safely mining the No.10 coal bed floor, where the water inrush coefficient of high pressure limestone exceeds its critical value; 4) potential threats to safe production from many insidious karst collapse columns located near the coal-mining areas; 5) potential water hazards from goaf water in the mining areas; 6) potential environmental pollution from a large amount of mine water which flows in at an average rate of 310m^3/h and is highly mineralised, including high hardness, and some harmful elements if directly discharged [4]; and 7) a potential decrease in groundwater level, subsidence of the industrial complex located nearby, and the damage of mine shafts resulted from subsidence during coal production which consumes great amounts of municipal water mainly from the surface loose layer.

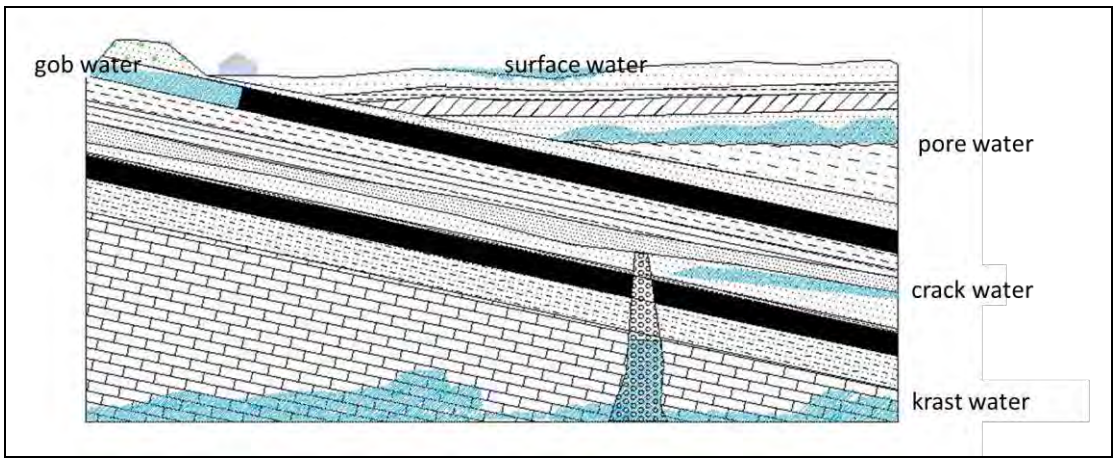

Figure 2 Schematic of coal mine water disasters

TECHNICAL COUNTERMEASURES AGAINST MAJOR MINE WATER ISSUES

Management System

It is necessary to establish 1) an effective three-in-one coal mine water disasters prevention and control system, consisting of a leadership subsystem, a technology management subsystem, and a technology, finance, and materials safeguard subsystem, 2) a sound eight-in-one coal mine water disasters prevention and treatment operation system of exploration, prediction, underground drilling, evaluation, measures, examination, monitoring, and protection, with the aim to form a complete mine water forecast and treatment pattern of "full members' attention, advanced equipment, leading technology and sound system.

Technical concept of water-controlling mining

The concept of water-controlling mining is proposed as 1) optimizing the rules for responding to catastrophes caused by sudden changes in rock and water coupling mining-induced rock fractures through the means of artificial and controllable factors such as pillar scale and mining sequels; 2) mastering the inherent and universal laws between catastrophe mechanisms and the natural/man-made controllable factors, i.e. understanding i) the enclosure conditions and control mechanisms of coal bed mining-induced fracture generation and propagation, as well as ii) the formation laws of channels connecting inrush water and collapsed sands; 3) proposing new water-controlling mining technical theory and engineering methods of coal seams subject to water inrush; 4) establishing and improving the water hazard prevention and treatment platform; and 5) completing the transition from passive water prevention and treatment to active water control. Overall, the following three objectives should be achieved: 1) water-protection and green mining; 2) safe and economic mining; and 3) clean production and resource conservation.

Exploration of advanced fine examination techniques of mine hydrogeological conditions

"Forecast and predict, explore when with doubt, investigate before digging, and mining after control" are not only the basic principles, but also the basic procedure of coal mine water disaster prevention and treatment. The exploration of mine hydrogeological conditions is based on forecasting and prediction [5]. In recent years, studies on the implementation of advanced fine examination techniques of mine hydrogeological conditions at Wanbei mine areas are mainly focused on the following areas:

1) High precision 3-D seismic exploration techniques: A series of processing techniques have been applied to achieve high precision 3D seismic exploration such as i) high-density, wide-azimuth 3D seismic data acquisition technology, ii) high-precision iterative static correction, pre-stack noise removal, amplitude maintaining, resolution improvement, pre-stack shifting processes, iii) forward modeling guidance, multi-character analysis, and comprehensive 3D visualization analysis [6].

2) Ground and underground collaborative, integrated advanced exploration techniques: Combined applications of the ground electric surveying, ground 3D seismic exploration, and dynamic data processing and interpretation with underground advanced geophysical exploration and advanced shield drilling exploration were implemented to accurately explore the hydrogeological tectonics, water-rich abnormal areas, and various water inrush risks for the purpose of safety production.

3) Underground multi-parameter monitoring and pre-warning and advanced exploration and treatment techniques of insidious water-bearing and -conducting karst collapse columns: Based on previous determination of insidious collapse columns, a management idea integrating "Geological pre-judgment, hydrological pre-warning, geophysical positioning, and drilling control" was implemented for active and preventive treatment. An online testing platform was established and studies on rapid identification of both water inrush sources and channels based on water quality, temperature, amount, and potential outflow points were conducted. Based on pre-judgment and following pinpoint positioning of collapse columns by integrated geophysical probing, both the underground roadway sealing-off and the ground, high-precision angle directional boreholes as well as multiple borehole combined dislocated grouting were jointly used for prevention of insidious collapse columns. Many such columns were found in advance and successfully treated, thus avoiding the occurrence of water inrush accidents.

4) Efficient, precise, and directional drilling exploration techniques: A series of techniques and measures such as borehole precise positioning and whipstocking branches, underground long-distance, nearly horizontal directional drilling, measurement while drilling, and safe and efficient construction in drilling and grouting were taken to achieve efficient, accurate, and directional drilling exploration.

5) Mixing water sources recognition techniques: The conventional water chemistry, trace elements, stable isotopes, and other means were applied to systemically study the primary control mechanisms of water chemistry in multiple aquifers. Combination of mathematical statistics, neural networks, and other measures was used to establish a water-sources identification model suitable for mine water prevention and treatment. An identification method for water source containing rare earth elements, a proportion calculation method for mixed water sources in mine were

proposed for the first time, which solved the technical difficulty in fast identification of mixing water sources at multiple water-bearing strata, and pioneered the studies on the mines' mixing water source.

6) Ongoing research projects include the seismic and electromagnetic method combined ground hydrogeophysical prospecting technique for mine water, the advanced exploration techniques integrated with roadway-borehole electromagnetic method, drilling and geophysical exploration, and the like.

Research on mine water inrush mechanisms and its forecast and pre-warning technology

Wanbei mining area is one of the earliest areas for studies and application of mine water inrush prediction and pre-warning technology. In this area, a series water hazards forecast and early warning techniques such as prevention and control of floor limestone water inrush, goaf water inrush, and roof's Cenozoic bedrock water inrush have been consecutively implemented, a mine water quality monitoring system and water chemistry information database of various water-filled and water-bearing strata were established, a water source identification model and calculation software were developed, and an effective early warning of mine water disasters was completed. In addition, researches in the mining area are focused on the deep-mining induced water hazard evaluation and prediction technologies as well as the real-time face water inrush forecast and early warning technologies. Considering the three prerequisites for the occurrence of mine water disasters (water sources, channels, and amount), a real-time, linear, and planar monitoring and early warning was implemented to achieve the goal of simultaneous monitoring and warning of mining-induced deformation and water inrush potentials. For example, a series of researches were conducted on water inrush prediction and early warning techniques of 1) floor limestone water at 6112 Face, II621 Face, and II615 Face of Hengyuan Coal Mine, 2) gob water from adjacent faces at 6131 Face of Qidong Coal Mine and 1018 Face of Wugou Coal Mine, and 3) Cenozoic roof and aquiferous floor at 7131 Face of Qidong Coal Mine. These researches on water inrush prediction and early warning techniques were effectively applied in water disaster prevention at mine faces.

Research and implementation of mine water disaster control technology

After years of research and innovation, Wanbei Coal Electricity Group co. Ltd. has solved a series mine water hazard control issues and constructed relatively complete and advanced coal mine water disaster prevention and treatment technology systems. Firstly, the insidious water-bearing and -conducting column collapse forecast and control technology has successfully detected insidious hazards in advance, thus avoiding many water inrush accidents in a timely manner. Secondly, the coal seams mining techniques under Cenozoic loose layer aquifers have been improved by using seam roof pre-split blasting and gangue backfill mining and implemented to effectively prevent and treat roof water inrush and sand downpour disasters. Thirdly, the coal seams mining technique on floor limestone confined water has been applied to perform a series of advanced face floors exploration, grouting reinforcement for ground floor ,and aquifer improvement, thus efficiently controlling limestone floor water inrushes. Fourthly, advanced

detection techniques of roof and floor sandstone fracture water were used to monitor and discharge water in a targeted manner, thus ensuring safe production. Below is an application example of presplit blasting technique for the face roof under confined water.

Qidong Mine coal measure stratum is covered by Cenozoic thick loose layers. Its bottom aquifer (the Quaternary aquifer) directly overlays the coal-bearing strata, and has characteristics of greatly varied lithologic composition, thickness, and water richness, as well as complicated ancient riverbed distribution condition, which directly threaten its safety exploitation. Since the operation of Qidong Coal Mine, its eight fully mechanized faces, Faces $3_2$22, $7_1$14, $7_1$12, $7_1$30, $7_1$21 and others, consecutively underwent 17 support failure accidents, among which, 15 ones were accompanied by water inrush. On November 25, 2001, both support failure and water inrush occurred at the first mined $3_2$22 Face, resulting in flooding the mine. The analysis of the Face data found that the development of damage to hard overburden stratum induced by fully mechanized mining was very large, the relationship between the maximum damage height of the overburden stratum and the mining depth didn't meet the general mining rules which complied by other mines in the hard overburden stratum exploitation. Under the conditions of Quaternary high water pressure and original fissures' great angle, longitudinal cracks development, the damaged height of overlying rocks sometimes increases significantly. Therefore, roof water disaster prevention and control for Qidong Coal Mine should focus on the determination of types and rational sizes of coal seam roof pillars and supports, the specific methods are as follows:

1) Roof's advanced pre-split blasting:

According to the physical characters of roof strata, advanced pre-split blasting of the face roof was taken. With the mining advancing, the construction blast parameters were constantly adjusted to reduce the periodic weighting step distance and the two-zone height of the roof. The measured two-zone height was 43 m, 10 m lower than that in the previous similar mining faces.

2) Comprehensive monitoring of roof water seepage physic field:

Through the monitoring of early warning boreholes in the face, the characteristics of ground electric field parameters of roof deformation and failure, as well as the migration of roof water seepage in its face mining process were measured to rightly forecast the face mining states.

3) Application of high resistance supports:

According to the combination of roof rock properties, high resistance supports were used to strengthen the face's supporting capacity for preventing support failure, water inrush, and roof caving, etc.

4) Ground monitoring and early warning:

Through long monitoring boreholes into the Quaternary strata, the level of water in the strata was real-timely tested; then, according to the relationship between the level of water and the cycle of

periodic weighting, face mining advanced scientifically under a reasonable wall pressure to avoid support failure.

Figure 3 Schematic of face roof pre-split blasting

Mine water resources utilization technology

Wanbei mining area actively launches a series of researches on groundwater hydrogeochemistry, mining area water environment and quality assessments, mine water resources reclamation and utilization, forms the mine water drainage and supply combined technology, the reasonable mine surface water and underground water adjustment and distribution technology, the mine waste-water treatment and reclamation technology, and the three-in-one optimized management technology of mine water discharge, water supply, and eco-friendliness [7]. The mining area has installed the water treatment device to each mine in the area, and the treated mine water is used for mine coal production and living water, achieving 100% mine water process and utilization .At the same time, the utilization of mine water directly reduces the water withdrawal from the surface loose layer, and protects the natural balance of the surface phreatic water, thus avoiding sink age of surface water level, subsidence of the industrial squares, well-bore failure, and other issues caused by excessive water withdrawal from the surface loose layer and having very significant benefits to environments and society.

CONCLUSIONS

Wanbei Coal Electricity Group uses" water-controlling exploitation", safety and efficiency as its motto, prevention of mine water disasters as its focus, and with exploration, forecast, prevention and treatment, and comprehensive utilization of mine disasters as its main line. The group conducted a series of in-depth researches from the aspects of 1)mine water containing laws, 2) hydrogeologic precise exploration techniques, 3) water inrush mechanisms and forecast and early warning techniques, 4) water hazards prevention and treatment techniques,5) mine water resources utilization techniques, to develop and apply such key technologies as 1) the prevention and treatment of mine water disasters, 2) the comprehensive utilization of mine water resources, and 3) the protection of water environment, and takes a lot of measures to tackle the challenges of mine water issues and form a comprehensive prevention and treatment and management system to prevent and control mine water disasters and coordinate water resource and eco-environment protection with the hope to achieve harmonious development between human and nature.

Overall, Wanbei Electricity and Coal Group has formed a set of advanced coal water disaster prevention and treatment technologies and management patterns and ensured safe mining and production for consecutive 13 years. These techniques have been widely promoted and applied to North China Coal Mines located in the eastern China with significant benefits and achievements. In 2014, Wanbei Electricity and Coal Group established the National Engineering Technology Research Center for Coal Mine Water Disaster Prevention and Control to improve China's overall technological level, tackle coal mine water issues and promote safe, eco-friendly, and healthy development of the coal industry.

MINE DEWATERING

Dewatering of Opencast Mines Using Model-Based Planned Horizontal Wells

Holger Mansel[1], Richard Eichler[2] , Marcel Nitz[1], Maik Biedermann[1], Rene Blankenburg[1] and Carsten Drebenstedt[2]

ABSTRACT

As part of many mining and civil engineering projects that involve surface excavation, rock layers must be drained first to allow excavation, removal, and disposal of rock and soil. Today this drainage is mainly achieved by using vertical wells. Especially in thin aquifers the extractable water quantity by a single well is limited due to a very small length of the screen section. Since vertical wells may interfere with land use rights over the location of water catchments, horizontal drainage using Horizontal-Directional-Dewatering (HDD) is of increasing interest. There is a high potential to achieve the drainage capacity of many vertical wells by using fewer HDD wells. Furthermore, this allows for significant reduction in material and energy use, land use, and groundwater resources. Based on the results of the first phase of the project which dealt with the oncoming flow in HDD wells, the second phase addresses the hydraulic effects of the elements environmental impacts, cost effectiveness, and application on an industrial scale.

Keywords: PCGEOFIM, Groundwater modeling, horizontal wells, Horizontal-Directional-Dewatering (HDD)

INTRODUCTION

Dewatering of near-surface unconsolidated rock material is an important prerequisite for the technical implementation and safety of mining projects. The removal of water from the overlying rock is also a basic necessity for stable slopes and benches. For this purpose, considerable volumes of water are pumped annually in the construction and mining industries, about 1 billion cubic meters in Germany's open-cast lignite mines alone. Regarding the geological/hydrological conditions of deposits, particularly in basin structures, the piezometric pressure may also have to be reduced, and sometimes drained below the base of an excavation. Otherwise there would be a risk of footwall failure with water escaping from the ground. Higher residual water levels in overburden operations and out-of-control rising ground water levels could cause slides. A lot of negative experience has been gained through such hazards in lignite mining.

Nowadays vertical filter wells are commonly used on a large scale to lower the groundwater table and to relieve groundwater pressure. Depending on hydro-geological conditions, the lowering of ground water tables cannot usually be limited to the immediate mine area itself, even more so as this process must take place in advance to guarantee compliance with geotechnical and hydrological target values. This has a negative impact on the regional hydrological balance and must, therefore, be minimized.

METHODOLOGY

Based on the results of a successfully completed phase 1 the aim of the 2nd phase of the research project (both phases funded by the Deutsche Bundesstiftung Umwelt, DBU, [German Federal Foundation for the Environment]) is to develop the scientific and practical basis for the application of an alternative dewatering method , i.e., curved filter wells (Horizontal Directional Drilling - HDD) and to overcome the environmental drawbacks of the use of vertical filter wells as efficiently as possible.

Currently, the curved dewatering technique in lignite mining is limited to a few individual cases, but has great potential for easing the environmental burden of mining projects (Müller et al. 2009). Figure 1 shows how curved horizontal directional drilling can be performed with relatively little effort beneath an area that otherwise could only be accessed underground (with difficulty) or not at all.

Figure 1 Schematic presentation of horizontal drilling (Tracto-Technik 2010)

As a rule, installation of HDDS is divided into three successive steps – pilot bore, reaming(s) and pulling in pipes or filters.

A complete dewatering of the overlying rock, e. g., of an open-cast mine, or of the relieved aquifer of a footwall opens up a complete new range of applications for the curved filter well technique.

The basic principle is to let the water that is produced by the HDD filter wells discharge freely at the lowest point of the well.

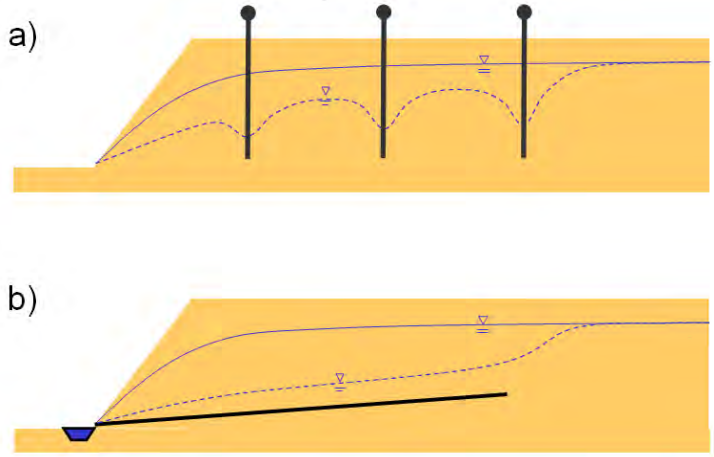

Figure 2 Drainage of overburden material at slopes of open-cast mines, a) using conventional vertical wells, b) using horizontal filter wells (Eichler 2013)

Figure 2b shows how the HDD well is installed in the rock formation next to the slope. Thus the water flows out by gravity continuously. Due to the mining progress material of the slopes is excavated and the end of the well will be cut time and time again. However, the water produced by the HDD flows out at the in-pit end of the well. The water will be collected by a trench on the bench and led to a central pumping station at the deepest point of the open-cast mine. By this means, there is no need for pumps or installations at every single well. Consequently, no pipelines are required to receive the water from the individual wells and to pipe it to a central water station as it is in the case of using vertical wells. The real field of an open cast mine is directly used only prior to the actual surface excavation when the HDD wells are installed. Furthermore, while the length of the effective filter section of vertical wells is reduced due to sinking water level, the effective filter length of horizontal wells remains constant. As a result, the number of required wells may be much lower due to the several times longer wetted filter screen compared to vertical wells.

The freely outflowing water will be collected at a central water station and pumped by large pumps whose efficiency is much higher than that of many small pumps that ought to be installed in the vertical wells. As a consequence power consumption will decrease. Such wells may be used in both, active slope systems and final and periphery slope systems.

Depending on geological and hydrological conditions and the geological structures, various modifications and designs respectively are possible due to the flexible installation of HDD filter wells. Based on preliminary studies, several options are conceivable.

Option 1: As illustrated in figure 3, a drill hole with an exit opening can be equipped with a submersible pump if the dewatering takes place close to the surface. Alternatively, a close-to-surface filter well can also be connected to a collection shaft (figure 4) allowing gravity flow from the HDD and extraction from the collection shaft as needed.

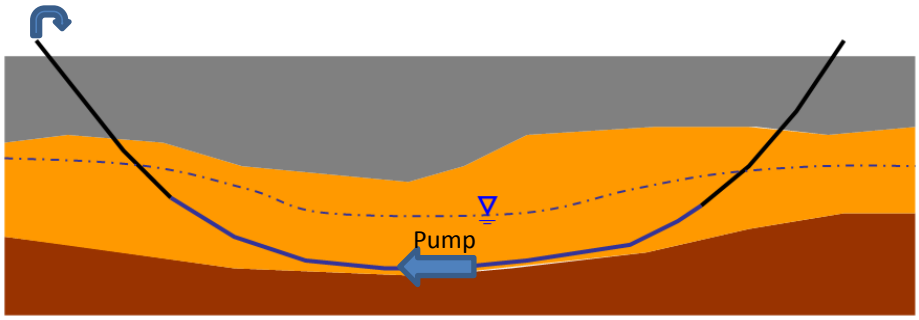

Figure 3 HDD well with submersible pump close to the surface with exit opening (Struzina 2012)

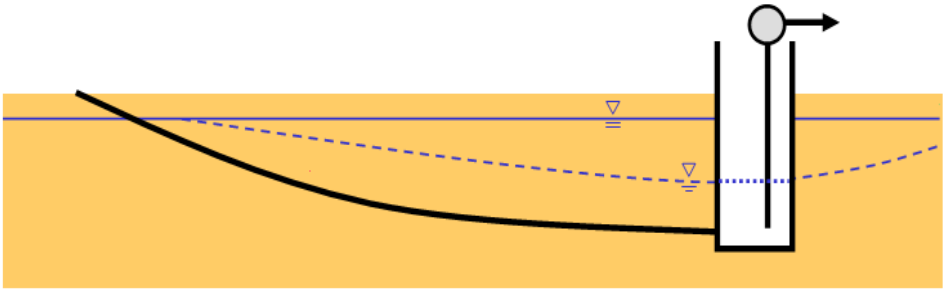

Figure 4 Close-to-surface HDD filter well with collection shaft

Option 2: In a mine's border slope system, HDD wells are drilled along the slopes. The water flows through their entry opening into water collection trenches put in place at the bottom of the slope from where the water is drained. Such a solution is illustrated in figure 5 whereas in certain cases several slopes can be dewatered by one HDD well.

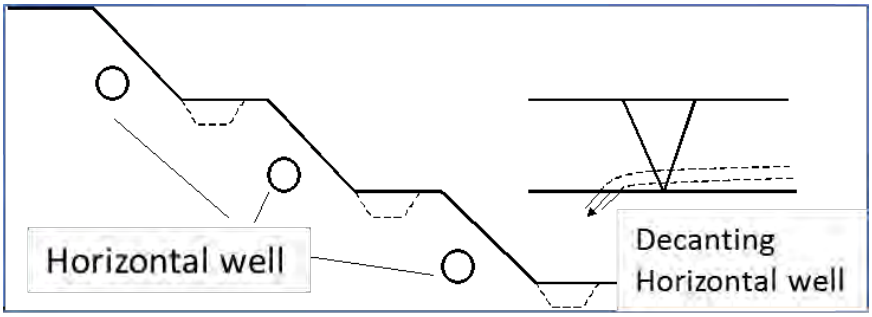

Figure 5 HDD filter well in a mine's border slope system

Option 3: The only alternative to vertical filter wells for dewatering projects with multiple aquifers are either HDD wells to be drilled in each aquifer or the connection of vertical infiltration wells with curved horizontal wells .

In addition to HDD drilling, which is comparably expensive, this option offers a cost-efficient alternative for continuous concentrated drainage of all horizons using one HDD well for all aquifers. For this purpose, all vertical injection wells are directly or indirectly connected with the horizontal filter train in the deepest aquifer to be drained. The water of low lying and hanging aquifers drained by injection wells flows to the bottom or deep-lying aquifer and is pumped through the HDD well wich has been put in place there (figure 6).

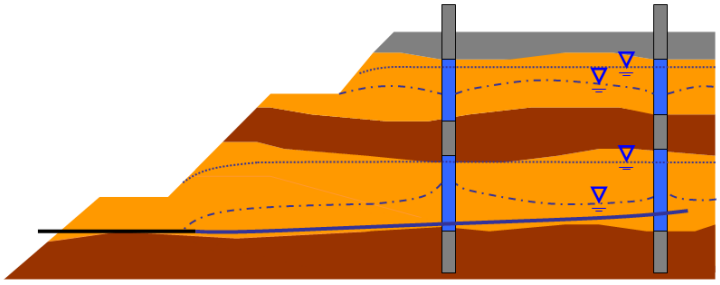

Figure 6 HDD well in connection with vertical injection well (Struzina 2012)

Further options and opportunities for the modification of HDD wells shall be examined and developed subject to the geological conditions and technological boundary conditions of construction sites and mining

Development of improved calculation methods and modeling

For planning and consulting engineering activities, the Ingenieurbüro für Grundwasser GmbH (IBGW) uses the PCGEOFIM® program (Sames et al. 2011) developed in house. This program was developed primarily for active mining and reclamation mining and is used for these purposes by other institutions as well, among them are the Mitteldeutsche Braunkohlengesellschaft mbH (MIBRAG), Lausitzer und Mitteldeutsche Bergbau-Verwaltungsgesellschaft mbH (LMBV), TU Bergakademie Freiberg, Vattenfall Europe Mining AG, Dresdner Grundwasserforschungszentrum e.V. (DGFZ) and more.

Based on the results from bench-scale and field tests and their model-aided monitoring in project phase 1, new knowledge was gained concerning the open channel pipe flow in the horizontal well as well as the pressure pipe flow by involving the pressure losses.

Figure 7 shows the impact of an HDD filter well on the groundwater flow when the well is fully flown and a pressure flow occurs in the filter pipe (left) and when the well is subject to a non-full flow and open channel flow in the filter pipe (right). Only the case of a full flow with pressure flow in the filter pipe has so far been correctly modeled and tested. Further possible are the case of full flow and open channel flow (this case was observed in a field test during project phase 1), the case of non-full flow and pressure flow and the case of no flow.

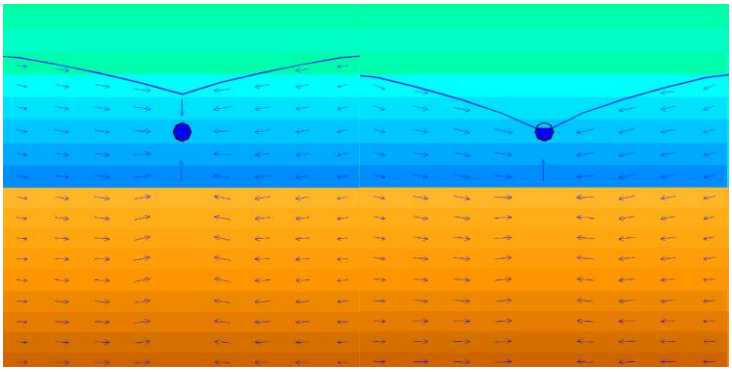

Figure 7 Full (left) and non-full flow (right) to a horizontal well with pressure pipe and open channel flow

On the basis of the results and knowledge gained from the tests performed in project phase 1, open channel pipe flow was realized in the groundwater model of the PCGEOFIM software system and

theoretical findings were made with regard to pressure loss behavior in pressure pipe flow scenarios.

For a comprehensive algorithmic presentation of the possible impact of HDD filter wells on the groundwater table, it will be necessary to develop further algorithms clearly describing the connection between the water level in the filter pipe and the water volumes flowing – in sections - into and out of the horizontal well. However, a solution has not been found for a case yet where both flows, i.e. open channel and pressure pipe flow, occur in the HDD filter well. The tipping point between open channel and pressure pipe flow shall be subject to further investigations in bench scale testing.

The capacity of an HDD filter well is limited by the pressurized water flow. Only a limited amount of water can be transported per time unit subject to length, diameter, pipe roughness and gradient. The formulas for pressure and open channel pipe flows are known. However, in phase 1 of this research project, new knowledge has been gained after considering open channel pipe flow in the model and findings were made with regard to the calculation of occurring pressure losses. The use of HDD filter wells as open channels with a free water surface following the conventional approach of Manning/ Strickler (pipe channel) enabled a more accurate representation in the model. Inflows to the individual HDD well sections are shown in figure 8.

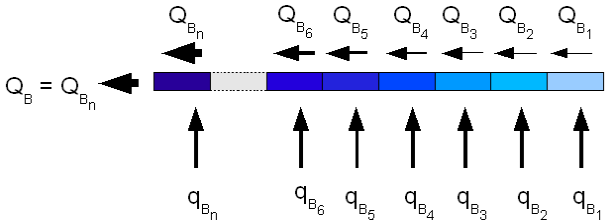

Figure 8 Calculation of the through flow in an HDD well used as an open channel

Fig. 9 shows a graph of water levels and pressure losses. Calculations follow the iterative method using an initial guess.

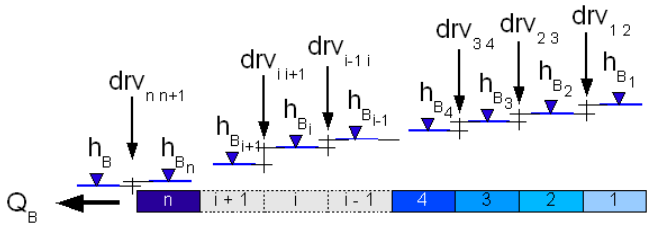

Figure 9 Calculation of pressure losses in a pressure pipe flow scenario

The theoretical knowledge gained in phase 1 with regard to the calculation of pressure, open channel pipe flows and pressure losses shall be implemented, verified and tested in the model algorithm within the scope of further research to be conducted in project phase 2.

Further work on the project will be focused on two parallel key subjects based on the results gained in the first project phase.

The first subject will include bench scale testing in order to evaluate the data for modeling. The focus will be on the extension of the data basis on one hand and on further investigation needs if identified as necessary from the results of the first project phase on the other hand. The second subject will be dedicated to a field test with a practical application of curved dewatering drilling in

a multiple aquifer scenario.Additionally, the investigations shall also include the exploration of opportunities for drainage modeling using curved horizontal drilling as a two-phase model.

RESULTS AND DISCUSSION

Within the scope of both the bench scale testing and field test to be done in the project phase, a geological structural model was created. Based on that model, a numerical groundwater model for the simulation suite PCGEOFIM was developed. By means of available measurement values, the groundwater model was calibrated for the startup time of an HDD-well to allow for prediction simulations. During the test phase, the model statement was continuously recalibrated on base of newly available observations (figure 10). The results obtained from both, the bench scale testing and the field test, were used to improve the knowledge of processes in the close range of HDD-wells. By means of accompanying research and mathematical model development, new algorithms were implemented into the groundwater simulation suite PCGEOFIM. A significant result is the consideration of head loss in the well pipe and its effects to the surrounding groundwater flow. The section below describes modeling results of the field scale test. It emphasizes the comparison of measured and computed values.

In Figure 10 the observed (red dots) and calculated (line) values of the outflow of an HDD-well are shown. The blue vertical bars depict the times of well development. Several well devleopments had to be conducted to achieve a good drainage. In general, the computed results show a very good agreement with the obervations.

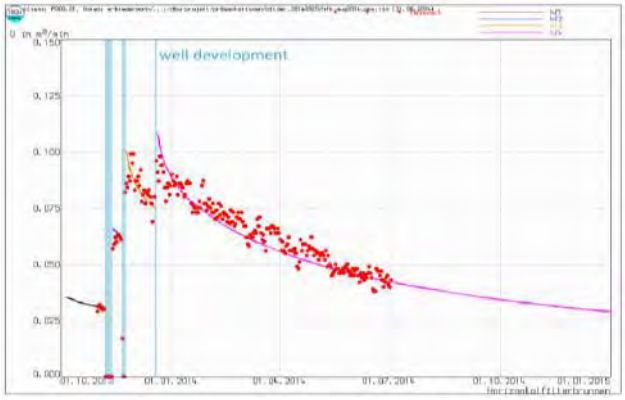

Figure 10 Simulation results (line) of an HDD-well including the head loss process.

Figure 11 a) and b) illustrates the situation in the groundwater at the startup time of the HDD-well. The thick blue line corresponds with the location of the HDD-well in the field test. Several observation points (black dots) are also drawn showing the results of the calibrated groundwater model.

In Figure 12 the groundwater situation is shown nearly 10 months after the startup of the HDD-well. The contour lines represent the groundwater level and show the draw down compared to Figure 11. The 2 circled observation wells are selected for a comparison of observed and calculated values over several months.

That comparison is shown in Figure 12. A very good overall agreement of simulated and measured groundwater levels can be stated.

Figure 11b) Groundwater situation 10 months after startup. Colored circles show the position of 2 observation wells.

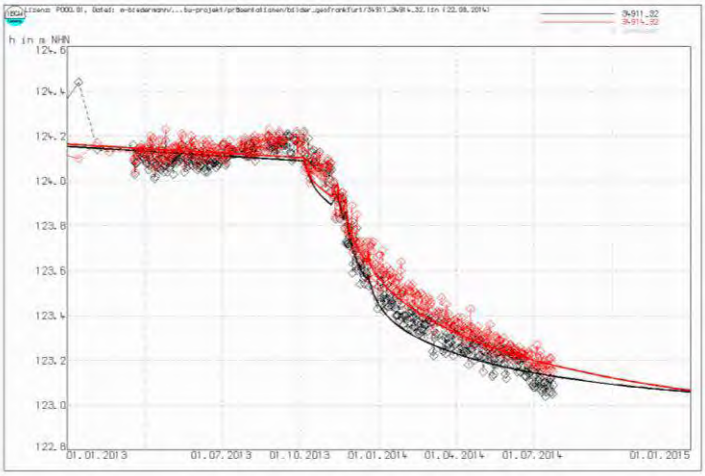

Figure 12 Comparison of observed (circles) and calculated values (line) at 2 different observation wells

CONCLUSION

Processing the data of the structural geological model, a groundwater flow model including a HDD was built up to enable the forecast of the dewatering. Therefore, the program PCGEOFIM, especially suited for mining drainage planning, was used. The calibration was conducted with the information of 28 monitoring wells. For the modeling, results of macroscale experiments regarding the incident flow of the HDD well, and differences between channel and pressure flow were taken into account. The results of several bench scale tests provide the possibility to forecast the dewatering of diverse HDD well configurations and different geological conditions.

Hence, the groundwater simulation suite PCGEOFIM is a tool to allow for the prognosis and planning of HDD-wells using groundwater models.

Removing of High Flows of Acid Water from Disused Mines in Johannesburg

Axel Döring
ANDRITZ Ritz GmbH, Germany

ABSTRACT

South Africa is currently dealing with the problem of acid water because underneath the old gold mining city of Johannesburg is a lake containing heavily contaminated water, which spreads horizontally and vertically into the abandoned pits of the former gold mines.

Meanwhile, the water line has reached a critically high level. The corrosive sulphuric acids can in the worst case scenario, result in a pH value of 2, which is enough to cause lasting damage to humans and the environment.

Two state-of-the art pumps have been running since June 2014 in the middle of Johannesburg city centre with each pump capable of bringing 1,500 cubic meters (=1.5 million litres) of water to the surface per hour.

Because of this corrosive acid, these pumps are a customised construction. The design is based on a proven double-flow technology, which uses the concept of a double-suction pump. By the counter-rotating arrangement of the impellers the pumps run without axial thrust. With this design, delivery heads up to 1500 m can be reached. Due to the corrosive acid, the Johannesburg pumps were redesigned. Part of the new system is an encapsulation of the submersible motors. This technology enables the creation of an internal pressure higher than the external pressure, preventing the intrusion of the corrosive water and the components inside the motor being attacked and possibly destroyed. The water being drained is used to cool the motor and if required the motor can be extended by additional heat exchangers.

INTRODUCTION

The city of Johannesburg located in South Africa was founded as a result of the Witwatersrand Gold Rush. Since 1886, when gold was discovered in the Central Basin, 40.000 metric tons – 30 percent of the gold of the world – have been extracted from the mines. The two deepest mines in the world are found in the Witwatersrand basin, extending nearly 4 kilometres below the surface.

While mining was operational, the inflowing ground water was pumped out of the mines by the ongoing infrastructure in place. But after the last mine closed down and pumping ceased altogether, the voids began to fill. The Western Basin filled and began to decant in 2002. Pumping ceased in the Central Basin in 2008 and in the Eastern Basin early in 2011.

These abandoned mine shafts of the former gold mines are gradually filling with water and need to be dewatered to avoid contamination of underground water and keep the water at an acceptable and safe level, or to bring this potentially contaminated water to surface for treatment.

Mine Drainage, has become an ecological issue and challenge. The metamorphic rock of the mining district contains abundant pyrite (iron disulphide) which reacts with oxygenated rainwater or groundwater resulting in elevated sulphate concentrations and eventually low pH values. With pH levels as low as two, the sulphuric acid mobilizes aluminium, potentially toxic metals and uranium from the rock and produces iron oxide as a by-product when the pH rises.

Figure 1 Map of South Africa (from http://superiormining.com/properties/south_africa; 13.11.2014)

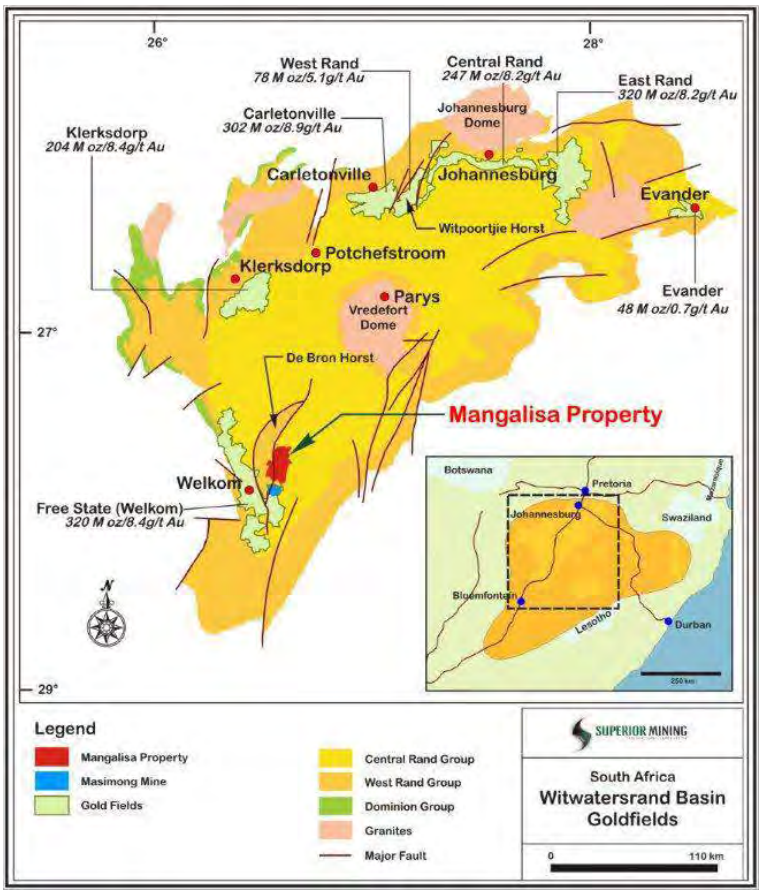

Figure 2 Landscape of Witwatersrand (from http://superiormining.com/resources/maps/20120213_witwatrand_basin.jpg; 13.11.2014)

RECOMMENDED MEASUREMENTS

Pumping out underground mine water to prevent reaching the environmentally critical level, controlling the ingress of water into mine shafts and in short term treating the contaminated mine water by neutralising the high acidity.

CHALLENGE – PUMP SOLUTION

The responsible technical experts looked for a long term draining solution to face the problem. Two main challenges had to be matched in this issue.

The materials which are in contact with the mine water – metals and elastomers – have to resist the medium for a long time. Therefore, the best material to face the medium and the mechanical properties had to be chosen. Multiple material options were taken into account and qualifying tests were necessary. Therefore, the renowned institute FEM (Forschungsinstitut für Edelmetalle) rebuilt artificial mine water based on the chemical analysis out of the mine and put test materials for a term of three months into this medium. Additionally by using higher temperatures, the reaction time gets

faster and a longer period of time could be simulated to get findings of the long-term behavior of the materials.

As a result of these tests, the material selection was refined. Out of the remaining materials the materials with the best mechanical properties for the parts of the pump unit were chosen to enable a compact design of the pump unit.

The used duplex steels combine the features of stainless chromium steels (ferritic or martensitic) and stainless chromium-nickel steels (austenitic). They have those rust and acid resistant properties which are necessary to resist the medium influences. Further they have the required mechanical properties.

Nevertheless, the water analysis may always only be counted as a snapshot of the current situation. As caused by environmental influences the water composition may change. But due to the selected high value materials absolute safety and resistance in operation can be expected.

As a further step and in order to protect the motor of the pump unit against the entrance of the contaminated medium it has been designed encapsulated. That means that the motor is packed into an additional casing to protect the motor materials against the acid medium.

The motor itself is filled with drinking water and put under overpressure. Fresh water is led to the motor through a long pipe from a quench placed on surface. The pressure is controlled constantly and in case of abnormal pressure signals, messages are displayed. Further, the filling level, the flow and the head (*Q* and *H)* are also monitored. The pump performance can be watched from all over the world by remote monitoring. Selected and qualified persons can also change parameters if it is necessary.

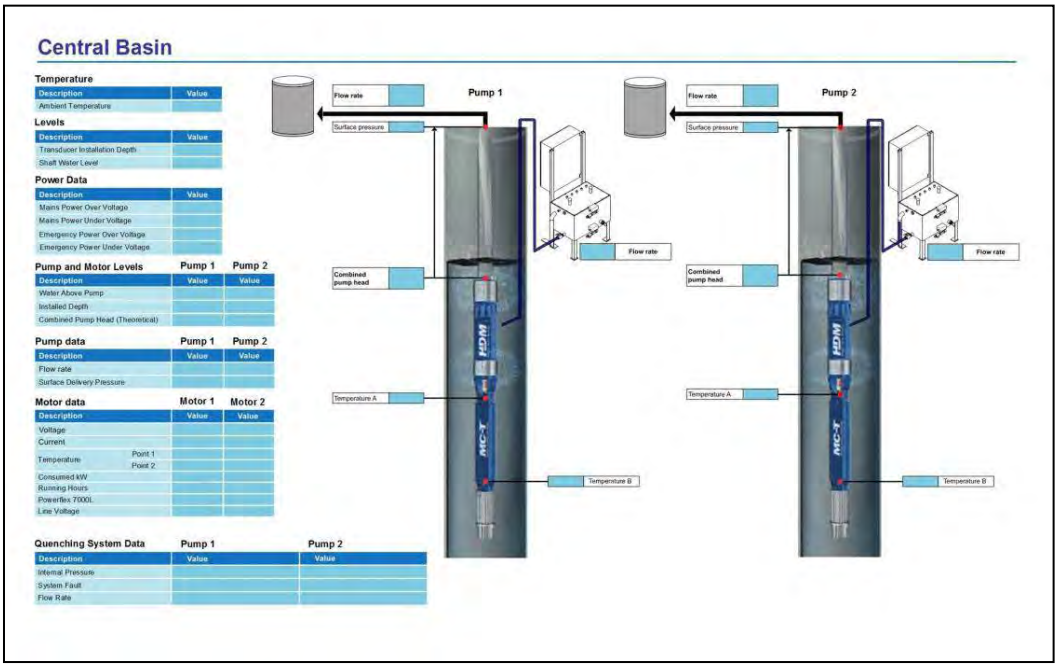

Figure 3 Monitoring scheme

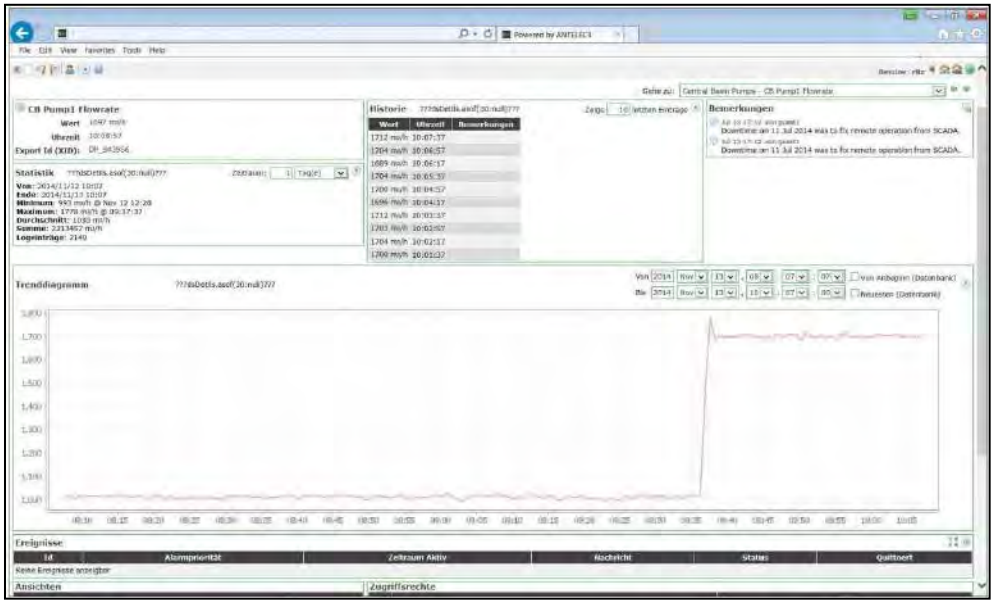

Figure 4 Remote monitoring display

The mechanical seal is tailored to the requirements of that special application. The sliding surfaces of the mechanical seal are specialized and all components are also matched up to the medium. A special construction of the mechanical seal guarantees absolute reliability and best operational characteristics. It is also charged with the inner pressure from a quench.

Weather conditions like rain influence the medium level as experienced with ground water all over the world. The changing water level requires a specific pump hydraulic to drain the water. Additionally, the level gets more or less steadily lower because of the dewatering. The more medium is pumped the lower is the level of the contaminated mine water. So the pump has to have a widely spread operation range.

The pump works with medium 70 m below the level of the contaminated water. When the level has reached the next lower marking, the pipe is enlarged with another pipe part. For the planning team it was important that the pipe can be enlarged easily and without loss of time. Therefore, quick snaps are used. Additionally to the quick assembly they score with their compact design, low weight and less effort in comparison to conventional screw connections.

With every step down, the pump has to manage a higher pumping head. This has also been considered in pump selection. Furthermore, the pump is equipped with a cooling shroud to guarantee the necessary cooling flow.

The used double-suction design of the pumps reduces any axial thrust nearly to zero. As a result, the pumps are extremely persistent and nearly maintenance free. Some pumps of that type had run in best performance up to 25 years without the need of maintenance. But considering the critical medium the terms of maintenance are shorter in this case. In case of maintenance the use of the quick snaps show their advantages. The pumps can be disassembled and reassembled in a comparably short time.

All pump units are identical, they have the same hydraulic. At least one complete pump unit is stored disassembled at site; which means that one set of parts is immediately available. Additionally a number of selected spare parts are stored at site, too.

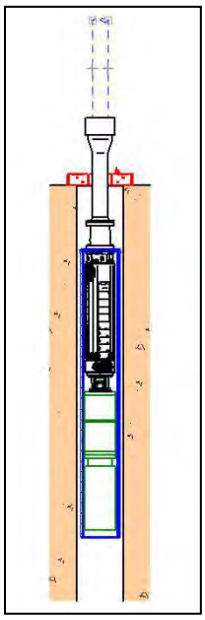

Figure 7 Assembly scheme

Figure 8 Assembly

CONCLUSION – ECOLOGICAL ASPECT

The mine water is being transported to the surface and onwards into an adjacent treatment plant. There, through the addition of lime, the pH value is raised, the acid is neutralised and the dissolved metals in the water are (co-)precipitated as hydroxides.

The South African authorities are planning a total of three pumping stations, which will each be developed at the mines' disused extraction shafts. In addition to the Central Basin in Johannesburg's city centre, pumping plants for the Eastern Basin and the Western Basin are currently in progress. The long term measurement is to force the water level in the flooded mines back from its current level of approx. 200 metres to a depth of 1000 metres and to keep it there, to then be able to begin mining gold and gold ore in the drained upper layers of the mines once again.

ABSTRACT

The Pumpkin Hollow Project proposes to mine high-grade, Iron Oxide Copper Gold (IOCG) deposits within a porphyry copper and skarn district in the State of Nevada, United Sates. It is estimated that the district-wide mineral inventory is over 24 billion pounds of copper. As part of the Phase I underground mine, a 655 meter deep exploration shaft is being advanced to exploit a proven and probable reserve of 27.6 million tons of 1.5% copper with associated gold and silver. Existing hydrogeologic data suggested that substantial groundwater inflow would not occur until intersecting a low-angle fault at a depth of approximately 430 meters below ground surface known as the Flat Fault. A dewatering well and observation wells were initiated when water inflows were greater than the shaft excavator's grout program could mitigate. A 457 meter deep dewatering well (DW-1) and three multilevel vibrating wire piezometers (VWPs) were installed near the shaft as part of a staged approach to dewatering. Monitoring data from the first 40-days of DW-1 operation, in combination with the VWP and shaft inflow data, were used to calibrate a mine scale groundwater flow model. The model was used to locate a second dewatering well that was constructed to further minimize inflow and depressurize the Flat Fault during shaft construction. Subsequent testing and analysis of this second dewatering well (DW-2), additional packer testing and geophysical logging resulted in a significantly different hydrogeological conceptual model in the shaft area and as a result, different groundwater flow model results. The project highlights the utility of a well-designed, site specific hydrogeologic characterization program for major mine development.

Keywords: groundwater, dewatering

INTRODUCTION

The Pumpkin Hollow property is located 8 miles southeast of Yerington, Nevada. Four of the five known copper deposits on the project are currently in pre-development with drilling and engineering studies being conducted by Nevada Copper Corporation and an exploration shaft has been advanced in the East deposit (Figure 1). The Pumpkin Hollow Project is in the Basin and Range Province of western Nevada, just east of the Sierra Nevada. The site lies in eastern Mason Valley, bounded on the west by the Singatse Range and on the east by the Wassuk Range. The climate is arid, with hot summers, relatively mild winters, and mean annual precipitation ranging from approximately 101 millimeters at the lowest elevations to 406 mm at the highest.

Extensive hydrogeological studies were completed on the property and the immediate area of the proposed shaft was considered adequately characterized. In November 2013, significant groundwater inflows were encountered as the shaft excavation advanced beyond the static groundwater elevation in an andesite sill unit. Prior hydrogeologic characterization suggested that groundwater inflow through low permeability Tertiary volcanic rocks would be minimal until a low-angle normal fault (the Flat Fault) was encountered at approximately 430 meters (m) below ground surface (bgs). In order to mitigate groundwater inflow into the shaft a grouting program, a hydrogeologic characterization program and initial dewatering works were initiated.

This paper details the enhanced hydrogeologic understanding gained during dewatering and hydrogeologic studies to decrease inflow into the shaft and depressurize the Flat Fault. Additional characterization of the surrounding bedrock improved the ability to predict groundwater inflow into the Phase I underground mine and design appropriate dewatering infrastructure. This project demonstrates the necessity to elucidate hydrogeologic complexities in mine areas to effectively predict inflows and design appropriate dewatering and depressurization programs and explores variability in the effectiveness of two grouting programs.

Geologic Setting

At the project site, a thin veneer (0 to locally 150 feet) of Quaternary unconsolidated sand and gravel (Qal) covers most of the surface. Bedrock is exposed in the periphery of the site primarily as Tertiary volcanic rocks (tuffs) and underlying Mesozoic formations. The Mesozoic section is comprised of carbonaceous calcareous argillites, tuff, and limestone intruded by granitic dikes and sills. These rocks transition locally into skarn, marble, and hornfels with associated copper and iron mineralization forming the five separate but associated deposits; the North, South, Southeast, East, and E2. The deposits are blind with no outcrop and were discovered by aeromagnetic methods and subsequent drill delineation. A geologic model was developed from drill data without the advantage of projected surface geology.

A series of low-angle normal faults separate the Tertiary from Mesozoic rocks (Figure 2) and are zones of 15 to 50 m of enhanced fracturing, breccia development, and variable clay gouge. A pair of generally NNW-SSE trending normal faults bound a graben that down-drops the Tertiary and Mesozoic sections through the middle of the site.

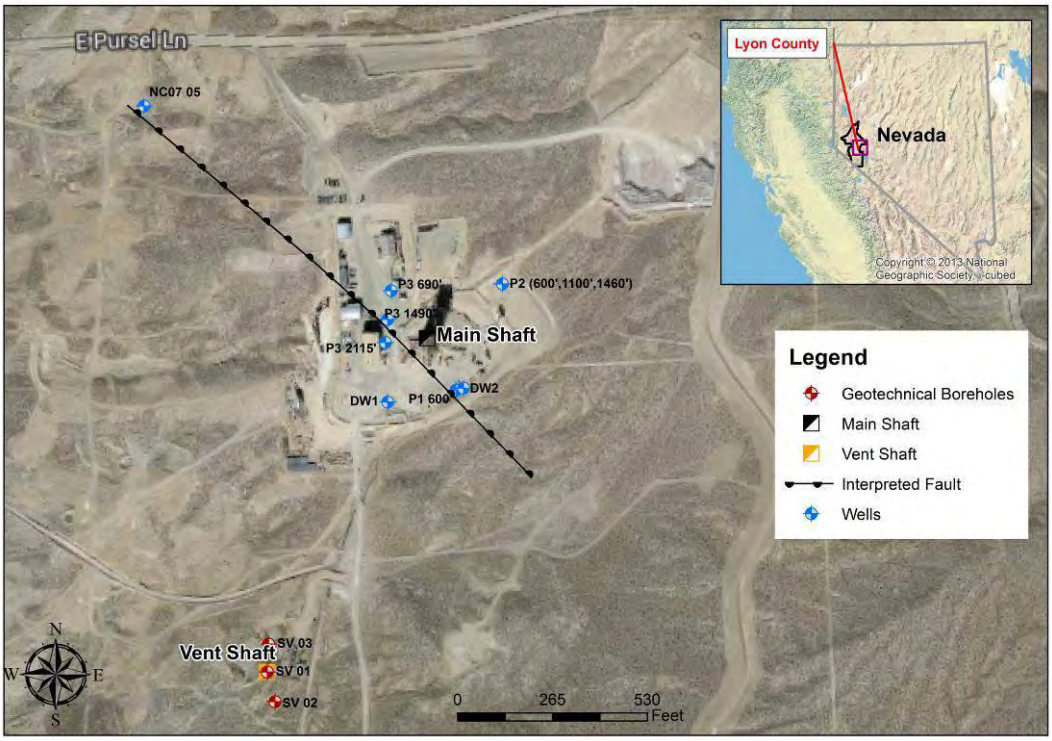

Figure 1 Project Location and Shaft Area Features

Mine Area Hydrogeology

An extensive hydrogeological characterization program was completed for the proposed mine including reviewing core data, testing of 34 boreholes to determine geothermal gradients, installation of monitoring wells and vibrating wire piezometers, packer testing in 3 boreholes, 5 injection tests, 3 slug tests and 2 air-lift drawdown and recovery tests and aquifer pumping tests on 2 wells. Groundwater occurs within the bedrock at a depth of approximately 100 m to 135 m bgs and flows toward the north and northwest, paralleling the flow of the Walker River valley. The bedrock is of generally low hydraulic conductivity except where fracture networks create secondary permeability and transmit groundwater.

Mean mine area estimates of bulk hydraulic conductivity for the Tertiary and Mesozoic bedrock are 1×10^{-2} m/d and 1×10^{-1} m/d, respectively. Tetra Tech (2012) reported that the Flat Fault had elevated hydraulic conductivity relative to the Tertiary and Mesozoic rocks with a mean of 4×10^{-1} m/d.

Calculations using the Maxey-Eakin method to estimate precipitation-derived recharge, based on precipitation estimates made by the USGS Precipitation Zone Method, indicate recharge is zero in the mine area (Tetra Tech, 2012). Stable isotope and 14C data suggest the last recharge to the Flat Fault occurred more than 30,000 years ago. Given the limited recharge potential, identifying lateral connectivity of the Flat Fault and other permeable horizons are considered critical to predicting groundwater inflow and related pore pressure responses in the bedrock. At property wide scales Tetra Tech (2012) used aquifer testing responses and geologic data to conclude that most faults are hydrologic boundaries interpreted to impede groundwater flow across the fault plane and thereby tend to act to compartmentalize the flow system.

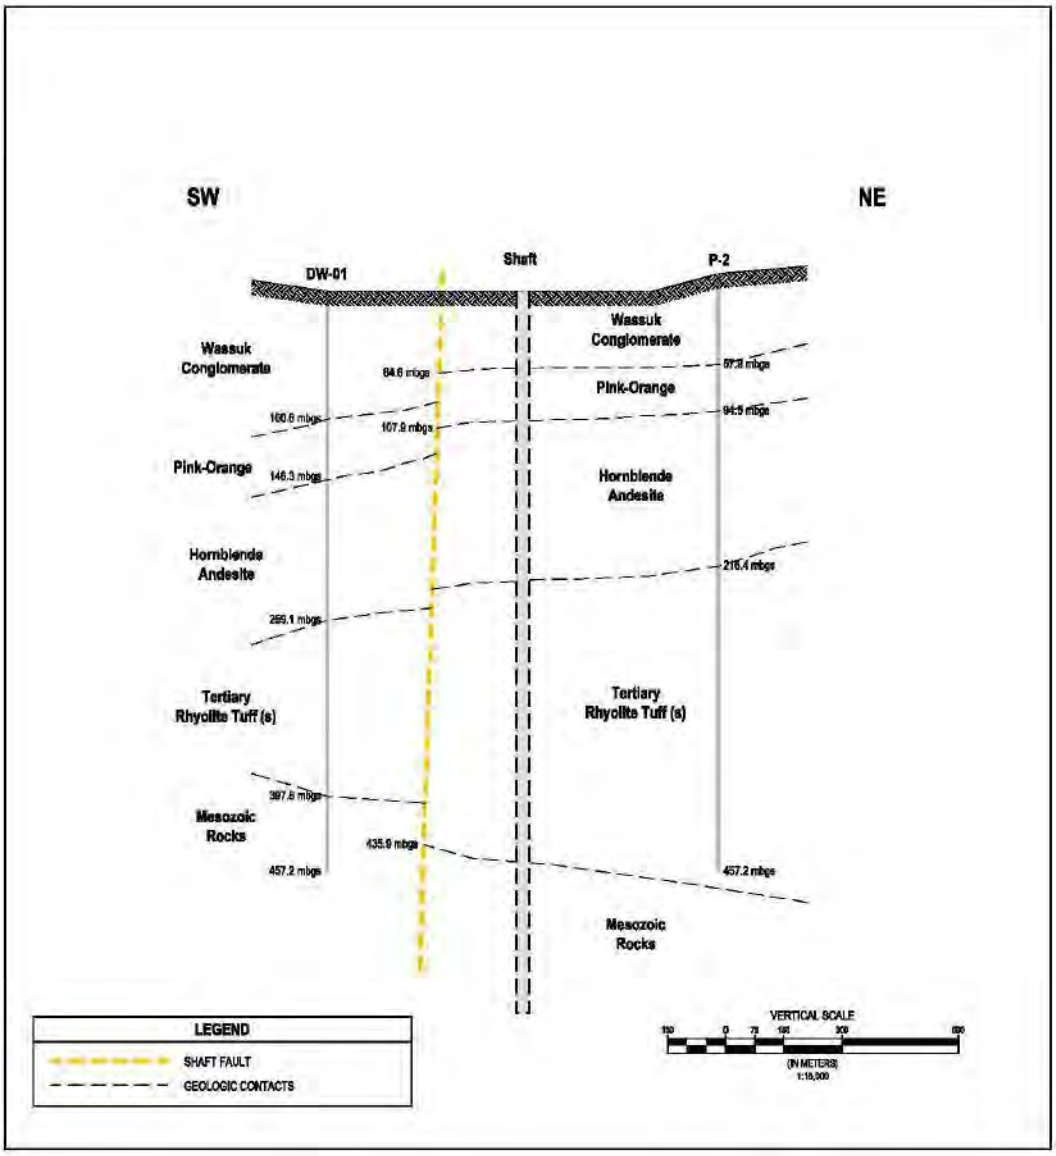

Figure 2 Geologic cross-section in the vicinity of the shaft

SHAFT DEWATERING STUDIES

Beginning in November 2013, the shaft excavation advanced into an andesite sill and below static groundwater elevation where inflow became significant. A grouting program was implemented to mitigate inflow and was only partially effective, groundwater continued to enter the shaft through bolt holes that penetrated the grout envelope and intersected fractures in the andesite. An initial dewatering well (DW-1, Figure 1) was advanced to a depth of 457 m with screen from 256 m to 457 m bgs. Three sets of nested vibrating wire piezometers were also installed at that time (Figure 1). An aquifer pumping test was performed on DW-1 at a rate of 28.4 liters per second (lps), the maximum achievable rate with the installed rental pump. The achieved drawdown in the pumping well was 76 m and 6 m was observed in VWP-01S at a distance of 130 m. The hydraulic

conductivity (*K*) was determined to be between 0.6 and 3.3 m/day, more permeable than mean site values. The storativity was estimated to be 1.2-percent. The time-drawdown data was indicative of a modest negative boundary condition, attributed to the perceived displacement of the Flat Fault between DW-1 and the shaft, P-2 and P3 piezometers by the Shaft Fault (Figure 2 and Figure 3). The test responses varied significantly with depth, with the greatest response in P3 445 m piezometer in the Flat Fault, suggesting the Flat Fault was yielding the most of the water to the well.

Significant available drawdown remained during the DW-1 pumping test (approximately 215 m). However, step-testing in April 2014 indicated that higher rates could not be sustained. As a result, initial DW-1 operations began pumping rates between 25.2 lps and 27.4 lps. Since that time, the operational pumping rate of DW-1 has steadily declined, likely the result of compartmentalization of the Flat Fault (Figure 4). Shaft inflow rates have also steadily declined as the andesite has dewatered, the shaft has advanced beyond the andesite, a new substantially more effective grouting program was implemented in late January 2014 and DW-1 began operating (Figure 4).

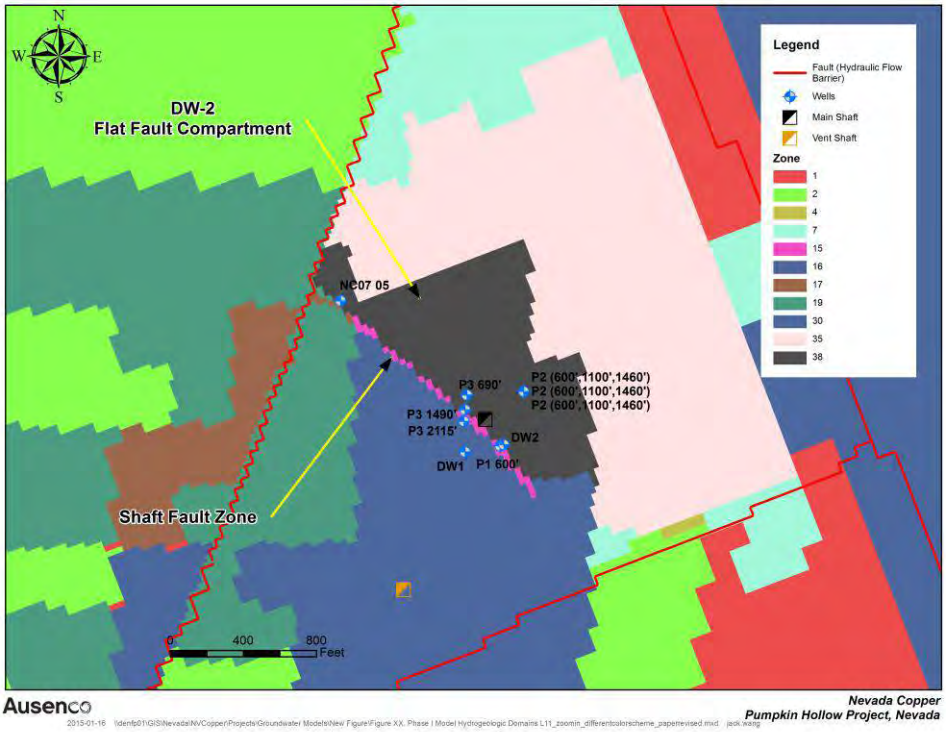

Figure 3 Geometry of the Flat Fault and Shaft Fault

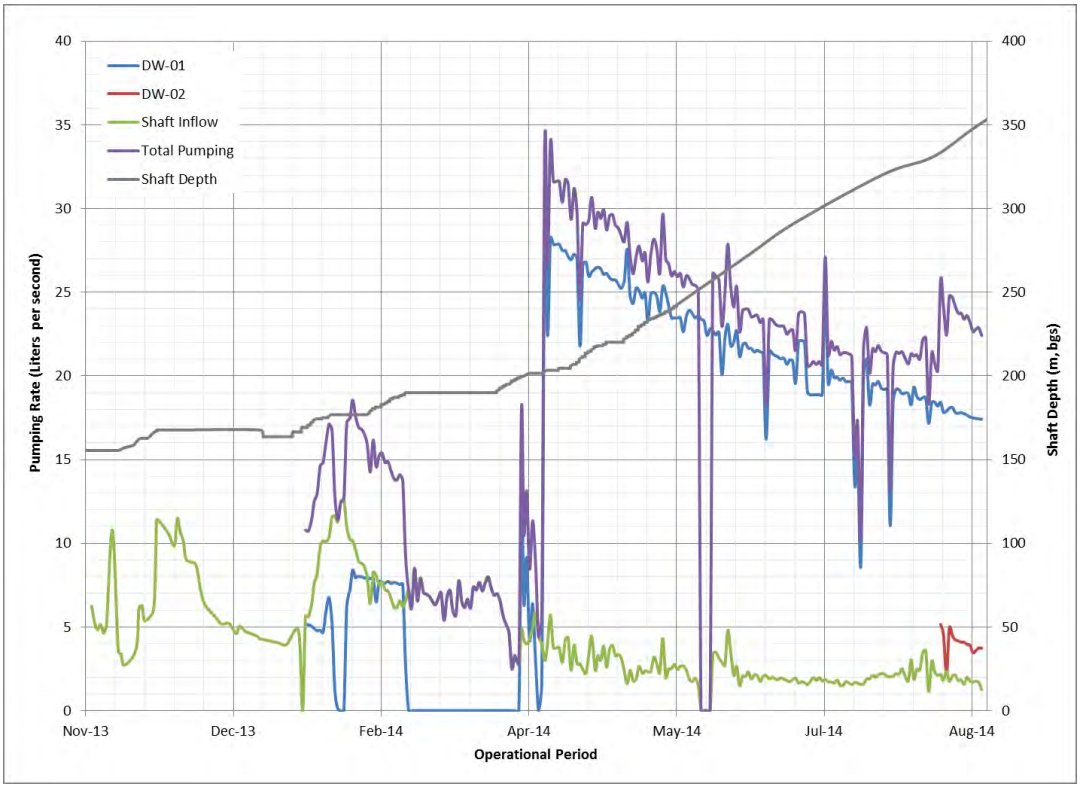

Figure 4 Operational Pumping Rates

A packer testing program and heat pulse flow meter testing were completed in geotechnical coreholes near a proposed vent shaft (Figure 1) to test the permeability of the deeper Mesozoic bedrock. Packer testing resulted in moderate *K* estimates for Mesozoic bedrock, between 2.0 x 10^{-4} m/day (746 - 759 ft bgs) and 4.9 x 10^{-1} m/day (609 – 624 m bgs) and heat pulse flow meter results yielded between 8.5 x10^{-3} m/day and 2.2 x10^{-1} m/day.

To further minimize groundwater inflow into the shaft, reduce pressure heads and reduce the need for costly grouting operations an additional dewatering well (DW-2; Figure 1) was installed upgradient of the shaft. DW-2 was completed to a depth of 632 m with screen between 198 m and 223 m bgs and 382 m bgs and 632 m bgs. DW-2 was commissioned August 16, 2014 pumping between 3.8 lps and 6.3 lps, much lower rates than what DW-1 (approximately 18 lps versus 4 lps) and numerical modeling suggested for DW-02.

Figure 5 presents the water level responses in vibrating wire piezometers at P3, including one in the Flat Fault (P3M 454 m), from the pumping of DW-1 and DW-2. Responses indicate the pumping of DW-1 in April impacted water levels in both the andesite and Flat Fault. It can also be seen that water levels within the Flat Fault were very sensitive to development and pumping at DW-2, despite the much lower pumping rate relative to DW-1. This is attributed to unforeseen geologic complexities, including compartmentalization of the Flat Fault by the Shaft Fault, the amount of clay gouge within the fault breccia and the discrete nature of the water bearing fractures in the Mesozoic rock beneath the fault gouge. These complexities result in a hydrogeological conceptual model (HCM) for the "DW-2 compartment" of the Flat Fault (Figure 3) that is significantly different than elsewhere on the property.

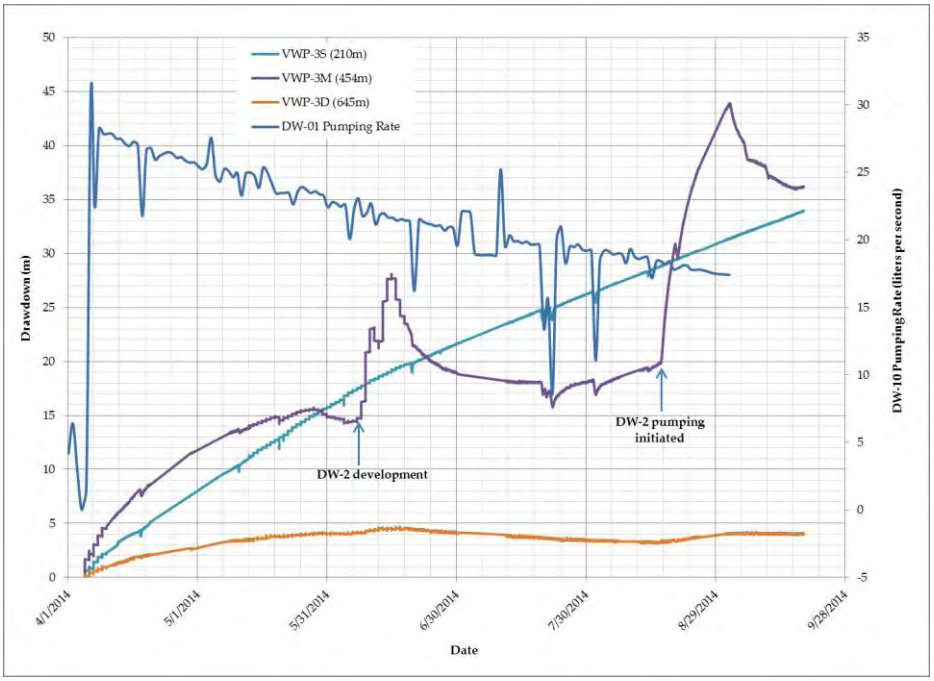

Figure 5 Measured drawdown and DW-1 pumping rates

Despite the lower pumping rate, considerable drawdowns occurred in the Flat Fault, Tertiary and Mesozoic bedrock. Accordingly, the seeps in the shaft walls dried up and inflows in the shaft appeared to decrease. Water levels within the Tertiary rhyolite tuff have also been significantly affected by pumping, with water levels in P2 (VWP at 335 m bgs) dropping by more than 90 m, since DW-2 began pumping.

GROUNDWATER FLOW MODELING

The objectives of the groundwater flow modeling were to develop a working tool to assist in improving our understanding of the hydrogeology in the area of the shaft and proposed East underground mine in order to predict the magnitude of groundwater inflow during shaft sinking, evaluate the effectiveness of the initial grouting program, evaluate pore pressures near the shaft and siting of dewatering wells and ultimately predict the groundwater inflow to the proposed East underground mine. An initial mine scale groundwater flow model (Hydro-Logic, 2014) was developed and calibrated using the 40-day DW-1 pumping test (initial model) and a second updated version of the model was calibrated using both the DW-1 (178 days) and DW-2 (15 days) transient calibration data sets and the updated hydrogeologic framework model (updated model) by Ausenco (2014). Both models also used the available shaft inflow data as part of the transient calibration. As a result of space limitations, some details of the models are not discussed here, instead the focus is on how incorporating the geometry and compartmentalization of the Flat Fault affected shaft inflow predictions and estimates of groundwater inflow.

Model Domain, Grid and Boundary Conditions

The Shaft Model domain (Figure 6) was extracted from the Regional Model (Tetra Tech, 2013) with the primary objective of having sufficient size to minimize boundary effects but also have an

appropriately small size to allow for refinement in the area of interest near the shaft (7.5 m^2 cells). The grid was rotated to be consistent with the direction of groundwater flow in the area (Figure 6) and to align the axis with the primary fracture network orientation. General Head Boundary (GHB) conditions were developed for the Shaft Model based on the heads from the steady-state Regional Model results. Faults are generally interpreted to be hydraulic barriers and included using the hydraulic flow barriers (HFB), based on updated structural modeling in the project area. The model utilized Groundwater Vistas Version 6 (Environmental Simulations Inc., 2011) as a pre- and post-processor and groundwater flow was simulated using MODFLOW-USG (USGS, 2013).

In addition to incorporating well pumping rates and piezometer water level responses, transient calibrations included calibrating the conductance of HFB and the drain cells used to simulate faults and grouted sections of the shaft. The simulated shaft inflows (Figure 6) during the 40-day calibration period of DW-1 testing are on the order of 3.8 lps and are relatively consistent over the 40-day calibration period (Figure 4).

The calibrated *K* values for grouted shaft cells indicate that grouting activities through January 2014, were minimally effective as evidenced by high calibrated effective *K* (0.12 m/d). This is a reasonable assertion because the preferred pathway of water through the grout was through bolt holes and not through the grout matrix or remaining ungrouted fractures. Inflow data suggest that revised grouting methods have been significantly more effective with a calibrated effective *K* of 0.02 m/d or between level 2 and level 3 grouting as defined by Wilson and Dreese (2003).

A predictive version of each model was developed to simulate the dewatering of the shaft from the end of the respective calibration period May 5, 2014 (initial model) or September 30, 2014 (updated model) to the terminal depth of the shaft, 590 m bgs and 660 mbgs, for the two models respectively. The assumed *K* values for grouted sections of the shaft also evolved between model versions as a result of changes to the HCM and hydraulic properties. Principal differences include achieving level 3 ($K = 8 \times 10^{-3}$ m/d) grouting the Flat Fault in the updated model (versus level 2 or $K = 8 \times 10^{-2}$ m/d in the initial model) based on lower pressure and permeability expectations within the "DW-2 compartment". The assumed dewatering well pumping rates for the predictive model differ as well evolving from 18.9 lps for both DW-1 and DW-2 in the initial Mine Model to 17.3 lps and 3.1 lps in the updated Mine Model.

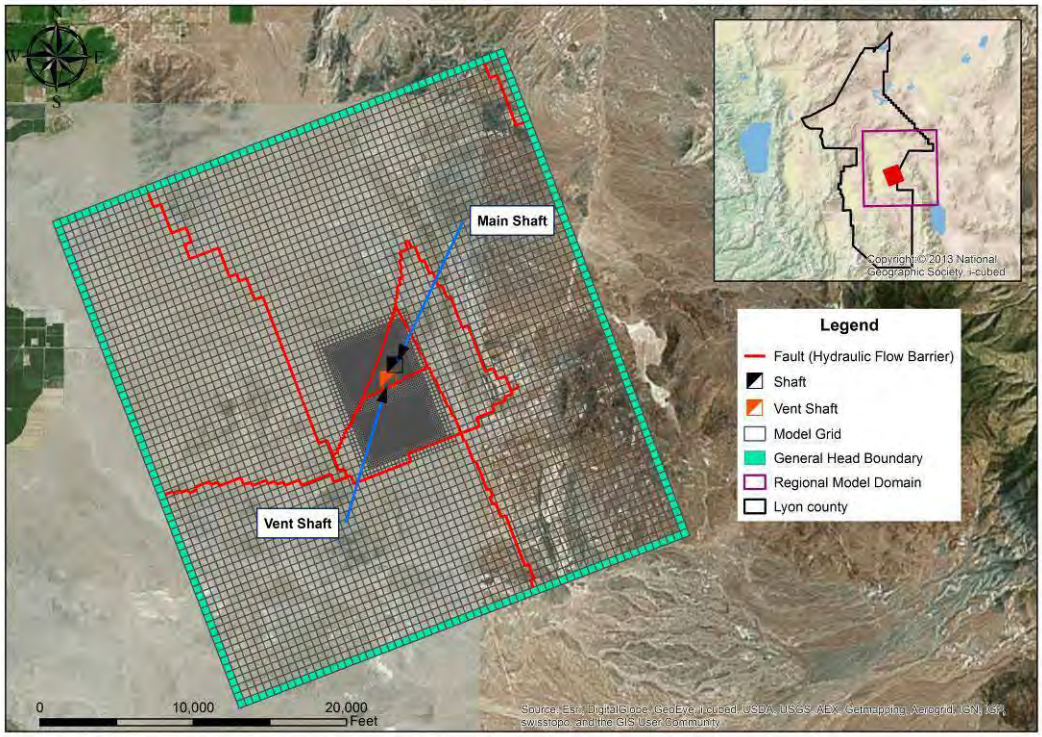

Figure 6 Shaft Model Grid, Boundary Conditions, Steady-State Groundwater Elevations

The calibrated *K* and storage parameters of the updated model were generally lower than in the initial model for both the Flat Fault and the Mesozoic bedrock. The calibrated Flat Fault response for the newly developed "DW-2 compartment" for the Flat Fault calibrated to a low specific storage, indicative of a discrete rock fracture response. Such values were required to mimic the hydraulic response at P3M to DW-2 pumping (Figure 5). This is consistent with an updated conceptual model of the Flat Fault in the "DW-2 compartment ", which suggests a discrete fracture confined by fault gouge, is able to rapidly transmit changes in pressure but dewaters rapidly due to limited transmissivity and storativity and the effects of compartmentalization. The expectation is that shaft probe holes may encounter high pressures but that the inflows in this zone will be short-lived.

Model Results

The model results were post-processed and examined as they related to the stated modeling objectives. Both models suggest that initial grouting performed in the shaft (up to February 2014) was relatively ineffective as the calibrated andesite *K* values (K_h = 0.6 m/d) are not reflective of overly permeable bedrock or values outside what would have been for such a rock type. Predicted inflows into the shaft have decreased in the updated model relative to the initial model (Figure 7), as the localized characterization (e.g. extent of clay gouge, lower *K* and storativity) and compartmentalized geometry of the Flat Fault have modified localized interpretations and calibrated hydraulic property values. Predicted mine inflow inflow through the Mesozoic rocks is lower than the initial model, as are the calibrated hydraulic properties. Available data suggest that, at most, periodic grouting will be required in higher yielding fracture zones of the Mesozoic bedrock.

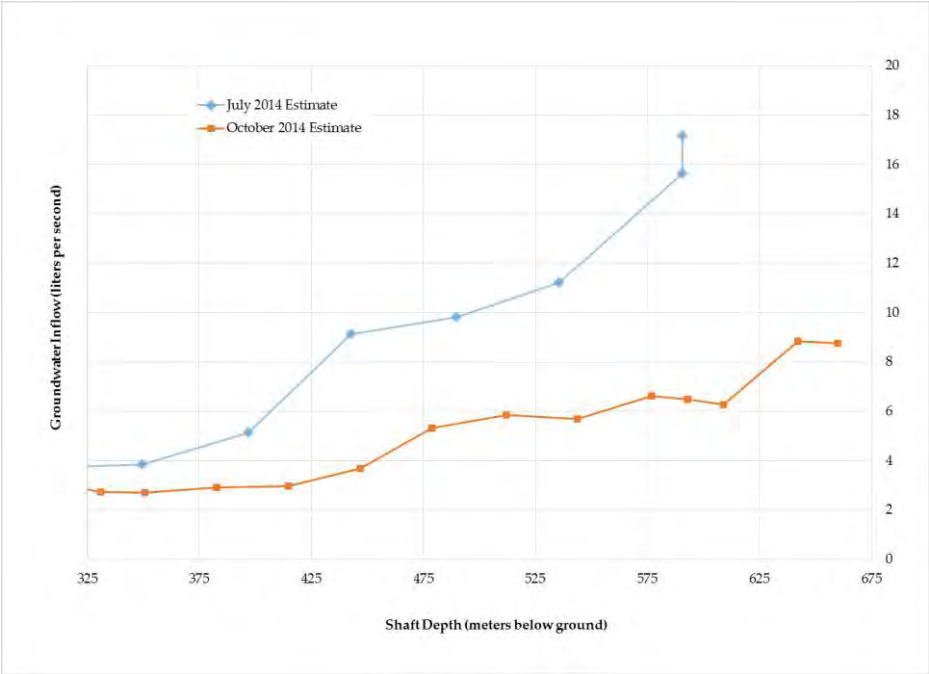

Figure 7 Predicted Inflow to the Shaft during Construction

The updated Mine Model was also used to predict groundwater inflow into the Phase I underground mine (first two years of mining). The base case estimated average monthly mine inflows for the first sixteen months are predicted to be 80 lps and for the last 12 months of operations the predicted monthly average is 120 lps. The Phase I mine simulation assumes that limited grouting will be completed and the groundwater inflow is governed by the native permeability of the surrounding bedrock.

CONCLUSIONS

The flow model results indicate that the calibrated *K* andesite sill (K_h=0.3 m/d) is greater than the range of values tested for Teritary Volcanic bedrock (2.0×10^{-4} m/d to 1.2×10^{-1} m/d) on the rest of the property, more than order of magnitude greater than the mean value (1.0×10^{-2} m/d) and two orders of magnitude greater than the median value of 1.8×10^{-3} m/d. This highlights the importance of not lumping hydraulic test results and HCMs in broad categories such as a 700 ft sequence of Tertiary volcanic rocks. The andesite sill in question was not being differentiated in the geologic model developed for quantifying ore reserves that was ultimately applied in geotechnical and hydrogeological assessments.

The inflow during shaft construction through the andesite was exacerbated by an initially ineffective grouting program. This assertion is supported by the decreasing shaft inflows and lower calibrated K values of the drains used to simulate grouted sections of the shaft. The revelation the DW-2 compartment of the Flat Fault and its differing hydraulic properties has led to a significantly different HCM than originally conceived. The depressurization of the DW-2 block of the Flat Fault

is expected to result in lower groundwater inflows and pore pressures during shaft construction. As a result grouting will be less frequently required during shaft advancement.

These findings highlight the need for having a well-designed, site specific hydrogeologic characterization program in place prior to shaft sinking or other major development. However, on sites such as Pumpkin Hollow, where groundwater is compartmentalized and the hydrogeologic characteristics of the water bearing units are highly variable, changes in inflow can occur rapidly and shaft sinkers should be prepared to meet such challenges. As the project moves towards the underground mine development, the hydrogeology-geology team will work to improve our understanding of the compartmentalization at depth and the hydraulic properties of the Mesozoic bedrock and identify any potential zones of concern.

ACKNOWLEDGEMENTS

The authors thank Nevada Copper for allowing for the insights gained as part of this project to be to be shared with mine water community.

Comparison of Borehole Testing Techniques and Their Suitability in the Hydrogeological Investigation of Mine Sites

Michael Palmer and Houcyne El-Idrysy
SRK Consulting, United Kingdom

ABSTRACT

Analytical and numerical groundwater flow models are usually used to estimate groundwater inflows into mines and assess the need for dewatering and/or depressurisation of the rock formations around the mine. These models require various input parameters that have a defining control on the model results and the subsequent design of dewatering and/depressurisation systems. Therefore to increase confidence in model predictions and the efficiency of the mine water management design, it is essential to achieve accurate estimation of the hydraulic parameters.

Hydraulic parameters of geological formations are usually estimated from data obtained from borehole testing. There are five main hydraulic testing techniques commonly used in the hydrogeological investigation of mine sites: (1) Slug tests, (2) Airlift tests, (3) Flow logging (also called spinner tests), (4) Packer tests, and (5) Pumping tests.

In this paper the degree of suitability of the above borehole testing techniques is investigated, taking into consideration the data collection objectives, the expected water management challenges, and project stage. The paper also highlights the advantages and disadvantages of each of these tests, and compares ballpark cost and logistic requirements.

Keywords: Hydrogeology, borehole, hydraulic testing, techniques, mining.

INTRODUCTION

The type of hydraulic testing carried out in mine sites depends on the hydrogeological setting and geotechnical characteristics of the rock formations, and the mine project stage. At an earlier stage of a mine project (often called Scoping Study or Preliminary Economic Assessment), limited hydrogeological data collected from exploration boreholes or from an existing mine can provide enough information for the hydrogeological assessment of the project. However, as the project progresses toward advanced level (Preliminary Feasibility Study, Feasibility Study and Detailed Design Study) site specific data collected from specialist hydrogeological boreholes are necessary. This is particularly more relevant if the results of the initial study suggest significant challenges in the mine groundwater management. The degree of challenge and complexity of the water management aspect of a mine project usually depends on the project location and the hydrogeological and geotechnical setting of the mine, which may entail the followings:

- The proximity of the mine to surface and groundwater reservoirs and the hydraulic properties of the geological formations around the mine will have a significant control on the amount of groundwater inflows into the mine and dewatering requirements;
- The geotechnical and hydraulic parameters of non-aquifer saturated formations around the mine may have direct implication on mine stability and depressurization requirement;
- In cases where groundwater is the only potential water supply source for the project, investigations and borehole testing, possibly for a longer period of time, are required.

To assess the water management risk and challenges that a mine project may face, the hydraulic properties of the geological formations around the mine should be sufficiently investigated. This is usually achieved with the use of well positioned boreholes and testing techniques appropriate for obtaining the vertical and lateral variations of the parameters. The hydraulic parameters often obtained from borehole testing are: hydraulic conductivity (K), transmissivity (T), storativity and specific yield (S and Sy), conductance (C) and leakage coefficient, hydraulic boundaries, and anisotropy of aquifer response.

In this paper we compare five different types of borehole testing, namely: slug tests, airlift tests, flow logging, packer tests; and pumping tests. Other types of test, such as tracer test, exist but these are not widely used in the industry and usually carried out for specific purposes such as the delineation of contaminants and estimation of travel time. Laboratory testing of drill cores and grain size distribution of bulk samples are also sometimes used to estimate hydraulic conductivity when field tests are not possible. Therefore these are not considered in this paper.

Hydraulic test techniques are sometimes combined in one form or another depending on site characteristics and available equipment. For example packer tests can be combined with falling or rising head tests in a way that the target test zone is isolated with the packer and the borehole standpipe is either filled with water or pumped, and water level in the borehole measured subsequently for a certain time to obtain a drawdown-time curve that can be used to estimate the hydraulic parameters of the test zone. Water level in the borehole standpipe can also be kept constant in such configuration and the injection flow measured over time.

DISCUSSION

Slug tests

A slug test consists of displacing a known column of water instantly in a borehole and monitoring the subsequent water level recovery to the initial static state. Since water level recovery can be very fast in permeable formations, the use of a pressure transducer (or water level logger), is more suitable to achieve accurate and frequent measurements of water-level.

An appropriately sized slug should be selected that can produce enough displacement to provide a measureable change in water level. A water level change of 1 to 2m is adequate (Cunningham & Schalk, 2011). In high permeability formations a larger displacement is desirable due to the rapid recovery of water level towards equilibrium conditions.

In open coreholes falling head tests are not suitable because of interference with the unsaturated zone, contrary to rising head tests that can provide reliable results in such case.

Airlift Tests

Airlift testing can be conducted in exploration holes in order to provide an early estimate of permeability. Airlift tests can easily be implemented as part of early resource drilling programmes and are useful for projects where expensive hydrogeology programmes cannot be justified.

The most effective method for completing an airlift test in the early stage of a project is through the use of a drill rig that is equipped with a compressor (usually reverse circulation [RC] or rotary air blast [RAB]). In airlift tests using a drill rig, the drill bit can be removed and a bespoke airlift attachment threaded to the end of the rods. Subsequently air is injected down the drill rods into the hole and the air bubbles rise in the column of water, entraining and lifting water up the rods and out of the discharge hose (Howell, 2012). Careful consideration must be given to compressor capacity and dynamic submergence of the airline. The attachment diverts injected air and incorporates a chamber for a data logger at the base. The water level logger allows accurate measurements of drawdown and the recovery of water level during the test. More dedicated airlift testing outside a drilling programme involves the use of a drop pipe and air injection pipe, a compressor, and water discharge hose. The air flow is usually directed upward and the drop pipe ensures that water is flushed out of the hole with a smooth variation of water level and pressure, which can be measured using water level logger installed outside the drop pipe.

Airlift testing may also be conducted during drilling at pre-determined intervals in order to assess cumulative vertical permeability variations. If there are open holes located nearby then it is possible to monitor water level in these as in observation wells for a conventional pumping test (Beale & Read, 2013).

Spinner tests

Spinner flow logging is a well-documented technique used to determine vertical variation in hydraulic properties of geological formations (Molz et al 1989, Hill 1990, Paillet 1998). A rotating impellor is lowered at a constant low speed down the hole using a geophysical logging winch from which the impeller rotational velocity is measured and converted into a vertical flow profile. The analysis of spinner test data should preferably be completed in combination with caliper logging data (borehole diameter), acoustic televiewer (ATV) survey, and/or geotechnical core logging in order to improve the level of structurally-related interpretation (Pedder & El Idrysy, 2013).

The success of spinner testing is highly dependent on the condition of the hole that is being tested. Newly drilled diamond holes are suitable and commonly used for spinner testing since geotechnical core logging and ATV survey results, if available, yield useful validation data. However, it is imperative that the borehole design and drilling practices and procedures during planning stages take into account the subsequent use of the hole for flowmeter logging. This includes pre-collaring of any unstable overburden, drilling mud management and borehole cleaning/development techniques.

Flowmeter logging can either be conducted under ambient condition (i.e. water level is static; without pumping), or with a simultaneous pumping at a constant debit. The former is referred to in this paper as a static spinner test, and the later as a dynamic spinner test.

Typically, if vertical differences in hydraulic head exist between the geological formations in a borehole, groundwater inflow into the hole will not be uniform under ambient conditions and the flow will preferentially enter at permeable horizons (West & Odling, 2007). Ambient flow can be measured using static spinner tests. Non-detectable ambient flow during the test would suggest uniform hydraulic head or negligible hydraulic gradient. Detectable ambient flow would suggest vertical head differences.

Pumping of the borehole is necessary in order to sufficiently reduce the hydraulic head and induce flow from all permeable horizons. Assuming that the well is pumped with reasonable drawdown, the resulting hydraulic gradients should promote flow from all permeable horizons, with differing contributions based on permeability (Lloyd & Jeffery, 1983). This is an important consideration to ensure that the test result is representative of all permeable horizons. An open borehole with vertical head differences will exhibit a composite groundwater level and the level of drawdown during pumped spinner testing becomes of greater importance in order to draw water from all permeable horizons. The depth of the pump intake should not have a controlling effect on borehole inflows, providing that drawdown is sufficient. Instead of pumping, water injection (constant head/debit) can be used in some circumstances but the application of this method has more disadvantages and limitations.

Since pumping of an open borehole will initially draw water from borehole storage, it is important to achieve an appropriate flow regime prior to running the spinner test. Various authors (West & Odling, 2007; Paillet, 1998; and Molz et al, 1989) have cited that pumping should achieve a pseudo-steady state. This is achieved when all boundaries have been reached and pressure drop becomes proportional to time (Lu & Tiab, 2010, Bourdet, 2002 and Kruseman & De Ridder, 1994). Pseudo-steady state may take a long time to reach, particularly in unconfined aquifers and where multiple boundaries exist. This may be uneconomical when conducting spinner testing in line with other programmes (such as geotechnical drilling).

The outcome of dynamic spinner tests is a vertical profile showing cumulative reductions in inflow contribution. The relative reductions can be proportioned and analysed using established methods to calculate discrete fracture permeability. In numerical groundwater models for mine projects, fractured layers are often represented as “Equivalent Porous Mediums”. Consequently the availability of individual fracture estimates are of limited use. Instead, the test results will feed into a conceptual hydrogeological model to define the numerical model geometry and set-up. Also equivalent hydraulic conductivity for each model layer can be derived by incorporating fractured and non-fractured horizons into the analysis of spinner test results.

Packer Tests

Packer testing involves the use of an inflatable rubber packer to isolate an interval of a borehole for hydraulic testing. To conduct such a test, the packer is lowered down the hole and inflated using water (or compressible gas) that is injected and controlled from the ground surface. The packer tool channels the pumped water flow through a central pipe (the mandrel), which is blocked at one end by a blow-out plug, retained by a shear pin. When inflation pressure exceeds the shear pin rating, the blow out plug is ejected and the flow is directed into the test zone (rock formation), thus shutting down water flow into the packer element. Water is subsequently either injected or withdrawn from the test interval while flow rates and pressures are recorded. Once the injection/withdrawal of water and monitoring is complete the packer is deflated and removed. This process is repeated until the entire borehole is tested in a series of discrete or cumulative tests.

Packer tests can make use of either single or double (straddle) packers. The packer element can be inflated using either water or compressible gas. The former presents the advantage of being capable of testing borehole of much greater depths, and the approach is considered safer. In this paper the discussion relates mainly to water-inflated packer, specifically the Standard Wireline Packer System (SWiPS ®) manufactured by Inflatable Packers International.

Packer tests can be carried out during borehole drilling, whereby once drilling reaches the desired test depth, the drill string is pulled out to a certain level where the packer element needs to be set for the test. Once the test is completed drilling continues until it reaches the next packer designed depth. The next test is normally carried out covering the interval from the depth of the previous test to the current one. The advantage of such techniques is that it provides more accurate data compared to cumulative testing or straddle packer tests because it involves less risk of leakage, and all intervals are tested separately without the risk of masking that may happen if the hydraulic conductivity of the tested formations is low and anisotropic. The disadvantage of this, however, is that it causes delay of the drilling operation and additional cost, which may not be acceptable in some resource drilling programmes.

The alternative to testing while drilling is to test the borehole once the drilling is completed. This type of test requires either the use of double packers to isolate the test intervals or alternatively cumulative testing of the entire depth of the hole. The former presents the advantage of isolating and testing shorter intervals, however this may be time consuming and presents higher risk of leakage from around the double packer seals which translates into errors in the test results. Errors in packer test results related to leakage are especially more significant if the hydraulic conductivity of the tested formations is very low. Another risk involved in the use of double packer is the loss of the equipment due to borehole collapse because the length of the double packer configuration is very long, far beyond the protection of the drill string.

When packer testing is carried out using injection under several pressure steps, the procedure is called Lugeon test (Lugeon, 1933). The pressures used during an injection or Lugeon test must be high enough to force flow into the formation, but low enough to avoid artificially increasing the formation permeability. Lugeon test is the most widely used approach to packer testing, compared to water withdrawal or falling head tests. Lugeon tests have the advantage of being fast; 3-step pressure tests are usually carried out quickly compared to groundwater level recovery time if a withdrawal or falling head test is used. Attention should however be paid to pressure level and rock condition to avoid artificial fracturing, especially in shallow formations.

Pumping Tests

Pumping tests are an important and widely used method for characterising bulk-scale groundwater flow behaviour. Pumping tests usually involve the use of a submersible pump to pump water from a large diameter central well while monitoring groundwater level in the pumped well and nearby observation holes. Observation wells can be located up to hundreds of meters from the test well and should either be drilled or sought from existing exploration holes located nearby. Pumping tests are probably the most widely used hydraulic tests used in hydrogeological investigations and are therefore well known to all hydrogeologists. A full description of procedures is beyond the scope of this paper, so the reader is instead pointed towards literature such as Kruseman & De Ridder (1994) and Brassington (2006). The most commonly varieties of pumping tests are the calibration, step-drawdown test and the constant-rate discharge test.

The aim of the calibration test is to assess what the maximum short-term pumping rate might be, and to define the discharge control valve positions for the step test. Once the calibration test is complete and water levels have recovered, a formal step-test can be carried out.

The step-drawdown test is important to determine an appropriate pumping rate for the subsequent constant-rate test. It is equally important in order to account for head losses, the latter consisting of aquifer, linear and non-linear head losses (Rorabaugh, 1953, Jacob, 1947). Linear well losses are the most preventable and can be caused by the development of a well skin. A positive well skin may consist of drilling mud invading the formation that results in a low K skin. Conversely, negative skin can consist of a high K zone around the borehole, essentially caused by inadvertent hydraulic "fracking" due to poor drilling practices. If head losses are not properly accounted for, analysing the pumping test data may result in serious overestimation of S and underestimation of T (Agarwal et al, 1970; Jargon, 1976). The implications for mining projects might mean underestimated mine inflow estimates, which would lead to an under-designed dewatering system. It is therefore essential to design the constant-rate pumping test in conjunction with the step-test analysis. Once head losses have been calculated, the well performance can be expressed as a well efficiency percentage (Kruseman & De Ridder, 1994).

The constant-rate test should be carried out at the maximum sustainable pumping rate defined from the step-test results. The purpose of the constant-rate test is to obtain information on the hydraulic characteristics within the radius of influence of the pumping well (Beale and Read, 2013).

Criteria for Selecting a Hydraulic Technique

A guideline transmissivity range for selecting a hydraulic technique is proposed in Figure 1. These are based on the authors' test results and experience and input from various literature as shown in the list of references. The transmissivity is the criterion used in this paper since this parameter is more directly relatable to the overall capacity of a well, whereas the hydraulic conductivity alone is not enough.

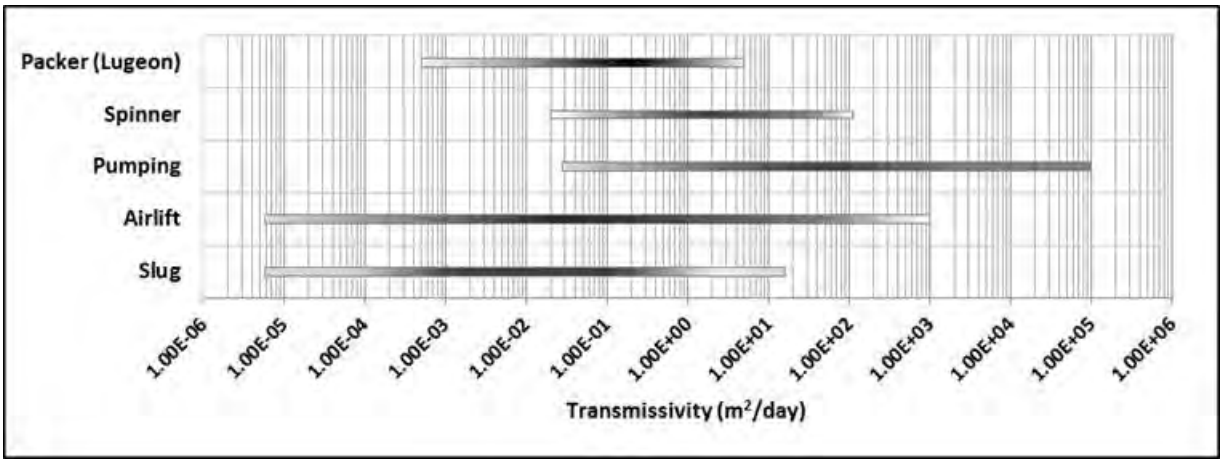

Figure 1: Approximate transmissivity range for the 5 hydraulic testing techniques

Hydrogeological investigations, and especially borehole testing, should be designed taking into consideration two criteria:

- The hydrogeological setting of the project and available logistics and resources;
- The level of confidence required in the mining study (PFS, FS, etc.). Usually each stage of mine development requires a certain level of design and justifies a commensurate investment.

Slug tests can be applied in a wide range of transmissivities, including very low permeability formations. Slug testing is limited to holes that are not highly transmissive due to rapid return of displacement towards original water level. This test becomes more reliable with decreasing permeability, however practical considerations (such as test time, seasonal impacts, etc.) may become relevant where measurement of displacement takes weeks or maybe months.

Airlift can be effective for a wide range of permeability conditions making this a very flexible test. Studies have shown (Howell, 2013) that conventional pumping test analysis of airlift tests that have produced less than approximately 0.1-0.2 L/s may result in unreliable estimation of permeability. Where airlift tests produce such yields they should be stopped early and the recovery data analysed as a rising-head test (e.g. Hvorslev, 1951).

Packer testing is applicable in a smaller range of transmissivity, from low to moderate. Previous packer testing programmes carried out by SRK in HQ boreholes suggest an upper limit of 3 m^2/d of transmissivity for packer testing results to be reliable. The results also suggest that packer testing can detect inflows for a transmissivity as low as 0.0005 m^2/d if the packer seal is placed within a non-fractured fresh rock section of the hole where the packer seal is effective to prevent leakage. It is less reliable at very low permeability because the accuracy of the data can be compromised by minor packer leaks, flow measurement, residual drill muds. The upper-limit is typically constrained by the maximum capacity of the packer equipment (pumps, compressor, etc.) and/or bore diameter.

Spinner tests can however be carried out in slightly larger range spreading especially toward the relatively higher transmissivities. The minimum start-up velocity of the spinner (velocity of water required) will vary depending on manufacturer and should be considered carefully. From the

authors' experience, spinner testing has yielded inconclusive results where the transmissivity of a tested formation is less than approximately 0.02m²/d.

Pumping tests can be used to test highly transmissive mediums, and the upper limit would depend only on the size of the submersible pump available and borehole diameters which is controlled by the available drill rigs capacity.

At the early stages of a mine project, hydrogeological investigations should attempt to utilise boreholes from resources drilling programmes and any existing historical drill holes. Rising head tests in such old boreholes may provide a coarse assessment of the hydraulic conductivity around the boreholes, although the results may be questionable. In newly drilled and cleaned boreholes with appropriate bentonite seal for the test zone, slug tests can provide useful data. Airlift testing may also be implemented very early in a project to test existing drill holes where the range in permeability is poorly understood. As part of exploration programmes, drill rigs often have the capacity to carry out airlift tests.

If it is necessary to characterise fracture flow or vertical variances in primary porosity, spinner tests may be considered. However, spinner tests are often not necessary at the early stages of the project, but rather at PFS or FS levels. Packer tests may be integrated into existing drilling programmes in consolidated and fractured rock. It is also important to consider the condition of the drill hole (packer seating) and experience of the driller.

Pumping tests provide the most reliable estimates of aquifer properties where groundwater management represents a high-risk to the project, and the required accuracy of the hydrogeological investigations has the potential to significantly affect the project engineering feasibility or economics. Given the associated high costs and required amount of resources, the justification for pumping tests should be based on existing data derived from integrated and retrospective programmes. Pumping tests are carried out in most of mining projects at PFS or FS stages, regardless of the level of risk of groundwater management. In fractured rock, when the control of groundwater is required, spinner or packer tests should be specified instead to define the vertical variation of rock mass and assess the dewatering requirement.

Cost and Logistical Comparison

The shipping of testing equipment into a project country requires consideration of cost, customs documentation (both departure and destination country) and insurance. Comparisons of these considerations are shown in Table 1. For simple hydrogeological tests (slug testing) there is no major cost or logistical issues. However, shipping equipment that is made up of numerous components (e.g. spinner, packer and pumping) increases the complexity of the process and can add significant time and cost. Therefore, the requirement for these tests needs to be considered carefully within the context of the investigation objectives in order to provide adequate justification for its use. Alternatively, good quality contractors should first be sought in-country where possible.

Table 1: Estimated Cost and Logistical Comparison of Common Tests

Test Equipment	Equipment Capital Cost (GBP)	Annual Maintenance Cost (GBP)	Shipping Cost (GBP)	Shipping Preparation Time
Slug	50 - 200	n/a	50-150	1 hour

Spinner	10,000 – 15,000	250 – 1,000	1,000 – 4,000	1-3 days
Packer	20,000 – 50,000		1000 – 8,000	
Pumping	8,000 – 20,000		1,000 – 6,000	

Advantages and disadvantages

Table 2: Advantages and disadvantages of various hydrogeological tests

Method	Advantages	Disadvantages
Slug Tests	-Quick and inexpensive. -Good for early-stage projects. -Good where permeability is low to moderate. -Can be used in polluted water wells because abstraction is not necessary -Very simple logistics and low cost -Maybe the only test suitable underneath a flowing-river bed to estimate conductance. -The stability of the borehole is not a problem.	-Less reliable where permeability is very high. -Less reliable than all other tests. -Only tests immediate area around the hole. -Sensitive to near-well conditions (low K skin, gravel pack, etc.) -No storage estimate. -Falling head test is not suitable for testing unconfined aquifers in open hole. The unsaturated zone requires bentonite seal.
Airlift Testing	-Cost-effective, if no significant rig standby time. -Good for early-stage projects and exploration hole testing. -Easily incorporated into existing drill programmes. -Covers wide permeability range. -Can use observation wells to estimate S and increase radius of characterisation.	-Less reliable than other tests. -Not good in polluted water due to abstraction -Becomes time-consuming at very low permeability where rig time is at a premium. -May cause erosion of borehole walls and cavitation in some circumstances. -The debit may not be stable enough to assume steady state condition for data analysis.
Spinner Tests	-Good for hydrogeological characterisation of bedrock fractures. -Provides vertical variation of hydraulic properties and accurate depth of flowing fractures (±10cm). -Can be easily compared with geotechnical, structural and geophysical data. -Static test can reveal natural flow between aquifers due to vertical hydraulic gradient. -Can be completed without a drill rig. -Can be easily combined with other downhole tools such as salinity, temperature or other surveys.	-Requires a clean, open hole at the test interval. -May require significant drawdown if large vertical head differences exist. -Risk of equipment loss due to hole collapse. -Not suitable for very low permeability formations. -Requires specialised equipment that may not exist in all countries. -To quantify the hydraulic conductivity in the tested borehole, spinner test results are not sufficient; a small scale pumping test is required in parallel with the spinner tests.

Method	Advantages	Disadvantages
Packer Tests	-Can easily be incorporated into existing drill programmes. -Can provide hydraulic input parameters readily incorporable into groundwater models. -Provides approximate location of groundwater flow zones, especially in fractured rock formations. -Can be carried out in vertical or inclined boreholes even in angles as low as 50 degree. -The test can be carried out in various small diameter holes (PQ, HQ or even NQ sizes). The packer equipment comes in various sizes to fit into specific borehole sizes.	-Experience is critical. -Unreliable in non-diamond holes (RC, rotary, etc.) due to potential poor packer seating risk. -Typically requires a wireline drill rig. -Not suitable in very high or very low permeability formations. -Require specialised equipment that may not exist in all countries. -Leakage around the packer can cause false interpretation of the test results. -Requires a relatively clean borehole. -In shallow, soft formations packer tests may induce hydrofracturing or hydro-jacking.
Pumping Tests	-Provide accurate and reliable estimations of more hydraulic parameters. -Wider aerial characterisation. -Many hydraulic parameters can be estimated (e.g. T,S, Sy, Kz/Kr, etc...). -Diagnose borehole efficiency. -Suitable to identify boundaries and flow regimes. -Comprehensive literature. -Tests can locally mimic dewatering operation. -Test wells can be used for dewatering and monitoring water level and quality.	-Time consuming and can be expensive. -Typically involves drilling of large diameter pumping wells and observation holes. -May not be suitable in polluted groundwater due to potential discharge permit. -Require more human resources and logistics than all other tests. -Not suitable in low permeability media, as low rate pumps may not be available. -Pumping tests are not suitable in fully open or steeply inclined boreholes.

CONCLUSIONS

Five hydraulic testing methods of boreholes for mine studies have been discussed in the present paper. A brief definition of each type of test has been presented, and their limitation and suitability discussed. Also the advantages and disadvantages of each of the tests have been highlighted. The material presented in this paper is mainly based on existing literature and the authors' work carried out using such techniques in various types of environments and hydrogeological settings.

At early stages of a mine study, slug tests and airlift tests are widely used; because these are simple and cheap and yet provide preliminary assessment of the hydraulic parameters of the rock formations around the mine. Further specialised testing is usually designed based on the results of these early stage testings and groundwater monitoring. At advanced feasibility studies pumping tests are usually carried out. Although such tests may be the most expensive option, they are usually carried out in most mine projects because they provide more representative values of the hydraulic parameters. Pumping tests usually require the use of contractors, but the availability of pumps and pipes in almost every country, however, justifies their use.

In projects where the vertical variation of the hydraulic parameters is predominant and the risk of groundwater inflow management is high, characterisation of the vertical profile of the hydraulic parameters is required. Pumping tests cannot provide such results, unless a very expensive investigation programme involving drilling many boreholes in various geological horizons is carried out. The alternative methods to pumping tests in this environment are the use of packer testing or flowmeter logging. The former can provide readily usable parameters for groundwater models if the tests are designed for such purpose. Spinner tests provide continuous profile of the hydraulic parameters thus accurately depicting the depths of open fractures and flow zones. The results of spinner tests however can be quantified for use in groundwater model only if a pumping test is carried out in the tested hole. Spinner tests and especially packer tests can be carried out in inclined and/or very deep boreholes. However, hole collapse and loss of equipment remain a major risk in packer testing and flowmeter logging. Also borehole cleaning is required prior to these tests to obtain more meaningful results.

CHAPTER 14

MINE WATER MANAGEMENT FOR CLOSURE

Practices in Setting Sustainable Water Management Closure Performance Criteria

Henning Boshoff
ATC Williams, Australia

ABSTRACT

The processes and sources of acid rock drainage from mine wastes are well described, as is the definition of sustainability. However, the practices used to define closure performance criteria for mine water management do not always intersect with these definitions, nor does the water from operating mine sites or discharged from a closed mine site always meet sustainability criteria. The problem lays in that mine designers and planners develop initial mine water management objectives and criteria that are not always inherently linked with operational implementation. Furthermore, the same designers generally do not prepare these documents nor are they prepared at the same time creating further disparity. Setting suitable water management closure performance criteria are further complicated through not knowing definitively when closure related efforts will translate into a sustainable outcome.

It is recognised that appropriate and effective mine water management alone cannot ensure sustainable closure outcomes, which are made clear through environmental risk identification and the management thereof. However, experience shows that water management is key to achieving successful mine closure. Regulators require mining operations to closely manage mine effected water during and post mining, which are monitored through activities such as assessment of the receiving environment's water quality.

This paper provides perspective on the current guidelines and practices followed in setting mine water closure performance criteria and references current relevant Australian guidelines. Furthermore, it provides discussion on examples that are presented and recommendations to improve the current practices.

Keywords: Water Management, Closure, Performance Criteria

INTRODUCTION

Mine sites often face challenges to manage mine effected water, which vary from routine to the unexpected. Personnel responsible for mine water management will reference site procedures and guidelines when making some of these day to day decisions. However, in non-routine situations these decisions become difficult and more so, if the overall mine site water management objectives and performance criteria are unclear.

Those responsible for the planning and design of mine sites are not normally involved in the management of the mine site, and do not consider all management scenarios. Nor are they generally involved in closure planning or in implementing the closure and rehabilitation plans.

Various reports and planning documentation are developed during the feasibility and approval stage, during which high level mine management commitments are developed. These commitments include mine water management, which will provide the basis for setting mine water management objectives and criteria.

Significant work has been done in the field of assessing the potential and describing the formation of acid rock drainage with the aim prevent acid mine drainage. More strict legislation and setting better water management performance criteria aid in the drive to reduce the number of mine sites with acid mine drainage.

There is a lack of continuity in the design stage, and the operational and closure stages that results in developing mine water management criteria that are not sustainable. The paper highlights available the guidance, current practices and examples in setting sustainable water management criteria, and recommendations for further improvements.

METHODOLOGY

A desktop investigation was completed to identify relevant guidance documents and current practices followed in setting sustainable water management criteria. Information was compared to identify similarities and deficiencies to assist mine designers and planners to set sustainable water management criteria.

DISCUSSION

Mine water management is not the same for all mine sites, including the process followed to set sustainable mine water management closure performance criteria. The topic of mine water management is extensive and this paper will only focus on one aspect, which is believed to be pinnacle to the success of sustainable mine water management. Being, to identify and implement mine water management objectives and performance criteria.

Poorly defined performance criteria could lead to an anything-goes mentality. Unfortunately, this may result in long term closure liabilities such as acid rock drainage, saline drainage, erosion, flooding, etc. Furthermore, a lack of performance criteria will make assessment of closure performance nearly impossible.

What guidance is available for mine water management?

Regulators, scientific institutions and the mining industry develop many documents aimed at guiding the reader to undertake a specific activity. These documents are not developed by the same person or for the same purpose, and could duplicate information or contradict each other. Users of the information must therefore take care when using the information to ensure that it is applicable and of similar complexity to their situation.

The internet is a vast source of information and provides a multitude of relevant and irrelevant water management information. The following are some of the guidance information that are easily available:

- Water Management Leading Practice Sustainable Development Program- Australia (WMLPSDP, 2008);
- Managing Acid and Metalliferous Drainage Leading Practice Sustainable Development Program- Australia (MAMDLPSDP, 2007);
- Mine Rehabilitation Leading Practice Sustainable Development Program- Australia (MRLPSDP, 2006);
- Mine Closure and Completion Leading Practice Sustainable Development Program- Australia (MCCLPSDP, 2006);
- Guide to Leading Practice Sustainable Development in Mining- Australia (GLPSD, 2011);
- Managing mine water under extreme climate variability CSIRO project- Australia (CSIRO, 2013);
- Minesite Water Management Handbook- Australia (MWMH, 1997);
- Integrating the mining sector into water planning and entitlements regimes- Australia (Hamstead, 2012);
- Guidelines for Mining and Sustainable Development- International (UN, 2002);
- EU Water Framework Directive 2000/60- Europe (EU, 2000);
- Best Environmental Practices in Metal Ore Mining- Finland (Kauppila, 2013); and,
- Acid mine drainage prediction- United States (USEPA, 1994).

Other information that is not easily accessible on the internet, includes:

- Strategic Framework for Mine Closure 9 ANZMEC 2000. Strategic Framework for Mine Closure. Australian and New Zealand Minerals and Energy Council and Minerals Council of Australia (ANZMEC, 2000);
- Technical and Managerial Guidelines for Catchment Scale Management- United Kingdom (ERMITE, 2001);
- Checklists for sustainable mining- Australia (Barton, 2003); and
- Mining and the Environment from Ore to Metal- Australia (Spitz, 2008).

Guidance is also provided through legislation, licensing or policies. Mine sites identify site specific legislative requirements and manage these requirements. Not complying with relevant legislation or license conditions could result in legal action, under:

- The Environmental Protection and Biodiversity Act 1999 (EPBC Act), which protects and manages national and international important flora, fauna, ecological communities and heritage places. Notably, the EPBC Act on 22 June 2013 made water resources a matter of national environmental significance in relation to coal seam gas and large coal mining.

- The Queensland state government has released a number of environmental protection policies under the Environmental Protraction Act of 1994 (EP Act, 1994). The Environmental Protection Water Policy 2009 is one such policy relating to protection, monitoring and reporting of Queensland waters.

One common message was identified when reviewing the available guidance information. Being, that water management planning must be integrated at the beginning and throughout the project. Setting specific mine water management performance criteria gives focus to planning and design, and forms a common basis for setting related project objectives.

The guidance information is also clear on the importance of sustainability, which is well defined and discussed on many levels of society and industries. Water plays a vital role in the viability of economic activities (ATSE, 2012), such as mining and is one of the key resources assessed to ensure that a project is sustainable. This assessment includes both the reliance on water, as well as the potential risk to the water resource (NWI, 2011).

Guideline documents further identify the importance of setting water use regimes that support the mine water management performance criteria. A water use regime is set to ensure environmental and resource sustainability, while still allowing development. The 2011 National Water Initiative (NWI, 2011) identified the effect of mining on the sustainability of water resources, and raises concerns about the recognition and integration of the minerals industry in water reform. This is primarily due to historically treating the minerals and other extractive industries different to other water users, such as in the case of special water licenses giving mining operations the right to take and interfere with water (NWI, 2011).

Following the guidelines will assist in setting mine water performance criteria, however there are a number of issues to consider to ensure the sustainability of the mining project, these include:

- assuring an adequate water supply during the life of the project;
- ensuring that only water of an acceptable quality is discharged;
- providing infrastructure to prevent the flooding of mine workings and others;
- selecting a logical sustainability assessment process (Gasparatos, 2012); and
- considering project stakeholders and decision makers (RAC, 1992).

There are many sustainability assessment processes available (Gasparatos, 2012) however, selecting a suitable assessment process is not discussed in this paper.

Planning for effective mine water management in the initial design process

Mine water management has evolved over time and is a key focus area for many mining operations (Boshoff, 2014). Mine sites plan the mine water management layout based on the overall mine plan to ensure effective water management during all the stages of mining. Planning is generally based on modelling with limited verification of the assumptions and often no calibration of models, which could cause operational issues and redesign.

Mine designers also consider closure during this planning process and generally aim for a maintenance-free post mine closure water management system. Water management post closure will only be successful if supported through proper water and waste management during the life of the mine. This includes proper closure design for tailings and waste rock facilities. Integrating of closure requirements with the life of mine planning reduces the long term liabilities (Boshoff, 2014).

A water management plan is required for new mining projects seeking a license to operate. The Queensland government Department of Environment and Heritage Protection states that a water management plan must be developed by an appropriately qualified person and implemented by

the mine, as per the documented plan (EM944, 2013). Water management plans must further conform to guideline requirements (EM324, 2012), which include the following:

- study of the source of contaminants;
- a water balance model for the site;
- a water management system for the site;
- measures to manage and prevent saline drainage;
- measures to manage and prevent acid rock drainage;
- contingency procedures for emergencies; and
- develop a program for monitoring and review of the effectiveness of the water management plan.

Mine water management is not limited to the boundaries of the mine site, specifically in areas of high precipitation and for mine sites with an annual water excess that will most likely discharge frequently. Planning must include local and regional considerations to assess the impacts on water resources, including climate, topography, drainage and the receiving environment.

Mine planners and designers will assess the impacts, select objectives and develop cost effective mitigation strategies to ensure that the impacts post closure will be acceptable. Post mining water management performance criteria provides the basis for developing operational stage objectives. It will be difficult to meet more stringent closure performance criteria following an operational stage that had laxed performance criteria.

The mine designers involved during the feasibility stage of the mine are most likely not involved in operating of the mine (Bullock, 2011). Their objectives include cost effectiveness, which stems from pressures to make a mine feasible (McCarthy, 2013). The operating mine will also have an objective to keep overheads and production costs low, and the end result is a mine with inadequate water management considerations during the life of the mine and after closure.

Expertise and skill are required when planning, designing and implementing cost effective mine site water management that meet key cost effectiveness objectives. Even then, the water management plans should be considered living documents and altered as conditions change during mining or detecting unauthorised environmental impacts.

Setting effective mine site water management performance criteria

Will mine water management activities during mining and post closure result in sustainable outcomes? This is a question that cannot be answered qualitatively or quantitatively during the planning stage. Mine designers and planners consider project objectives and project design criteria during the design process (Elkington, 1997). The potential issues with project objectives and project design criteria includes:

- providing objectives that are not clear;
- selecting objectives that are general to the mining industry;
- selecting objectives prior to identifying environmental values;
- writing objectives as criteria or providing criteria as trigger limits;
- developing objectives that are not clear how and when it is relevant;
- quoting specific legislation or guidelines as objectives; and
- developing closure objectives not considering water management objectives and vice versa.

Below are some examples of water management objectives:

- General surface water management objectives (McArther River Mine, 2012):
    - **Separate** 'clean', 'dirty' and 'contaminated' water runoff as much as possible; and
    - **Minimise the area** of surface disturbance, thus minimising the volume of 'dirty' and/or 'contaminated' runoff.
- Site water management project operational and environmental objectives (RASP Mine, 2012):
    - **Prevent discharge** of potential contaminated surface waters from active mine areas off-site.
- Site water management principal objectives (Tarrawonga, 2006):
    - To ensure sufficient quantities of water can be obtained through the capture of "dirty" water, harvesting of "clean" water, and extraction/harvesting groundwater to meet the **requirements for dust suppression** on the mine site.
- Site water management objectives (Alpha Coal, 2011):
    - **Avoid** the need for **discharge** of contaminated water under normal operating conditions through preferential onsite reuse of contaminated water stores.

Similarities are observed, although planners and designers with different experiences and skills developed these objectives, of which the main similarities in the objectives consist of:

- meeting legislated mine site water management requirements;
- minimising the use of water from natural water resources on the surface and below;
- minimising the impact on surface water and groundwater flows and water quality;
- identify and control mine site erosion; and
- establishing a monitoring program to assess the actual impact on natural water resources.

Mine water management performance criteria, as with the objectives, are specific to the mine site. No one mine is the same or are located in exactly the same environmental setting resulting in different water management performance criteria. This is evident when comparing a number of environmental impact statements. The following are examples of water management performance criteria, of which the tabled water quality performance criteria were excluded:

- The characteristics of clean water are pH of 6.5 – 8.5 and suspended solids of **less than** 50 mg/l as well as hydrocarbons less than 10 mg/l (RASP Mine, 2012);
- Discharge **water quality will meet** the Australian and New Zealand Environment and Conservation Council Water Quality Guidelines for Fresh and Marine Waters (ANZECC, 2000);
- **Groundwater levels** in privately owned bore will **not exceed** more than 3 m sustained reduction over a 3 month period (RASP Mine, 2012);
- Long-term 'dirty' **runoff** drains that will be active for longer than 2 wet seasons **will be** constructed to **contain** the 1% Annual Exceedance Probability (100 year Average Recurrence Interval) design discharge (MacArthur River Mine, 2012);
- The performance of the water management plan in achieving the objectives and targets shall be **reviewed at least** quarterly (Ulan, 2014);
- Regularly **report environmental performance** to the environment and community manager (Ulan, 2014);
- **Runoff** from all disturbed areas across the mine site during the operational phase **is contained** by a mine water management system (Alpha Coal, 2011); and
- Mine closure runoff quality **meets** the water quality **objectives** for the identified surface water environmental values (Alpha Coal, 2011).

It was found that most of the water management performance criteria are focused on water quality and predominantly discharge water quality (as a lagging indicator), as required by the mine site license to operate. Regulators provide the discharge water quality requirements once the mine designed and approvals process are completed. The requirements are therefore based on the outcome of environmental studies, modelling and the mine's agreed/negotiated commitments. These commitments are therefore based on objectives, performance criteria and legislative requirements identified during the design and planning of the mine. More specifically, these commitments are specific to the environmental values relevant to the mine site and described in the key objectives to be enhanced or protected.

The main reason for selecting and describing water management performance criteria is to enable quantitative measurement of the effectiveness of the mine's water management activities.

Recommendations in setting mine water management performance criteria

Defining performance criteria for mine water management cannot be conducted by one person from a single engineering discipline (Gasparatos, 2012). This is due to the complexity of the issues associated with water management and closure objectives.

It is recommended to involve various disciplines; including civil engineering, mechanical engineering, structural engineering, environmental engineers, human resources, social and community studies in developing water management performance criteria.

Modelling of the water systems and assessing the potential effectiveness of various management options could provide early indications, however it is recommended that assumption must be verified once more tangible data becomes available.

A fully integrated planning and implementation process is recommended, which is broadly outlined as follows for all the stages in the life of the mine, including post closure:

- Identify surface water and groundwater environmental values relevant to the mining project;
- Set key closure objectives that will either enhance or protect the relevant surface water and ground water environmental values;
- Set water management performance criteria for the surface water and ground water relevant to the mining operations during;
- Undertake a risk assessment and identify the control measures, mitigation activities and responsibilities to ensure that closure objectives are met or exceeded;
- Set water management infrastructure design criteria relevant to the mining operations and key objectives;
- Plan, design and adequately cost the control measures and mitigation activities;
- Develop water management performance monitoring and reporting requirements;
- Develop a water management plan integrating closure;
- Obtain a social license to operate the mine committing to the water management plan;
- Verify all assumptions at the earliest possible stage of the design process; and
- Implement the water management infrastructure design and water management plan, as specified.

CONCLUSION

There are many freely available guidance documents that provide guidance in the development of water management performance and closure criteria. These objectives and performance criteria are best developed and agreed at the beginning of the planning and design process. Forward planning assist to ensure that selected water management objectives can be met during all stages of the mining project and after closure.

It can also be concluded that the development of objectives and the subsequent performance criteria needs input from individuals with experience and skill from a number disciplines. Site documentation must be linked back to the water management objectives and specific water management performance criteria. It is critical to develop effective objectives and criteria for water management performance and closure to ensure that site activities will drive to a common goal and that adequate budget is available during operations and after closure.

ABSTRACT

Understanding reclamation effects on surface water balances in mine-affected watersheds is critical to both prediction of, and design for, water movement through the post-closure landscape, and for development of appropriate reclamation and revegetation treatments for mine closure. Substantial effort has been invested in increasing knowledge of the effects of mine-waste cover systems on key water-balance terms such as net percolation, but there is a lack of tools to extend that knowledge to effects of cover systems on vegetation establishment, and the subsequent effects of these vegetation-substrate interactions on water-balance terms. The concept of a "soil moisture regime" is used worldwide to understand edaphic conditions and plant communities. However, in most applications, soil moisture regime is a relative or unquantified parameter estimated from the presence of indicator plants or soil properties observed in natural ecosystems. Applications of these approaches to post-mining landscapes are challenging, because soils/surficial materials are reconstructed, and often reference plant communities are not fully re-established. Some quantitative approaches to estimation of properties that influence soil moisture regime (e.g., available water storage capacity) have been developed, but these are generally based on agricultural soil science, and have limited utility to many post-mining materials.

The authors propose new methods for estimating soil moisture regime on post-closure landscapes, using concepts from existing biogeoclimatic-ecosystem classification systems and new analyses of effects of particle-size distribution on soil water retention. Key variables in the proposed estimation model include regional and local climate, material particle-size distributions (including distributions typical of mine-waste materials) and organic-matter accumulation, and topography. This paper discusses methods development, application, and testing of this estimation approach across a number of mines, and presents suggestions for broader application of the approach for quantifying surface-water-balance components (e.g., net percolation) and for reclamation planning (e.g., revegetation species selection) in closure landscapes.

Keywords: reclamation, soil, moisture, regime, water

INTRODUCTION

One of the principal knowledge gaps in mine reclamation is that of characterizing soil water dynamics within surficial materials used in reclamation cover systems. The concomitant water balance in these materials is a dominant control on both ecosystem development and watershed performance, and better understanding of these water balances is critical for improved reclamation planning and projection of long-term characteristics of reclaimed ecosystems. It is also critical for improving our understanding of the hydrologic behavior of reconstructed mine-affected watersheds, including the role of net percolation on flushing of constituents of interest (CIs) from the mine wastes within these watersheds. Although substantial effort has been invested from an engineering perspective in investigating the effects of cover systems on rates of net percolation, this effort has generally not been coupled with understanding soil water dynamics within the same cover systems for the purposes of reclamation planning and execution. To date most ecological approaches used to address the above knowledge gap, where it has been addressed at all, have been borrowed from ecosystem classification systems, and are limited by some or all of the following factors:

- they are qualitative or semi-quantitative, and there is limited attempt to evaluate and demonstrate their hydrologic validity;
- they rely substantially on the presence of existing natural vegetation communities to provide information on edaphic conditions – these techniques are not applicable to mine-reclamation settings where vegetation communities are absent or introduced; and/or
- they have a narrow focus on a single aspect of the surface water balance, e.g., estimating water retention for revegetation planning. In these approaches, there is no attempt to provide a more comprehensive understanding of surface water balances, and of how water retention and use by vegetation may influence deeper percolation and the water balance of the underlying mine-waste landform.

This paper presents a quantitative method to relate the properties of landforms and cover-system materials to plant-available water and surface water balances, based on particle-size distributions and biogeoclimatic ecosystem classification.

BACKGROUND

Biogeoclimatic ecosystem classification

Biogeoclimatic ecosystem classification (BEC) is an ecological classification system developed primarily in the western Canadian province of British Columbia (B.C.) in which biogeoclimatic units ("zones") represent broad geographic areas of similar macroclimate, and are recognized as influencing biological characteristics of resulting ecosystems (Meidinger and Pojar, 1991). In the BEC system, biogeoclimatic zones can be subdivided into subzones, which can in turn be subdivided into variants, with each subdivision representing a reduction in climatic variability and geographic area (Lloyd et al., 1990). Within each subzone or variant, there are sequences of distinct ecosystems ("site series"), with associated vegetation communities reflecting differences in topography and soil depth, texture, drainage, moisture regime, and nutrient regime. In this system, soil water availability is believed to have the greatest influence on ecosystem development. This availability is in part determined by climate, but since climate is relatively uniform within a biogeoclimatic subzone or variant, variation in soil water availability at this level of classification

results from influences of soil and topography on surface water balances (Lloyd et al., 1990). These influences are manifested in resulting plant associations, i.e., each site series has an assemblage of plants that are adapted to its edaphic conditions – a fundamental principle of the BEC system is that sites with similar physical properties have similar vegetation potential (Meidinger and Pojar, 1990). A subset of plants on a site – "indicator plants" – are diagnostic of edaphic conditions due to their adaptation to narrow ranges of conditions, e.g., soil water availability.

Soil water availability

In the BEC system, soil water availability is estimated using a concept termed "soil moisture regime" (SMR), which reflects "the average amount of soil water annually available for evapotranspiration by vascular plants over an extended period of time (several years)" (Pojar, Klinka & Meidinger, 1985). The BEC system incorporates nine SMR classes ranging from driest (Class 0, or very xeric) to wettest (Class 8, or hydric) – this spectrum is referred to as a hygrotope (Pojar, Klinka & Meidinger, 1985; Meidinger and Pojar, 1990; Klinka et al., 1984). The most common classifications of hygrotope – and those that are used in the BEC system – are classifications of *potential* hygrotope, based on subjective inferences from site and/or vegetation features (e.g., source of water, rate of water removal, slope position, soil textural class), and represent relative ranking of sites in terms of potential soil water availability. A common example of this approach is provided by Meidinger and Pojar (1991), although more complex and semi-quantified examples exist in the BEC system (e.g., Lloyd et al., 1990). Actual hygrotopes integrate the above information with climate and surface-water-balance inputs and losses such as precipitation and evapotranspiration to provide estimates of absolute rather than relative water availability.

Quantified estimates of both potential and actual hygrotope or soil moisture regime are uncommon, and those that exist are limited in their application to specific geographic regions and/or ecosystems (e.g., Waring and Major, 1964). In B.C., Green et al. (1984, and summarized in Pojar, Klinka & Meidinger, 1985) used a water-balance approach to develop an actual hygrotope, but it is based on intra-annual duration of water deficits and on presence of water tables, and although the authors provide defining features for their classes, methods for classifying sites according to this system are not provided.

Various land-capability classification systems in Canada – beginning with agricultural land-capability systems – have used available water storage capacity (AWSC) as an index of potential soil-water availability. Available water storage capacity is defined as the volume of water per unit area held within the active or rooting zone of the soil profile between the volumetric water content at field capacity (FC) and the permanent wilting point (PWP). The field capacity is the volumetric water content at which the rate of gravitational drainage becomes negligible relative to the current rate of evaporation or evapotranspiration (Zettl, 2014). This water content is often taken to be the water content at negative pore-water pressures of 10-33 kPa, depending on soil texture. The permanent wilting point is the volumetric water content at which soil water is no longer available for plant uptake. Although this water content varies by plant species, by convention it is defined as the water content at a negative pore-water pressure of 1500 kPa.

AWSC is generally expressed as a depth of water (mm) over a specified soil depth, or as a depth of water per unit depth of soil (mm water/cm soil). A common practice has been to assign AWSC values based on soil texture: for example, the document *Land capability classification for agriculture in British Columbia* (B.C. Environment, 1983) provides AWSC values in mm water/cm of soil depth for soils of different textural classes. However, these systems, being initially focused on agriculture, do

not link AWSC to soil moisture regime, and to occurrence of typical natural ecosystems and/or larger hydrologic performance.

In northeast Alberta, the *Land capability classification system for forest ecosystems in the oil sands* (or "LCCS" – Cumulative Environmental Management Association, 2006; first published in 1996) attempted to use earlier concepts (and values) of assigning AWSC to textural classes for application to mine-reclamation and forest-ecosystem settings. The LCCS equates a potential hygrotope to numeric values calculated from texture-class-based AWSC, and some topography and surficial-material-depth modifiers such as slope position and depth to impermeable layers. This approach represents an advancement in producing an objective and quantified relative hygrotope, but still has a number of limitations for broader application. Consistent with conventional soil-science principles, calculation of AWSC in the LCCS is based solely on <2-mm particle-size fraction, with particles greater than 2 mm discounted on a volume basis. This has not been a substantial limitation in oil-sands reclamation applications due to relatively insignificant coarse-fragment contents, but it limits application of the LCCS approach to higher-coarse-fragment-content settings like hard- and soft-rock mine wastes. In addition, texture-based AWSC values in the LCCS apply uniformly across texture or material classes, and do not recognize or account for variation in particle-size distributions within these classes. For instance, the LCCS applies an AWSC value of 1.0 mm/cm to oil sands tailings, regardless of actual particle-size distribution and whether these tailings are complete, or are cyclone overflow or underflow products. Finally, although there has been substantial investigation and validation of the LCCS AWSC values (e.g., Barbour et al., 2010), and thus of their use as a relative hygrotope, there has been limited evaluation of the relationship between these values and actual soil water contents (i.e., the actual hygrotope), and of the relationship between these values and ecosystem development and landscape/watershed hydrologic performance.

The concept of soil moisture regime has been applied globally, based on duration or magnitude of growing-season water deficits, but typically involves relatively broad classes that can be mapped at a continental scale (e.g., Soil Survey Staff, 1999), versus application to differentiate between ecosystems and hydrologic behaviors at a local or regional scale.

METHODS DEVELOPMENT

Objectives of the proposed classification system

The classification system proposed here is substantially informed by the biogeoclimatic, hygrotope/SMR, and land-capability classifications described above, but is intended to derive estimates of plant-available water, surface-water-balance performance, and associated ecosystem characteristics from landscape, landform and surficial-material properties, using objective and quantified methods that can be consistently and easily applied. Further, the proposed system is designed to be broadly applicable to a range of climatic, physiographic, and surficial-material conditions (e.g., globally), yet have sufficient resolution to differentiate ecosystem characteristics and hydrologic performance at a local scale. Additional goals for the classification system are that it:

- be capable of derivation solely from information on material properties, topography and climate, and not rely on observations of intact above-ground ecosystems for diagnosis;

- be capable of evaluation and validation or adjustment through analysis of related empirical observations, including relationships with non-mine ecosystems classified through standard BEC methods; and
- provide useful interpretations for a range of mine-planning and reclamation-management considerations, including both cover placement/revegetation and understanding hydrologic behavior at the mine landform-landscape-watershed scale.

Classification framework

The proposed classification framework is based on three primary factors, with decreasing geographic scales of application (Table 1, adapted from Devito et al., 2005). For the first classification factor, AWSC is determined from particle-size distributions of materials in the upper one metre of surficial material. This determination can be applied globally, as it is based on universal principles of soil physics. The next classification factor involves modification of the profile AWSC estimate for topography-based energy regime – these modifications are specific to latitudinal ranges, and thus must be developed specifically at the continental to sub-continental scale. The final classification factor applies regional and local climate information to the potential hygrotope resulting from application of the first two factors to generate an actual hygrotope and identify ecosystems associated with this hygrotope. Thus application of the first classification factor (AWSC) requires only information contained in this paper; application of the second factor (topography/energy) may require modification of information contained in this paper, depending on latitude of application; and application of the third factor (climate) requires information on climate local to the application site and biogeoclimatic or similar classification information.

Table 1 Soil water regime classification framework

Factor	Range of factor		Scale of applicability	Classification outputs
1. PSD of surficial materials	High silt and clay contents, low sand, gravel and cobble contents: higher AWSC	High sand, cobble and gravel contents, low silt and clay contents: lower AWSC	Global	Profile AWSC in surface 1 m
2. Topography and energy	High latitude: slope and aspect significantly affect energy distribution	Tropical and sub-tropical: slope and aspect do not significantly affect energy distribution	Continental to sub-continental	Adjusted AWSC; relative SMR or potential hygrotope
3. Regional and local climate	Dry, arid to sub-humid (P < PET) • storage and ET dominant • runoff and NP may be reduced	Wet, humid (P > PET) • runoff and NP dominant	Regional to local	Actual SMR and hygrotope; identification of associated ecosystems

Determination of AWSC

A standard particle-size distribution (PSD) ternary diagram for engineering interpretations was used as a framework for generating PSD-based AWSC values. This framework (based on the Unified System of Soil Classification) was used both to allow evaluation of the contribution of particles >2 mm (as opposed to conventional soil-science approaches), and to facilitate communication between mine planners/engineers (who often use engineering PSD classification systems) and reclamation specialists (who often use soil-science PSD or texture classification systems). AWSC values were estimated from two databases of material characteristics[1] for all materials with measured PSDs and water-retention curves. The materials were separated into 100 textural groups corresponding to subdivisions of the PSD ternary diagram, based on gravimetric proportions of coarse (>4.75-mm), sand (0.075-4.75 mm), and finer (<0.075-mm) particles. The average AWSC for each group was used to populate the ternary subdivision position. If a textural group had little to no available AWSC data then an estimate was made from interpolation and/or extrapolation from surrounding positions. The resulting AWSC-populated ternary diagram is presented in Figure 1, where AWSC values are in mm water/cm material depth, and represent the center point of each subdivision. Values in this table are preliminary, in that they provide a framework and enable testing of the proposed system, but it is recognized that they require further refinement prior to broad application. In order to allow consistent and repeatable use of this tool, software has been developed that will take input PSD information and consistently interpolate an AWSC value from the center-point values, based on standard GIS interpolation algorithms. Input PSD information is based on all particles <100 mm. To facilitate more cost-effective and reliable

[1] Databases included an internal database from O'Kane Consultants Inc. (OKC), based on properties of mine-waste and cover materials observed by OKC at different client mining sites around the world, and the other internal to SoilVision Systems Ltd.'s numerical modelling software (www.soilvision.com).

classification, low-technology field equipment has also been developed to allow rapid determination of the cobble-and-gravel separate (>4.75 mm) based on a large volume of material, with subsequent determination of the sand and clay-and-silt separates based on laboratory analyses of smaller collected samples.

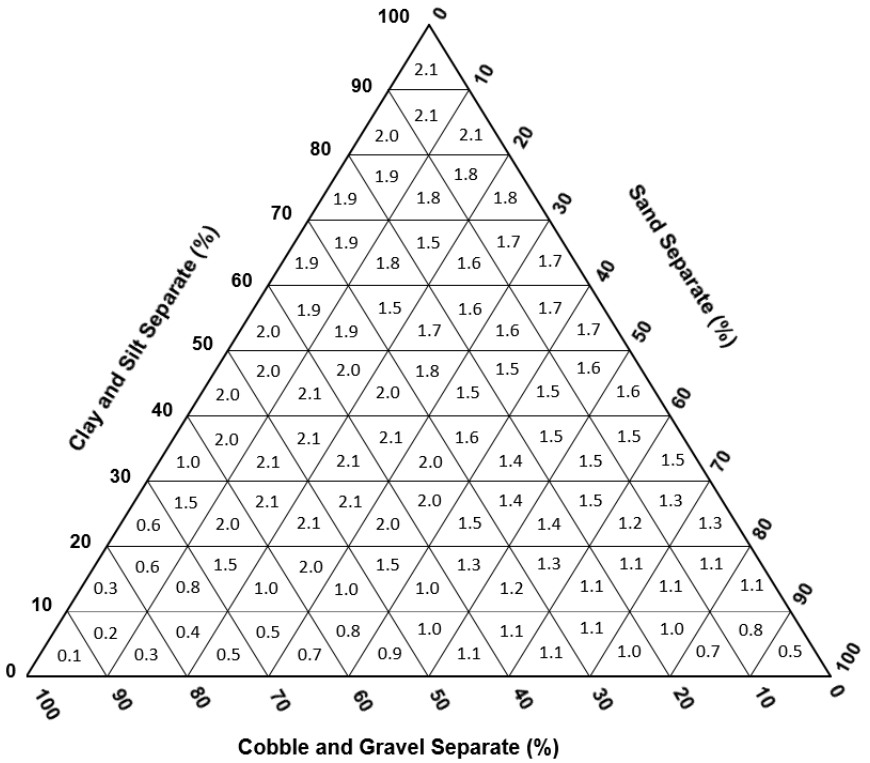

Figure 1 AWSC ternary diagram. AWSC values are in mm available water storage per cm of material depth, and represent the center point of each subdivision of the diagram

Values derived from Figure 1 are intended to represent a single material, and to be aggregated across a standard material profile or control section (typically 100 cm, but lesser sections could be used if stipulated). For instance, to estimate AWSC for a 50-cm soil cover placed on mining waste rock or tailings, one AWSC value is calculated for the cover material, another is calculated for the mine-waste material, and an aggregate AWSC is then generated by summing the values. If multiple layers are present within the soil cover (or mine waste), then an AWSC value is calculated for each layer corresponding to depth and PSD data. For natural soils, calculation is based on horizon depths and characteristics. In the case of shallow soils over non-rooting-zone materials, the AWSC for the control section is based only on the depth of the soil material, and thus is reduced compared to a 1-m potential rooting zone.

Modification of AWSC values for energy regime

In the British Columbia BEC system, the topographic effect on energy is recognized through "warm" and "cool" site modifiers. These modifiers are applied to slope angles >25% (14°), with warm aspects being southerly or westerly (135°-285°), and cool aspects being northerly to easterly

(285°-135°; Resources Inventory Committee, 1998). This approach was modified for the current classification system as presented below in Table 2 to include a neutral energy regime on southeast and southwest slopes. This modification is based on the fact that the shift in energy regime on slopes as aspects change is more accurately a continuous increase or decrease in insolation rather than a categorical shift – the modified classification still uses categories, but incorporates an intermediate neutral category instead of the immediate shift from cool to warm as implied by the BEC system. This modification is supported by evaluation of data on field-measured soil water-content profiles in comparison to estimated AWSC values, which indicates a better fit when southeast and southwest aspects are categorized as neutral than when they are classified as cool (southeast) or warm (southwest).

Modifiers in Table 2 are applicable to northern latitudes of approximately 48-60°. These magnitude of the modifiers could be increased for higher northern latitudes and decreased or eliminated for lower northern latitudes. For southern latitudes, the modifiers as presented or adjusted would be altered to reflect different warm and cool aspect relationships.

Table 2 AWSC energy modifiers

Energy class	Class definition	AWSC modifier
Neutral	Slopes <25% (<14°) Slope >25% (>14°); aspects 085-135° and 235-285°	none
Warm	Slope >25% (>14°); aspect 135-235°	Calculated AWSC – 30 mm
Cool	Slope >25% (>14°); aspect 285°-085°	Calculated AWSC + 30 mm

Equation of modified AWSC values to soil moisture regime[2]

Adjusted AWSC values (PSD-based AWSC from Figure 1 plus any applicable energy modifiers from Table 2) are used to determine soil moisture regime, as outlined in Table 3. This table uses the SMR classes of the BEC potential hygrotope, but replaces the relative ranking of various criteria with quantified ranges of adjusted AWSC. AWSC ranges for each SMR class are modified from the oil-sands reclamation land-capability classification system discussed above. The AWSC method for SMR determination applies only to upland (very xeric – mesic) SMRs, as wetter SMRs require input of seepage water or the presence of a water table within 100 cm of the soil surface, and are not dependent on soil storage. Thus determination of SMRs wetter than mesic in this system is based on observations of shallow groundwater seepage and/or the presence of a water table within the top 1 m of surficial materials. Note that these moisture regimes are intended to reflect dominant soil-water conditions over a multi-year period, consistent with the B.C. BEC-system hygrotope.

Table 3 Determination of SMR from adjusted AWSC

SMR	Primary water source	Water-table depth	Available water storage,

[2] The term "soil moisture regime" is applied in this paper both to soils and to surficial materials in reclamation landscapes due to its history of use and understood meaning. However, in mine reclamation, many of the materials for which SMR can be estimated are not soils, but are mine wastes and/or salvaged parent materials. Thus SMR should more properly be understood as a soil or surficial-material moisture regime.

		(cm below ground surface)	surface 1 m (mm)
Very Xeric (0)	Precipitation and soil storage	>100	<60
Xeric (1)	Precipitation and soil storage	>100	60-89
Subxeric (2)	Precipitation and soil storage	>100	90-119
Submesic (3)	Precipitation and soil storage	>100	120-149
Mesic (4)	Precipitation and soil storage	>100	>150
Subhygric (5)	Precipitation and seepage	>100	>150, seepage contributes to supply
Hygric (6)	Seepage	30-100	n/a
Subhydric (7)	Seepage or permanent water table	0-30	n/a
Hydric (8)	Permanent water table	Water table permanently at or above soil surface	n/a

METHODS TESTING

The methods discussed above were developed and tested at reclamation-monitoring sites at seven mining operations in 2012-2014: five metallurgical coal operations operated by Teck Resources Limited in southeastern B.C. and west-central Alberta; at the Teck Highland Valley Copper Partnership's Highland Valley Copper mine in south-central B.C.; and at Thompson Creek Metals' Endako molybdenum mine in central B.C. Of particular relevance to testing are the five Teck coal mines, as in 2011 Teck commenced development of an integrated, multi-year and multi-disciplinary applied research & development program focused on managing water quality in mining-affected watersheds. In 2012-13, this program included installation of soil and meteorological instrumentation and soils and vegetation assessments at 12 reclamation sites at these coal mines, to provide data on reclamation conditions co-located and concurrent with information on meteorological and soil-moisture variables at each study site. This instrumented-site network and the data it provides supports increased understanding of how surface water balances and soil moisture regimes are affecting reclamation responses over time, and *vice versa*, as well as how reclamation approaches affect reconstructed landform water balances and watershed hydrology.

Actual versus potential hygrotope

PSD data from 65 mine-reclamation and non-mine reference sites were plotted on the AWSC ternary diagram. Resulting AWSC values provide quantification of the potential hygrotope, as they indicate the *capacity* for soil water storage (and eventual release as evapotranspiration, interflow, and/or net percolation), not actual storage. Actual storage is a product of the interaction between the potential hygrotope and local climate, which delivers precipitation for storage and energy for evaporation and transpiration. To evaluate the relationship between potential (calculated) and actual hygrotope, analyzed volumetric-water-content (VWC) and matric-potential (ϕ_m) data collected by O'Kane Consultants from the Teck instrumented study sites were analyzed to derive mean growing-season *available* volumetric water contents (AWC) for each site. To do so, the VWC at permanent wilting point (PWP) was calculated for each material type (cover material, waste rock) from interpolated plots of VWC against ϕ_m for each sensor pairing. This gave each VWC

sensor a VWC-at-PWP value, which was then subtracted from each of its VWC measurements to calculate AWC (water content above PWP) for all sensors. To calculate mean AWC from all sensors over a profile depth, each sensor's AWC was mathematically weighted according to rooting patterns observed at vegetated sites, with weight assigned for both root abundance and root size. Where rooting data did not exist, mean root patterns from similar sites have been applied. Reported AWC values are means of all daily measurements made during the 2013 growing season, which was defined by site-specific meteorological data using the criteria of five consecutive days of average daily temperatures over and under 5°C as the beginning and end[3] of the growing season (Alberta Agriculture and Rural Development, 2009).

Predicted AWSC and SMR

SMR was assigned for each of the 65 study sites using the PSD-based AWSC estimates with energy modifiers as described above. For the Teck coal-mine research sites where AWC data are available, the AWSC-based SMR classification was evaluated using mean growing-season AWC (Figure 2Figure 2). These data show general support for the proposed classification system, with mean growing-season AWC increasing for every SMR class, despite differences in vegetation development across these sites. On average, very xeric sites have less than 30% of the plant-available water that mesic sites have during the growing season, while xeric sites have approximately 50% of the plant-available water of mesic sites. Research sites at Endako and Highland Valley Copper lack continuous measurement of soil water contents, and so cannot be added to this database, but reference sites in these studies provide some ability to evaluate system fit, as predicted SMR using methods proposed in this paper can be related to potential hygrotopic classification using standard subjective keys and the presence of indicator plants. All reference sites studied to date are zonal site series with mesic SMR – mean AWSC for these sites estimated with the proposed methods is 159 mm, which places them in the mesic SMR category according to the criteria presented in Table 3.

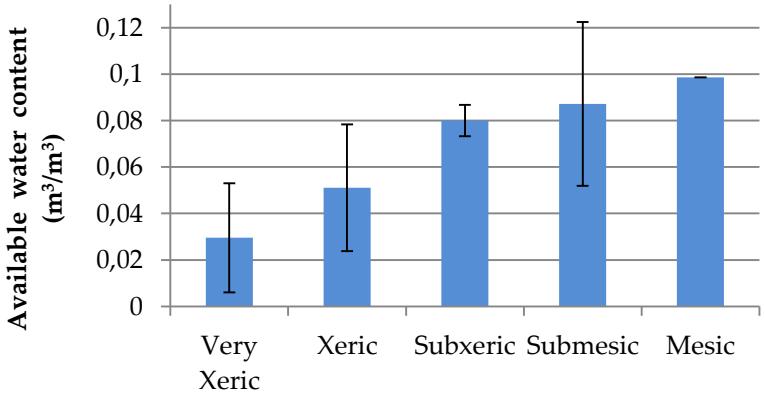

Figure 2 Mean AWC during the 2013 growing season at all sites classified by soil moisture regime – error bars show one standard deviation of the mean

[3] The end of the growing season cannot occur before August 1 regardless of temperature.

SUMMARY AND APPLICATIONS

This paper proposes a quantified and objective hygrotopic classification system that is broadly applicable to a range of ecosystems, including mine-waste-based landforms and mine-affected watersheds. Although the proposed classification system is initially based on potential hygrotope, the use of regional and local biogeoclimatic ecosystem classifications allows its translation into actual hygrotopes, based on regional and local climatic conditions. This translation from potential to actual hygrotope has been tested in two regions of western Canada on instrumented reclamation study sites. Initial results show promising relationships between predicted SMR using the proposed classification system and mean growing-season available water contents calculated from continuous measurement by *in situ* sensors, with increasing observed available water contents as SMRs predicted by the classification model progress from drier to wetter sites. In addition, the proposed classification system shows concordance with traditional ecosystem classification of non-mine reference sites where classification is based on indicator-plant presence and topographic/soil relationships.

The potential management applications of the classification system include:

- Reclamation and revegetation planning – using methods discussed above, soil moisture regime can be estimated for existing or planned landforms and covers, and locally appropriate candidate vegetation species adapted to these hygrotopic positions can be selected for reclamation.
- Assessment of pre- and post-development land capability – using estimated hygrotopic position and the BEC system or similar approaches allows comparison of anticipated post-closure ecosystems to pre-development inventories. These comparisons can then be used to evaluate the effects of mining on dependent values such as wildlife habitat, biodiversity, or land productivity, and can provide the basis for application for custodial transfer of reclaimed lands, or assessment of such applications.
- Quantification of the effects of surficial-materials management on landform surface water balances – when combined with information on local climatic conditions, the proposed classification system can be developed to provide relative estimates of surface-water-balance terms such as evapotranspiration and net percolation. This information can be used by reclamation practitioners to understand the effects of cover placement for reclamation on movement of water through the surface layers of the reclaimed landscape.

This proposed classification system and empirical approach to its evaluation represent a first attempt to populate the AWSC and modifier charts, and will continue to be updated and adapted as additional information is collected and as the classification system is refined.

Acid-Generating Waste Rock Encapsulation in a Subalpine Environment

Larry Breckenridge, Fred Bickford and Amy Livingston

Global Resource Engineering, USA

ABSTRACT

The Amulsar site, owned by Lydian International, is located at high elevations (2,500 m) in south-central Armenia. The site will produce two types of mine waste from an open pit gold mining operation: silicified andesite that is fully oxidized, and argillized andesite that contains sulfides. As a result, there is a risk that the mine waste will produce Acid Rock Drainage (ARD).

Global Resource Engineering (GRE) designed a Barren Rock Storage Facility (BRSF) that encapsulates the argillized andesite within envelopes of silicified andesite to isolate it from groundwater and surface water. Cell design included a degree of compaction to reduce the conductivity of the argillized waste.

Groundwater models were created to predict the following: infiltration and runoff into the BRSF during operations, the optimal design parameters of an evapotranspiration (ET) soil cover, and the impact of heavy spring snowmelt on the BRSF water balance. Geochemical models were then created to predict the quality of leachate and runoff during operations and postclosure.

The results of the groundwater models determined that the waste had sufficient storage capacity to absorb most of the operations-phase water, resulting in low volumes of ARD production during operations. The BRSF closure design included a three-layer soil cover 1.7 m thick, which was shown to provide excellent store-and-release performance, and greatly limited infiltration into the closed BRSF.

60-year-old mine waste piles exist on sites that have not produced severe ARD. Calibrating geochemical models to this data, GRE demonstrated that the region's cold climate and the argillized waste's low conductivity slowed sulfide oxidation reactions. The predicted water quality of BRSF leachate is suitable for passive treatment methods, thus saving the project millions of US dollars in active water treatment costs, and providing a path to clean closure.

Keywords: Mine waste encapsulation, predictive modeling

INTRODUCTION

Amulsar is an open-pit gold mining project being developed by Lydian International in the Lesser Caucasus Mountains of south-central Armenia. The deposit contains 94.9 million tonnes (Mt) of proven and probable reserves at an average gold grade of 0.75 g/t and average silver grade of 3.27 g/t. The life of the project is expected to be approximately 10 years, including two years of pre-mining construction. Ore mined from a series of coalescing pits near the top of Amulsar Mountain, at an elevation of approximately 2,500 m, will be crushed and then transported via a conveyer system to a heap leach facility.

The project will generate 283.1 Mt of waste rock. Disposal of some of that waste rock will be handled by backfilling early-mined portions of the pits, but 190.6 Mt will be disposed to the Barren Rock Storage Facility (BRSF). A portion of the waste rock has sulfide concentrations high enough to make production of Acid Rock Drainage (ARD) likely. Global Resource Engineering (GRE) was assigned the task of designing the BRSF to minimize ARD. This paper describes the waste rock and the methods used to characterize its ARD behavior, and explains the process used to generate a BRSF design that would minimize long-term postclosure ARD water production requiring treatment and optimize the quality of that water.

WASTE ROCK

The Amulsar deposit is hosted by an Eocene-Oligocene sequence of andesitic volcanic rocks that has been intruded by a sill-like porphyritic andesite intrusive. Waste rock that will be produced by the mining project can be divided into two lithologies. The Upper Volcanics unit (UV) is a strongly silicified variant of the andesitic volcanics. This rock type, which hosts the ore, is thoroughly oxidized, has low sulfide content, and has no appreciable neutralization potential. The Lower Volcanics unit (LV) forms a layer underlying the UV. The LV consists of alternating layers of andesitic volcanics and andesite sills. The sulfide content of the LV is variable, with sulfide contents of up to about seven percent. The LV is often argillized; most of the material observed through core drilling contains approximately 10% to 50% clay minerals.

Waste characterization

The waste rock was characterized using standard methodology of static geochemical testing followed by humidity cell tests (HCT). Results of the Acid-Base Accounting (ABA) testing can be seen in Figure 1.

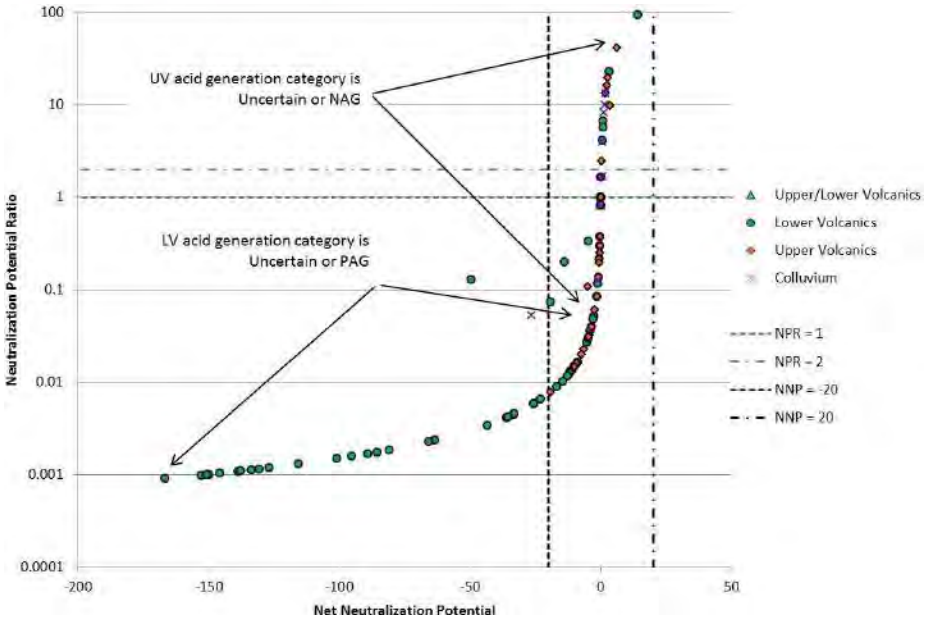

Figure 1 ABA test results

In Figure 1, samples that fall in the upper right-hand quadrant of the graph are non-acid-generating (NAG) based on accepted practice (INAP, 2009). No waste rock samples fall in this zone. Between the vertical dashed lines is a zone of uncertain ARD behavior. All samples of UV waste rock fall in this zone. In the quadrant to the lower left lie samples that are potentially acid-generating (PAG). Many LV samples and no UV samples lie in this zone, and no significant neutralization potential is present in either rock type.

Figures 2 and 3 show the graphs of pH over time and cumulative acidity over time for the HCTs.

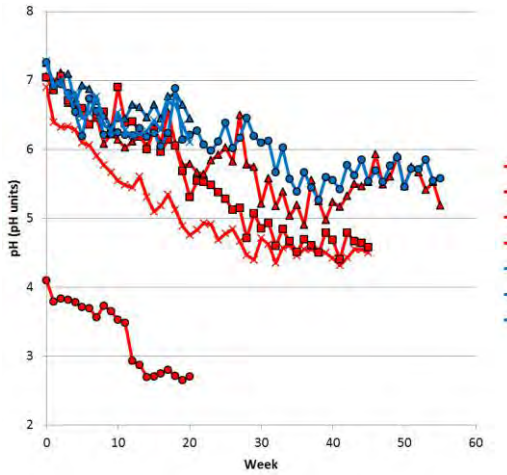

Figure 2 pH vs. time for HCTs

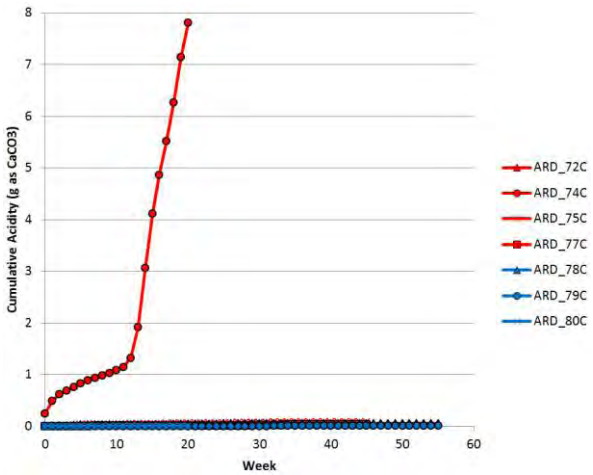

Figure 3 Cum. acidity vs. time for HCTs

No UV samples produced significant acidity, or produced elevated dissolved metals concentrations. LV samples showed variable behavior. Samples with high acid-generating potential (AP) produced acidic leachate, whereas many samples with lower AP did not produce significant acidity. One sample was oxidized prior to arrival to the lab. Two samples produced mild ARD for a full year, with the pH remaining above 4.5. One sample produced acidic leachate of significant quantity, and after 14 weeks exhibited the classic behavior of ferric iron oxidation catalysed by *Acidithiobacillus ferroxidan*s (biotic oxidation). However, in general, LV samples showed a remarkable resistance to biotic oxidation and strong ARD formation.

This behavior was reflected in LV waste piles left in the field by Soviet-era exploration activities on the Amulsar site. Two mine waste piles at the same elevation as the planned waste dump and from the same sulfidized LV formation have been in the field for sixty years. They generate ARD with ~100 mg/L total acidity, ~50 mg/L sulfate, and pH ranging between 4.0 and 3.3. Even after 60 years of exposure, these rocks have failed to undergo aggressive biotic oxidation despite the presence of abundant sulfides in the waste. Whether this behavior is primarily controlled by the cold climate (Sartz, 2011), the mineralogy of the rock, or the lack of microorganisms is uncertain at this stage in the investigation, but it is clear that the waste rock when exposed to the natural environment at this site displays some natural resistance to biotic oxidation. The ARD management plan will take advantage of this natural resistance to minimize the volume and intensity of ARD produced by mining activities.

BARREN ROCK STORAGE FACILITY

Waste rock that is not consumed in backfilling the pits will be disposed to the BRSF. The BRSF will occupy an upland topographic basin on the north flank of Amulsar Mountain, just north of the pit area (Figure 4).

BRSF basin characteristics

The southeast half of the upland basin that will host the BRSF is underlain by argillized LV and clayey alluvium and colluvium. The average hydraulic conductivity of surficial deposits in this area is low (~1x10^{-6} cm/s), which will limit the potential for seepage from the BRSF to impact groundwater beneath it. The remainder of the BRSF footprint is underlain by Cenozoic basalt flows with a higher average hydraulic conductivity. In places where the surface of the basalt is not already covered by an adequate thickness of low-permeability overburden, additional clay-rich material will be emplaced to minimize seepage from the BRSF into the foundation rock.

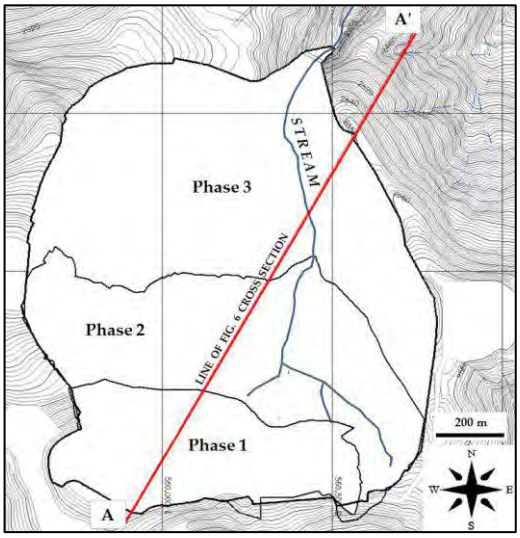

Figure 4 Map of BRSF basin

The north-facing southern slope of the basin hosts a set of springs. These mostly ephemeral springs largely drain perched water zones, whose recharge areas are on the mountain slopes upslope from the BRSF to the south. Springflows vary seasonally, with peak

measured flows of about 20 L/s corresponding to peak snowmelt flows in April and May. The BRSF will be built with an underdrain consisting of a five-meter-thick layer of crushed UV. The underdrain will allow unrestricted flow of the emerging springwater to the toe of the BRSF without coming into contact with the encapsulated LV cells. The water from the springs will mix with seepage from the BRSF, and the mixed water will be captured at a detention pond just below the BRSF toe.

Construction sequence

The BRSF will be built in three phases, Phase 1 occupying roughly the southern third of the ultimate facility footprint, Phase 2 built to overlie the northern slope of Phase 1 and extending northward to occupy the medial portion of the footprint, and Phase 3 overlying the northern slope of Phase 2 and extending to the footprint's northern extremity.

The phasing is required to establish an early platform for a low-grade ore stockpile on the south slope of the BRSF as it is being built up. The stockpile will be built during the first few years of mining, and at the end of the project's life the stockpiled ore will be processed.

An engineered evapotranspiration cover (ET Cover) will be placed over the final slopes of the BRSF concurrently with their completion. This will occur first over the Phase 3 northern slope. It will occur later on the slopes covered by the low-grade stockpile, as those slopes are exposed during removal of the low-grade ore. The BRSF is designed to encapsulate the LV waste such that it cannot easily come in contact with water or oxygen. The plan will benefit from the clay content in the LV waste, and the silicification of the UV waste. Cells of LV waste will be created through waste sorting. The LV will be contained in cells that are isolated from seeps, springs, and groundwater from below, and isolated from meteoric water from above. Once a final surface is achieved, the encapsulation will be completed with the placement of the ET Cover. Figure 5 shows the configuration of the final encapsulation cells down the axis of the BRSF in the interim between the completion of the BRSF and the processing of the LGS.

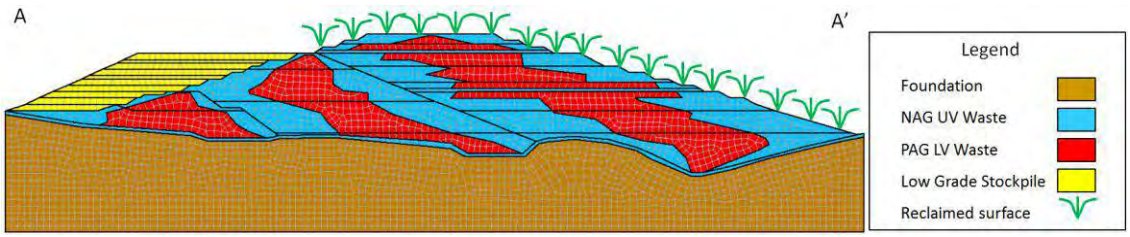

Figure 5 Cross section along axis of BRSF

PREDICTIVE MODELING OF BRSF LEACHATE AND RUNOFF

The BRSF encapsulation design is intended to minimize the quantity of mine waste leachate, and to isolate the LV formation from oxygen and water prior to the formation of biotic oxidation. Predictive modeling of moisture conditions within the BRSF was conducted to determine the quantity of leachate and surface runoff during operations and postclosure.

Numerical modeling of flow was done to generate a design that minimized seepage through the BRSF. The results of that modeling were then used as input to a geochemical model, which predicted the water quality of seepage. The flow modeling was done using Vadose/W (GeoStudio, 2014), a finite-element model that can comprehensively simulate the interaction of a range of

meteorological variables with the ground surface, and then simulate the flow of infiltrating water through both saturated and partially saturated material volumes.

Flow modeling approach

The flow modeling used a two-stage process. The first stage involved creating a series of one-dimensional transient column models, with each model representing a unique combination of materials and slopes. These models used daily variations in precipitation, temperature, wind speed, and relative humidity for a typical year, with the "typical year" based on several years of data from a nearby meteorological station representative of site conditions, to predict the variation of infiltration and runoff over time for each combination of material and slope for a single year. The typical year precipitation is ~680 mm, with half of the water content falling as snow. Summers are dry with rainfall occurring primarily in the spring or in October. The surfaces involved included LV waste, UV waste, and low-grade ore, as well as the various tested closure covers.

The second stage involved applying the infiltration predictions of the one-dimensional models to a transient two-dimensional model representing a cross section through the center of the BRSF (Figure 5). For the two-dimensional model, infiltration values determined for each combination of slope and surface material were set as prescribed boundaries, making it unnecessary to employ the computationally demanding climate functions for the larger two-dimensional model domain. Like the one-dimensional model runs, the two-dimensional runs included discretization of time into one-day increments, but the simulation covered the multi-year operations period and extended well into postclosure. The two-dimensional model dynamically tracked the development of the facility year by year, showing each phase's growth, the succession of phases, and the building and removal of the low-grade ore stockpile. Seepage rates were determined, and then those results were extrapolated to the third dimension to calculate the seepage flows that would report to the BRSF underdrain, and ultimately to the downgradient detention pond.

In addition to collecting seepage from the toe of the BRSF, the downstream detention pond also collects surface runoff from the facility. Runoff rates per unit area predicted by the one-dimensional models were used in conjunction with the scheduled change over time of areas of specified material and slope characteristics to predict the volume of ARD-impacted runoff water that would be received by the pond.

Predicted seepage rates

The modeling showed that seepage flow rates were comparatively small, both during the operations period and later during closure. This is largely a function of the climate. Essentially no infiltration occurs during the frozen-ground conditions of winter, and much of the year's precipitation total is lost either to sublimation of snow or to the spring runoff. Evaporative loss is also significant. During the operations period, when raw waste surfaces are exposed, the relatively dry waste has considerable ability to absorb such moisture as is available. However, the rapid growth of the waste pile means that any exposed waste surface has only limited time to take up additional moisture.

The cover consists of 0.2 m of soil over one m of compacted clay, above a capillary break layer 0.5 m thick. Because the crushed UV that will constitute the upper part of the encapsulation envelope is expected to have the hydraulic properties required for the capillary break, no separate layer is required.

Although infiltration of precipitation water into the accumulating waste is modest during the operations period, installation of the ET Cover further limits the amount of water that ultimately passes through the waste pile and emerges as seepage collected in the underdrain. This is not because the cover is impermeable; it is not. Instead, the cover functions as an effective store-and-release mechanism, allowing temporary storage of shallow-infiltrating water in the cover volume above the capillary break, but then yielding that water back to the atmosphere via evaporation in response to the high evapotranspiration potential that the site displays during much of the year. In the spring, the cover absorbs into storage to a maximum bulk moisture content of 20% (by volume). This storage is depleted by summer evapotranspiration.

Figure 6 shows the predicted flow of seepage from the base of the BRSF over time, subdivided according to the phase-footprint source of the water. The graph shows the gradual increase in total seepage flow as each phase is built, and as building of each succeeding phase begins. Seepage falls rapidly during the so-called "hiatus" period, when the flow of waste rock still being generated by ongoing mining is being diverted to backfill the early-mined pit volumes. Installation of the ET Cover takes place on the facility's completed final slopes (generally, those not occupied by the low-grade stockpile) at the beginning of that hiatus or earlier where possible, reducing infiltration rates over that area. When mining has been completed at the pits, removal of the low-grade stockpile begins. Concurrent installation of the ET Cover is done as the footprint of the stockpile recedes. After installation of the ET Cover is complete, seepage rates show a gradual decline in the early years of closure. The final predicted infiltration rate is ~1% of total precipitation. Field lysimeters will be installed to verify this modelled result.

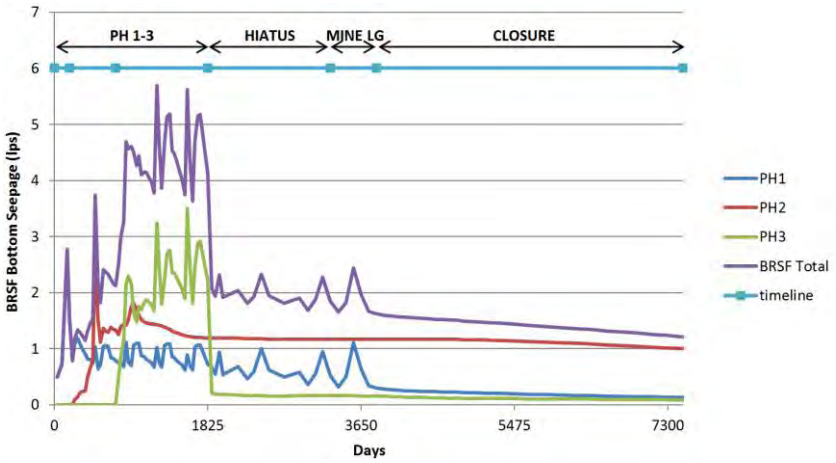

Figure 6 Predicted BRSF seepage flows vs. time

Maximum seepage rates of about five L/s are predicted during the three-year period that precedes the hiatus, with maximum rates around two L/s persisting through the end of removal of the low-grade stockpile. During operations all water is consumed, so that the cost of treatment is not an issue. From the beginning of the closure period onward, average seepage rates of less than two L/s are predicted, trending toward one L/s.

Moreover, the predicted seepage rates are small compared to the expected flow of water from the springs buried beneath the BRSF footprint. Although the spring-sourced flow rates will vary seasonally in a way that may not be synchronized with seepage from the BRSF, and the BRSF facility itself may cut off precipitation recharge to some of the source area of the springs, the water that ultimately reaches the toe of the facility will often be a mix of a small flow of ARD-impacted seepage with a larger flow of natural groundwater.

GEOCHEMICAL MODELING OF LEACHATE

In order to determine the effectiveness of encapsulation, the water quality in the BRSF was simulated using the PHREEQC geochemical model (Parkhurst & Appelo, 1999).

Oxygen penetration

Prior to geochemical modeling, it is necessary to simulate the depth to which oxygen can penetrate into the waste. This was done with Vadose/W, which has the capacity to calculate oxygen diffusion into materials based on pressure gradients, temperature gradients, and the degree of soil saturation. The oxygen consumption (from the production of ARD within the LV) and oxygen diffusion modeling showed that oxygen does not penetrate the ET Cover. It is assumed that the BRSF will always produce ARD and some oxygen consumption will occur within the LV. Figure 7 shows oxygen diffusion at its maximum extent in late summer, when moisture contents in the cover are at the lowest levels they reach prior to winter ground frost. As a conservative measure, it was assumed that the total depth of oxygen penetration was approximately 1.5 meters.

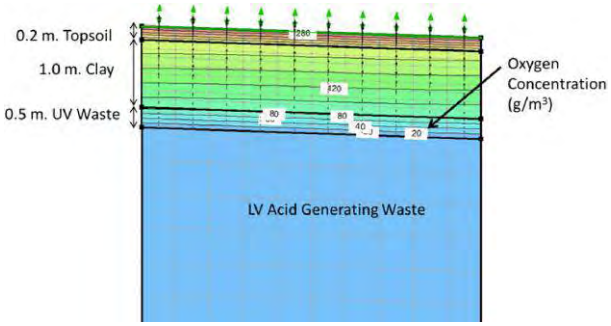

Figure 7 BRSF cover oxygen penetration

Conceptual model

The BRSF geochemical model determines the water quality of the BRSF basin discharge by determining the water quality of each of the flows that come together at the toe of the BRSF and by mixing the flows together in PHREEQC to come up with a resultant water quality.

Each flow is shown in Figure 8. Flows include: runoff from barren rock, runoff from unimpacted surfaces within the basin, seep and spring water, and seepage through the BRSF. The numerals shown in parentheses in Figure 8 represent the PHREEQC model solutions for the four designated water components discussed here.

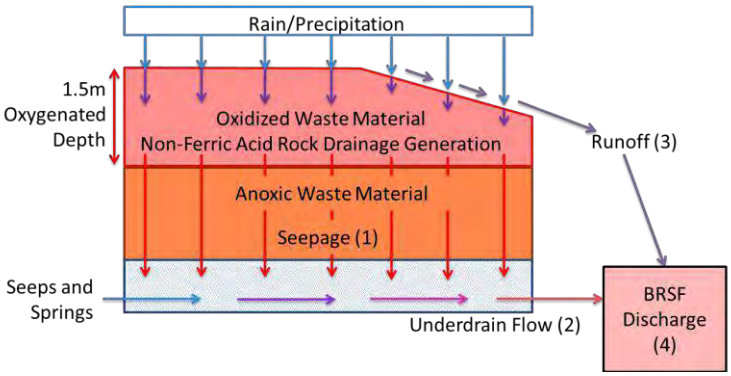

Figure 8 BRSF geochemical conceptual model

Seepage through the BRSF discharges into the BRSF underdrain (Solution 1 in Figure 8). Initial contact water solutions were compiled from weekly loading rates determined by the HCTs, total rock volume, and total seepage. Raw HCT results were used in order to provide a conservative ARD condition that reflects the ARD behavior of the samples tested. The loading rates were determined by first averaging the weekly concentrations of all constituents in the HCT leachate, then averaging each constituent's weekly averages. The rates were then applied to the total weight of rock within the oxygenated zone and the total seepage flow in order to simulate the initial seepage water quality (Solution 1). Solution 1 is then subjected to an oxygenated equilibrium followed by an anoxic equilibrium. These steps simulate the conditions in the top layer of the BRSF

(oxygenated) and deep within the BRSF (de-oxygenated), while allowing constituents to precipitate out in either condition.

Simulation of the underdrain water quality is derived by mixing the anoxic seepage mix (Solution 1) with the spring flow beneath the BRSF. The mix proportions are based on seep and spring surveys, and the seepage flows shown in Figure 6. BRSF seepage makes up from 16% to 37% of the mix. Spring water quality was based on samples taken during February, 2014. The mixture of spring water with the anoxic seepage greatly reduces the concentrations of metals and sulfate (Solution 2).

Runoff will also report to the BRSF pond, where it will mix with the toe discharge from the BRSF (Solution 2). Runoff water quality was determined by selecting a weighted average of the first eight weeks of the HCT results. Eight weeks is roughly the length of the Amulsar wet season (May and June), and therefore a reasonable contact time for runoff ARD reactions to occur. It is also important to note that rapid BRSF construction limits the potential contact time between runoff and LV mine waste. Runoff (Solution 3) mixes in the lined BRSF detention pond. During operations, this water is fully-consumed by the HLF. Upon closure, it must be treated prior to discharge. Figure 9 shows the predicted water quality. As a result of the LV waste encapsulation and the waste rock's natural resistance to biotic oxidation under site conditions, the modeling predicts that the Amulsar BRSF ARD seepage will be a moderate contamination source, with approximately 150 mg/L total acidity, 100 mg/L of sulfate, and pH of 3.8.

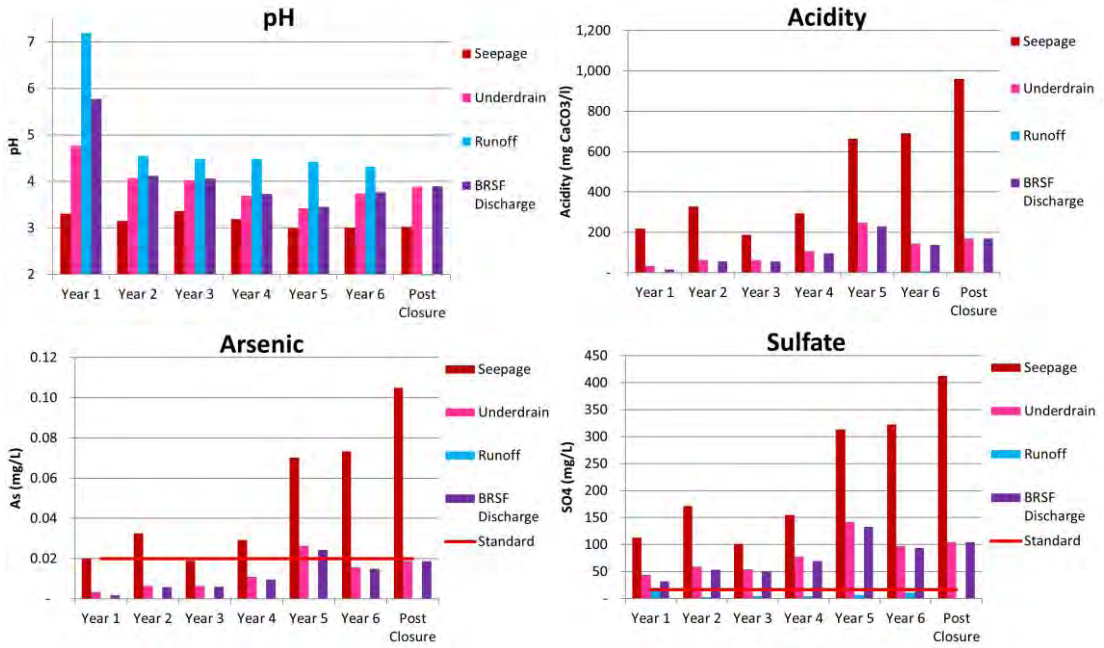

Figure 9 BRSF discharge water quality predictions

CONCLUSIONS

Characterization of Amulsar mine waste revealed that the LV formation has the potential to produce ARD. However, it is also apparent from mine waste exposed in the field that the waste has a resistance to the formation of the strongest level of ARD produced by sulfide-rich deposits. Biotic oxidation reactions catalyzed by *Acidithiobacillus ferroxidans* do not appear in the field, and only

occurred in two of eleven HCTs. The Project plans to take advantage of this natural resistance by encapsulating the LV mine waste within the BRSF in cells that isolate it from oxygen and water. Flow modeling confirmed that the mine waste maintains a low moisture content during construction, and when the waste is rapidly covered, flow through the mine waste can be reduced to a nominal one to two L/s. Oxygen also cannot penetrate the waste. Oxygen diffusion modeling showed that oxygen cannot penetrate the 1.2-meter-thick ET cover. Encapsulation is therefore feasible.

Geochemical modeling confirms that the encapsulation successfully controls and minimizes ARD. Not only is flow decreased, but the kinetics of geochemical reactions is sufficiently slowed to produce only mild ARD. Mild ARD makes passive treatment methods possible for long-term ARD management.

Prior ARD management plans, which did not consider the encapsulation option, required an active treatment system to control ARD. This would have necessitated construction of an active treatment plant for use during operations and continuing into postclosure, along with an extra clay under-liner in the BRSF. These factors resulted in a total project cost of US$101M for ARD management (net present value (NPV) calculated based on a three-percent discount factor).

The current plan, with the encapsulation and ARD mitigation measures described above, makes it possible for the mine to consume all ARD-impacted water during operations. In addition, the improvements in predicted water quality allow for passive treatment upon mine closure. These changes save the mine US$40M in capital and operating cost (adjusted for NPV). The resultant savings have a large positive impact on the NPV and IRR of the entire project while still meeting strict regulatory guidelines.

Geophysical Tools to Delineate ARD and Sulfate in Groundwater at a Former Sulfuric Acid Plant

Jennifer Cole[1], Albert Stoffers[1] and Roy Angelow[2]

ABSTRACT

During the operation of a former sulfuric acid plant located in Canada, sulfide minerals (e.g. pyrite, chalcopyrite), tailings and sulfuric acid were stockpiled on-site and imparted acidic solutions with high sulfate and metal concentrations to the subsurface. The topography is variable, from bedrock outcrops to 20 meters of overburden as clay, sand and gravel. Bedrock controls surface water and groundwater flows which include surface drainage ditches, marshes, an unconfined aquifer, and flow through fractured bedrock. After plant closure, historic remediation efforts included the removal of stockpiles, tailings and visually contaminated soil to the water table, lime amendment of soil at the water table, and importation of clean fill, which resulted in chemically heterogeneous subsurface conditions across the site. Most primary sulfide materials were removed except for sporadic zones that have the potential to generate acid rock drainage (ARD). Surface water and groundwater monitoring confirms near-neutral pH conditions with elevated concentrations of sulfate and metals at various locations throughout the site. Recent studies to delineate groundwater contamination and areas of active ARD included targeted soil and water sampling at select locations, which confirmed the heterogeneity of subsurface conditions. An electromagnetic geophysical survey was completed to minimize uncertainty and validate the results of previous investigations. It identified two zones of high conductivity, coinciding with high sulfate concentrations in groundwater and in static leaching tests on soil. Static test results confirm that soil collected from underneath the location of a former stockpile was depleted in buffering capacity, likely consumed by the infiltration of acidic drainage into the subsurface during plant operations. The results of the geophysical survey proved to be a cost-effective and efficient method to delineate the source and pathway of high sulfate in groundwater and thus demonstrated usefulness in assessing the environmental impact of high sulfide-containing mine wastes on groundwater quality.

Keywords: ARD, sulfate, conductivity, groundwater, geophysics

INTRODUCTION

The site is located on the north shore of Lake Huron (Aird Bay) in northern Ontario, Canada, near the community of Cutler. The 40 hectare site is the former location of the Cutler Acid Plant, a sulfuric acid production plant that was in operation from approximately 1956 to 1963. Iron sulfide minerals including pyrite and chalcopyrite were roasted to produce sulfuric acid, yielding a purple-red iron oxide/oxyhydroxide waste by-product. Historic facilities and structures on-site included the acid plant, pyrite unloading areas, sulfur stockpiles, acid storage tanks, fuel oil tanks, and a tailings storage facility and tailings pond. Site facilities are shown in FIGURE 1.

Figure 1 Site map showing operational facilities and site features

Plant operations resulted in subsurface contamination including the presence of sulfide minerals and acidic conditions in soil and elevated levels of sulfate and metals (Al, As, Cd, Co, Cr, Cu, Fe, Hg, Pb, Mn, Mo, Ni, Se, U, Zn) in groundwater and surface water . These contaminants were most likely introduced to the subsurface through sulfuric acid spills, leaking from acid storage tanks, and oxidation of sulfide minerals in the former stockpile areas and tailings pond.

In 1969, the acid plant and buildings on-site were demolished and debris was distributed across the site. Since then, the site has undergone several studies and remedial projects to address the presence of demolition debris and waste materials, as well as contamination related to the operation of the acid plant. Remedial efforts consisted of the excavation of building debris and visibly contaminated soils, after which both lime and clean imported fill was added in an effort to mitigate acidic conditions. These remedial efforts were limited to the depth of the fluctuating water table, leading to heterogeneous subsurface conditions observed presently on-site.

Past remediation efforts were not completely effective at removing all of the contamination associated with the former acid plant as localized areas of ARD potential in soil, high sulfate

concentrations in groundwater, and metal concentrations in soil and groundwater are still observed.

Various subsurface investigations have been completed in an attempt to delineate areas of contaminated soil in support of environmental site assessments (ESA), risk assessments, and remedial options analysis. Soil samples were recovered from test pits and boreholes to assess ARD and metal leaching potential through various static and kinetic test methods, and surface water and groundwater was also analyzed. Results of the various subsurface investigations confirmed the heterogeneous nature of the soil across the site. Local areas of ARD in the soil were identified, however it appears to be buffered locally as evidenced by neutral pH values in tested groundwater and surface water.

Due to heterogeneous conditions on site, a geophysical survey was conducted in lieu of an extensive drilling program in order to more efficiently delineate areas of subsurface contamination related to ARD and metal leaching, specifically those associated with historical plant operations and tailings storage. An electromagnetic geophysical survey well suited to mapping the apparent conductivity of the ground, including shallow buried metal objects, was completed on portions of the site. This approach has been used successfully at various other active and closed mine sites as documented by Gore & Olyphant (2010) and Schutts & Nicols (1991), Campbell & Fitterman (2000), and Paterson (1997). Areas selected for the geophysical survey were identified based on observed contamination and/or locations of historical operational infrastructure. The geophysical survey successfully identified areas of confirmed high sulfate in groundwater and was instrumental in delineating the probable sources and flow of high-sulfate groundwater on site.

SITE CONDITIONS

The site is located in an environment typical of the Canadian Shield with shallow bedrock, frequent outcrops, and poor drainage resulting in standing water. Undulating bedrock ranges from 16.5 meters below ground surface (mbgs) to surface outcropping. Three notable outcrops are present on site and control groundwater flow, including 1) the east shoreline bedrock outcrop, a large outcrop located at the shore of Aird Bay in the center of the site; 2) the west shoreline bedrock outcrop, a long and narrow outcrop on the west side of the site and on the shore of Aird Bay, and 3) the bedrock outcrop, a long and narrow outcrop in the southeast portion of the site perpendicular to the lake shore.

A large marsh is situated on the west boundary of the site and six streams and/or constructed ditches flow across the site and discharge into Aird Bay. The water table is shallow throughout most of the site; groundwater flows through both an unconfined aquifer and within fractured bedrock. Groundwater generally flows from northeast to southwest and discharges to Aird Bay between the west and east shoreline outcrops, as evidenced by downward vertical hydraulic gradients observed within all multi-level monitoring wells in this area. An area of up-ward groundwater flow (seep) exists between this zone of discharge to the lake and the adjacent marsh.

Overburden ranges from relatively coarse grained sand to a fine grained soil consisting of sand, silty sand, silt, and clay in varying proportions. Within the upper coarse grained layer, fill materials are largely comprised of sand similar in nature to that of native sand. Differentiation between native sand and fill materials is challenging unless obvious markers of fill material, such as an organic layer or anthropogenic debris, are present. Based on anecdotal information, it is understood

that fill materials of up to a thickness of two meters (m) have been placed over portions of the site. Field programs carried out to date have not identified any visible signs of lime in the soil.

Previous ESAs document metal concentrations above applicable provincial and federal guidelines in soil, groundwater, and surface water throughout the site (Ag, As, B, Ba, Cd, Co, Cr, Cu, Hg, Pb, Mo, Ni, Sb, Se, Sn, Tl, U, Zn). In soil, these elevated concentrations are clustered within several areas that generally correlate with previously identified and partially remediated contaminated areas and/or with former operational areas of the acid plant. Neutral to alkaline surface water and groundwater report various metal concentrations above guidelines at locations throughout the site; however metal concentrations are generally low and not observed to correlate with high sulfate above background concentrations. In Aird Bay near the east ditch discharge, the pH is neutral to alkaline and few parameters have been detected at concentrations above background concentrations and applicable guidelines.

METHODOLOGY

Subsurface Investigations and Soil Sampling

To date 105 test-pits and 33 boreholes have been completed in areas of previously identified contamination and near historic plant facilities to better delineate these zones. Test pits were excavated using a tracked excavator within and around previously identified areas of contamination as well as distributed in other areas of the site in an attempt to locate other previously unidentified areas of contamination.

Ten of the 33 boreholes were drilled using a hollow stem auger/rotary drill and a monitoring well was installed in each borehole. The remaining 23 boreholes were completed using a Geoprobe track-mounted drill rig and targeted areas of high conductivity identified in the geophysical survey. Of the 23 borehole locations, 11 were selected for the installation of monitoring wells screened within the overburden, two of which were multilevel wells. Boreholes were terminated after reaching refusal or to 1.8 m below the last visual sign of soil contamination. Sampling of overburden in each of the boreholes was carried out by the direct push of a 1.0 m long clear plastic Geoprobe sleeve into the subsurface at continual intervals. Geoprobe sleeves were inspected for any noticeable physical characteristics such as staining, evidence of lime or the presence of odors. Overall, 42 samples were collected for laboratory analysis on solid chemistry including sulfur speciation, acid base accounting (ABA), and soil leachate chemistry using the shake flask extraction (SFE) method.

Monitoring Well Installation and Sampling of Groundwater and Surface Water

Each monitoring well was constructed with threaded polyvinyl chloride (PVC) riser connected to a PVC well screen. The well screens were placed at depths intended to straddle the water table, and intersecting only a single overburden unit per screen where possible. Screen lengths were generally 1.5 m, however some subsurface conditions required a 3 m length.

Sampling of groundwater was conducted immediately following well development. Surface water was collected from identified monitoring locations in 4 streams / ditches. Samples were analyzed for general chemistry and total and dissolved metals; pH was measured in the field at the time of sampling.

Geophysical Survey

A geophysical survey was completed in order to further constrain localized ARD zones identified through the subsurface investigation, as well as areas between these zones that were not previously detected. This method was chosen because of its lower cost and short duration (two field days) compared with an extensive drilling program. The geophysical survey was completed using a Geonics EM31 and EM34-3, both of which are electromagnetic induction devices well suited to mapping apparent conductivity of the ground and shallow buried metal objects. The quadrature component measured by the EM31 system is sensitive to materials that have a low induction number, such as earth materials, or poorly conducting metallic targets. The EM31 quadrature response is calibrated to give a measure of the bulk apparent conductivity of the subsurface for a roughly hemispherical volume of radius 5 to 6 meters, centered at the measurement point. The in-phase component measured by the EM34-3 system is most sensitive to targets that have a high induction number and are good conductors, primarily larger surface and buried metal objects or very conductive groundwater such as brine. As such, the results provided by both the EM31 and EM34-3 are valuable in differentiating between buried metal objects and the apparent conductivity of the subsurface.

RESULTS AND DISCUSSION

Soil Chemistry

The soil chemistry of 81 samples was assessed through various static test methods. FIGURE 2 presents a frequency distribution diagram for pH values. A summary of select test results is provided in TABLE 1.

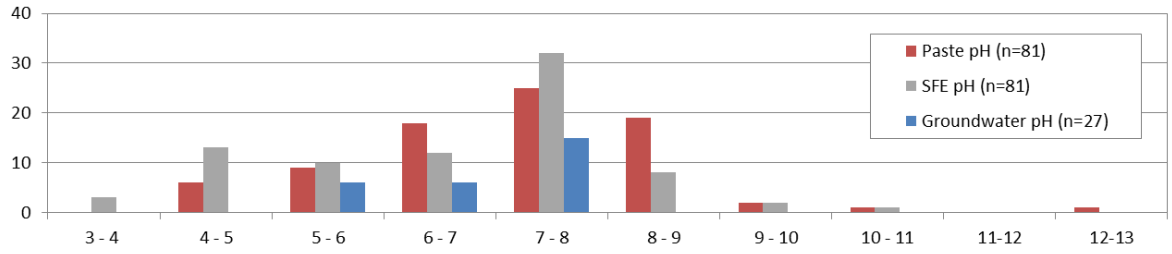

Figure 2 Frequency Distribution for paste pH, SFE pH, and groundwater pH

Table 1 Statistics for select static test results (n= 81 soil samples)

Parameter	Minimum	Maximum	Average
Total sulfur	<0.005%	5.4%	0.19%
Sulfide sulfur	<0.01%	5.3%	0.14%
Sulfate sulfur	<0.01%	1.3%	0.095%
NP	-7.8 t $CaCO_3$/1000t	166 t $CaCO_3$/1000t	13 t $CaCO_3$/1000t
CaNP	0.082 t $CaCO_3$/1000t	104 t $CaCO_3$/1000t	5.5 t $CaCO_3$/1000t
NNP	-164 t $CaCO_3$/1000t	166 t $CaCO_3$/1000t	10 t $CaCO_3$/1000t
NPR	-25	536	31
SFE Conductivity	24 µS/cm	2480 µS/cm	625 µS/cm
SFE Alkalinity	< 2 mg/L as $CaCO_3$	286 mg/L as $CaCO_3$	35 mg/L as $CaCO_3$
SFE SO4	2.1 mg/L	1800 mg/L	315 mg/L

Sulfate is the predominant form of sulfur in the tested soil, as indicated by high concentrations of sulfate compared with sulfide, resulting in low acid potential for most samples. Areas of high sulfide content are sporadically focused around the western part of the site near the former tailings pond, while the samples that dominantly contain sulfate sulfur are distributed throughout the site.

Mineral buffering capacity, defined as the neutralization potential (NP), is variable, with 72% of samples reporting low NP values between -7.8 and 11 tonnes $CaCO_3$/1000 tonnes. The buffering capacity of the samples is predominantly provided by alumino-silicate minerals with lesser carbonate minerals based on the lower calculated carbonate NP (CaNP).

Most tested samples (77%) have no potential to generate acid as indicated by net potential ratio (NPR) values greater than two (MEND, 2009) and neutral to alkaline paste pH values. Potentially acid generating (PAG) samples are sporadically located in the western half of the site around the former tailings pond area and were collected in shallow test pits (up to 3 m deep) above the water table.

Only a small portion of the tested soil samples (15%) were considered to be PAG under laboratory static test conditions. However, circum-neutral pH values in soil leachate and groundwater collected from within these areas suggest that there is sufficient buffering capacity in the system, possibly related to previous lime addition, to neutralize acid that may be generated from localized sulfide mineral oxidation. Therefore, ARD is not considered to be a dominant geochemical process on-site.

Short-term leach testing following the SFE method was used to assess the reactivity of the soil and its propensity to release metals to the receiving environment upon contact with water. Of the tested samples, 95% report circum-neutral SFE pH values. A handful of acidic pH values (3.0 to 4.3) were reported for soil from the eastern part of the site near the former acid storage tanks, but they were not associated with PAG areas and high sulfide content.

High sulfate concentrations in SFE leachate are documented from the following areas: former acid storage tanks, to the east of former process area, north and south of the former tailings ponds and around the former pump house. Samples from these areas also contain little to no buffering capacity (NP < 12 t $CaCO_3$/1000 t), yet report mostly circum-neutral leachate pH values between 4.5 and 8.0, suggesting no acid drainage is currently occurring in these areas. It is postulated that

previous sulfuric acid spills near the plant depleted the buffering capacity in the soil, resulting in a high sulfate charge and lower but not acidic pH values in the groundwater.

Groundwater Chemistry

In total 27 groundwater samples were analyzed for alkalinity, sulfate, conductivity, hardness and dissolved metals. A summary of the relevant parameters are presented in TABLE 2. A frequency distribution diagram for pH is presented in FIGURE 2.

Table 2 Select groundwater quality results (n= 27 water samples)

Parameter	Minimum	Maximum	Average
Conductivity	107 µS/cm	6150 µS/cm	1623 µS/cm
Alkalinity	<2 mg/L as $CaCO_3$	506 mg/L as $CaCO_3$	140 mg/L as $CaCO_3$
SO4	5.0 mg/L	5400 mg/L	886 mg/L

No correlation was identified between high sulfate concentrations in groundwater and the PAG conditions observed in soil samples from specific locations. Sulfate groundwater concentrations were measured above the maximum historical background groundwater concentration of 12 mg/L throughout most parts of the site (89% of samples), with average groundwater sulfate concentrations of 886 mg/L over three years of monitoring.

Anomalously high groundwater sulfate concentrations above 500 mg/L occurred in 56% of the samples. This correlated with high groundwater conductivity (>1500 µS/cm) and low alkalinity (<250 mg/L as $CaCO_3$) in the same samples. These trends were identified in the following locations: north of the west shoreline outcrop and south-southwest of the old Pow Wow grounds; east of the existing gravel parking lot; and northeast of the east shoreline bedrock outcrop in the area of the former acid storage tanks and sulfur stockpiles (FIGURE 3).

It is believed that historic plant activities in the northern part of the site introduced sulfate into the subsurface through sulfuric acid spills and leaks from the storage tanks, and/or infiltration from stockpiles where oxidation of pyrite was active.

These areas appear to be hydraulically connected to a zone of observed high groundwater sulfate (>1500 mg/L) in the southwestern portion of the site near the area of groundwater discharge (seep). In this area, the maximum concentration of sulfate in groundwater was observed (5400 mg/L). The high sulfate groundwater is believed to flow through fractured bedrock as evidenced by low sulfate concentrations in overburden groundwater between these two areas and higher concentrations of sulfate in bedrock wells (3300 mg/L) in the northeast area compared with adjacent overburden monitoring wells (470-1400 mg/L).

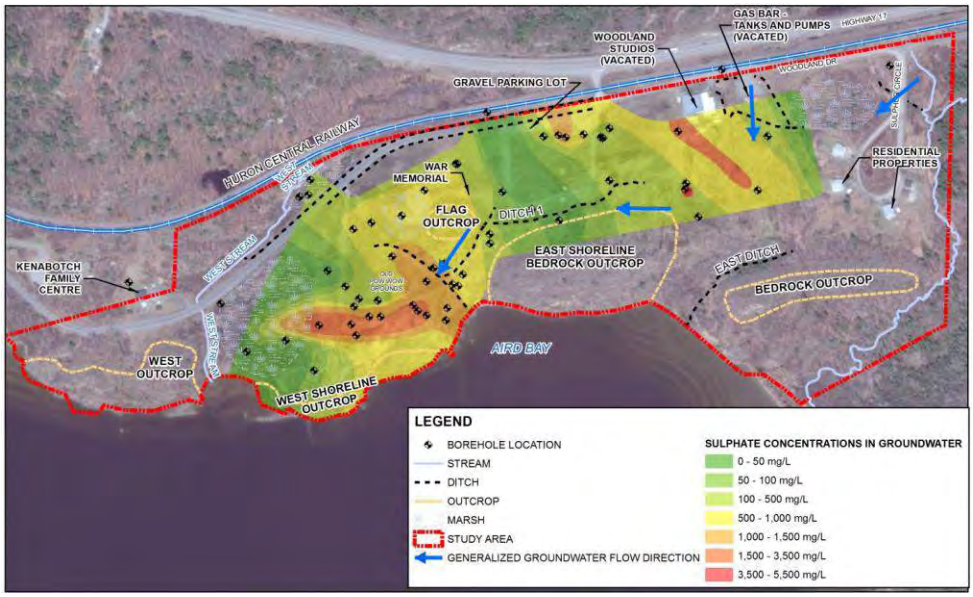

Figure 3 Sulfate concentrations in groundwater (mg/L)

Geophysical Survey

Geophysical survey results indicate that background terrain apparent conductivity values are between 10 and 20 millisiemens per metre (mS/m) in most soils and near 0 to 5 mS/m in the presence of bedrock outcrops or shallow bedrock. Anomalies above these ranges were observed in numerous areas on-site, with conductivity ranges between 75 to 115 mS/m. The results of the geophysical survey are presented in FIGURE 4.

Some of these high conductive areas are interpreted to have buried metal infrastructure from former and/or current site activities based on high in-phase results and documentation of historic remediation activities. The anomalous areas with elevated apparent conductivity readings that were not related to buried metallic objects are believed to be related to the occurrence of elevated sulfate concentrations in the groundwater or soil. These areas of high conductivity were targeted during a subsequent borehole program, with monitoring wells installed in some areas.

Sulfate concentrations measured within the bounds of the geophysical survey demonstrate strong correlation with the measured conductivity (Pearson correlation coefficient r=0.8 for n=15 samples). In the area where there is upward flowing groundwater (seep) in south west portion of the site, sulfate concentrations are greater than 1500 mg/L and up to 5400 mg/L. Conversely, in areas where the in-phase portion of the geophysical survey detected anomalies suggesting buried metallic objects, sulfate groundwater concentrations were in the 0-50 mg/L range (FIGURE 3 and FIGURE 4).

Figure 4 Electromagnetic geophysical survey results (mS/m)

CONCLUSION

During plant operations, sulfide minerals, tailings and sulfuric acid were stockpiled on-site and have historically imparted acidic and metal-loaded solutions to the subsurface through various processes. Site investigations to date identified that, despite remediation efforts, some soil remaining at site has the potential to generate ARD under laboratory conditions. However, sufficient buffering capacity maintains neutral pH conditions in groundwater in these areas.

The electromagnetic geophysical survey did not identify areas of active ARD but detected two conductivity anomalies that were found to correspond with areas of elevated sulfate concentrations in groundwater (500-5400 mg/L). The first anomaly is located in the northeast portion of the site where previous plant activities likely introduced sulfate into the subsurface. The second anomaly, which corresponds with the maximum sulfate concentrations detected across the site, is situated in the southwest portion of the site in the area of upward groundwater flow (seep) and is believed to be hydraulically connected to the first anomaly.

The strong correlation between the electromagnetic geophysical survey and measured sulfate concentrations suggests that geophysics is a useful tool to identify areas of high sulfate concentrations in the shallow subsurface. This tool could be an efficient method to monitor for acidic or neutral pH metal- and/or sulfate-rich waters that can migrate away from stockpiled waste rock and/or tailings storage facilities into the downstream environment.

ABSTRACT

The Osamu Utsumi uranium mine (Minas Gerais, Brazil) operated between 1977 and 1995. Today, INB (Indústrias Nucleares do Brasil) and CNEN (Comissão Nacional de Energia Nuclear) work in an attempt to recover the areas impacted by mining and mineral processing activities. In this paper, acid effluents and surrounding waters from a uranium waste rock pile were characterized. Hydrochemical computer modeling (PHREEQC 2) and spectral analysis of transient data were used. Superficial and groundwater samples were collected from the massive waste rock, bedrock, and surrounding areas. Results indicate the existence of two oxidation patterns within the waste rock. At the western region, waters coming from the massive waste exhibit low pH, high total dissolved solids and high levels of sulfate, iron and aluminum, which are characteristic of acid drainage. These ions are supersaturated or close to the saturation limit. The waters of the wells located to the east exhibit characteristics of natural waters and are saturated in iron oxides. Transient data analysis showed that manganese, uranium, and sulfate in the effluent have a delay of three months with respect to the peak rainfall during the rainy season. Under conditions of supersaturation, acid drainage products precipitate in the porous medium, they are washed out during periods of peak flow and then transported to the output point. The pH has a prolonged effect until the next rainy season, explaining the slight variations from 3 to 4, over the hydrological year. Spatial variations in oxidation within the pile and the residence time of water and discharge of reaction products should be used in the remediation design of this pile.

Keywords: acid rock drainage, decommissioning, hydrogeochemical modeling, waste rock pile, uranium.

INTRODUCTION

Mineral oxidation of sulphide ores is the main mechanism to generate acid rock drainage. These minerals, once exposed to ambient weather conditions, Eh and pH, and biological agents can generate acidity. Chemical species containing sulfur are the primary source of acidity. The formation of acid effluent is commonly associated with the occurrence of sulfide minerals such as pyrite (FeS_2), chalcopyrite ($CuFeS_2$), arsenopyrite (FeAsS), sphalerite (ZnS) and galena (PbS) (MEND/CANMET, 2009).

The sulfate ion (SO_4^{2-}) is the most oxidized sulfur form in natural waters. Dissolution of sulfated minerals can reduce the pH of the medium. The formation of acid rock drainage from pyrite follows reaction 1, where 2 moles of protons (H^+) are produced for each mole of the mineral:

$$FeS_{2(s)} + 3{,}5O_{2(g)} + H_2O_{(l)} \rightarrow = Fe^{2+}_{(aq)} + 2SO_4^{2-}{}_{(aq)} + 2H^+_{(aq)} \quad (1)$$

The oxygen from the air can oxidize sulphide minerals within waste rock piles. Sulphide oxidation is favored as greater is the availability of oxygen at the surface of the mineral. The oxidation produces a variety of secondary mineralogical phases, changing the characteristics of the solid phases, which can be leached upon contact with the aqueous phase of the system.

This paper presents a geochemical characterization of the water circulating through a uranium waste rock pile and adjacent regions. The studied uranium waste rock pile, named Bota-Fora 4 (BF4), is located in the ore Treatment Unit of Caldas (UTM), under management of the Indústrias Nucleares do Brasil (INB), in the city of Poços de Caldas, Minas Gerais, Brazil. The region where the project is located is named Campo do Cercado. The activities of mining and ore processing were closed in 1995, and currently the area lies in decommissioning and implementation of a plan of reclamation process. Poços de Caldas plateau consists in a round caldera of approximately 33km in diameter along the axis northwest-southeast, and extends over around 800km², constituting the largest alkaline complex of South America. Outer ring that forms the caldera has altitude between 1500-1700m, and the inner mountains have an average altitude of 1300m. The ring structure of the caldera is Mesozoic origin, composed of volcanic rocks (alkaline) and plutonic rocks, containing significant amounts of U, Th and rare-earth elements (REEs) (Holmes et al., 1990; Schroscher and Shea, 1991).

Uranium mineralization has been classified into three distinct ore bodies, named A, B and E, according to the concentration of uranium. The body A presents average uranium content of 600ppm. Structurally, it has been described as a monogenic volcanic gap formed by enclosing angular rock fragments of tinguaite. The body B has average uranium content of 680ppm, and it has been described as a large mass of holes, arranged in a matrix tube. The matrix showed a tinguaite rock texture with minerals like pyrite, fluorite, uranium minerals, molybdenum and zirconium. In small amounts galena, sphalerite and barite were found. The Body E has an average grade of 1000ppm uranium, and it consists of a package of host rocks, non-brecciated, containing secondary mineral phases arising from the action of redox phenomena (Gerência da Minas de Caldas, 1988 apud Souza, 1995; Cipriani 2002).

The Bota-Fora 4 (BF4) was built on the valley of Consulta stream, adjacent to the pit mine area, burying natural drainage. The valley was previously prepared with deep drains to receive waste rock. A diversion channel (approximately 500m length) was excavated in natural terrain along the

left flank of the valley. The channel was covered with a compacted clay layer to prevent infiltration of water from the stream in the pile (Souza, 1995; Franklin, 2007). Upstream of Consulta stream deviation channel, a basin was constructed in order to regularize the flow. Downstream of the pile, Nestor Figueiredo basin (BNF) was built to catch the acidic effluents generated in BF4. The Bota-Fora 4 (BF4) has $12.4x10^6 m^3$ and occupies an area of $56.9x10^4 m^2$. The waste rock pile contains cover material of the mine and sterile sorting of body B (Figure 1).

METHODOLOGY

Water sampling and chemical analysis

Two sampling campaigns were carried out during the dry season, in August 2011 and July 2012. The sampling method used to collect the surface waters and the procedures for the preservation of the samples followed NBR 9898 standard (ABNT, 1987). Figure 1 shows the sampling points of surface and groundwater. For groundwater sampling, disposable bailers samplers produced in high-density polyethylene (HDPE) with 19:35 mm in diameter and 970mm in length were used. The following parameters were measured in all water samples: pH, total dissolved solids (TDS), redox potential (ORP), temperature and electrical conductivity (in situ, with the aid of a multiparameter meter manufacturer Myron L. Company, Ultrameter IITM model 6P). Table 1 shows the parameters and analytical methods used.

Table 1 Methods used in chemical analysis.

Ion	Analytical method	Ion	Analytical method
Na	Atomic Absorption	Al	ICP-OES
K	Atomic Absorption	Mn	Atomic Absorption
Mg	Atomic Absorption	F^-	Potentiometry
Ca	Atomic Absorption	SO_4^{2-}	EDXRF
Fe	Atomic Absorption	Alkalinity	Titration

Time series of discharge of acid drainage and its chemical composition, monitored monthly during 30 months from January 2007 to June 2009, were selected for spectral analysis (Fig. 2, Fig. 3 and Fig. 4). Time series for U, Mn, SO_4^{2-}, pH, acid discharge and precipitation (Fig. 5) were used. Selected chemical species have relevance for the treatment of effluents and for understanding the process generation of acid rock drainage.

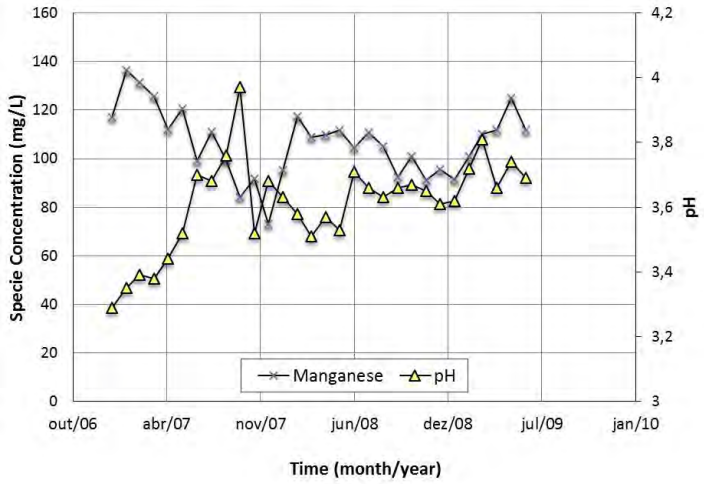

Figure 3 Time series of manganese and pH monitored from January 2007 to June 2009

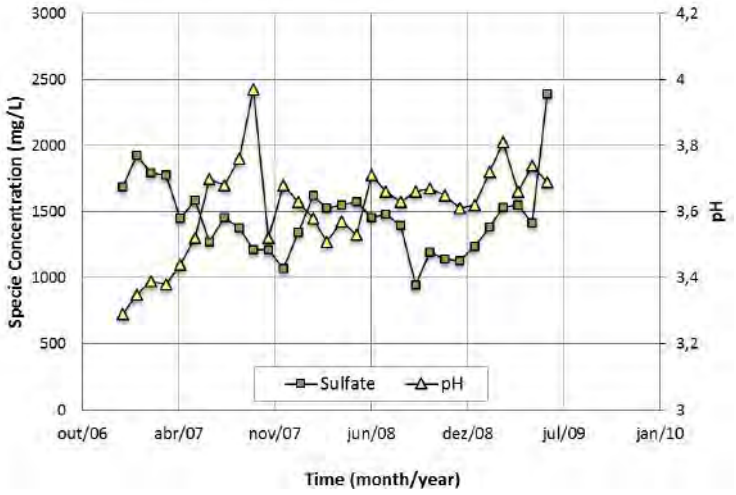

Figure 4 Time series of sulfate and pH monitored from January 2007 to June 2009

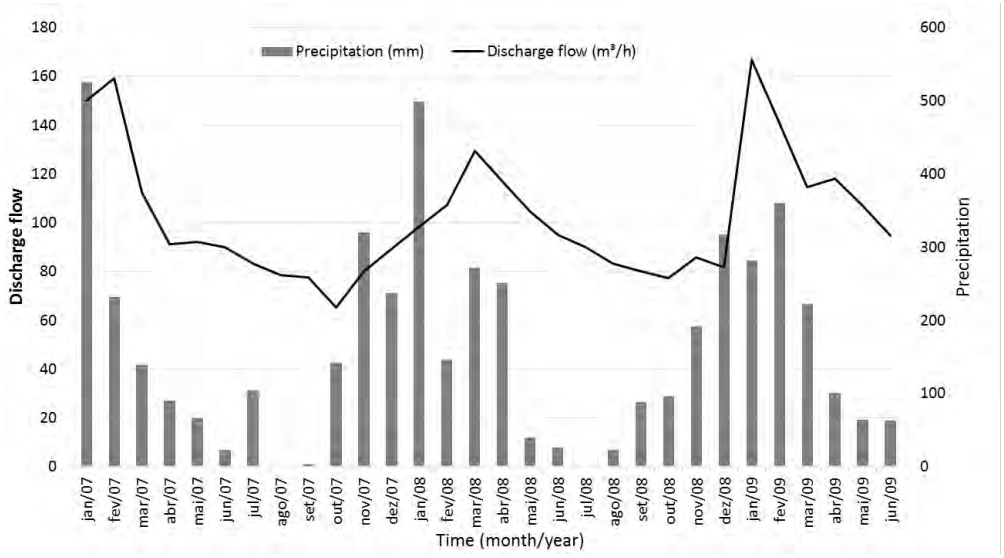

Figure 5 Time series of discharge flow of acid rock drainage and precipitation from January 2007 to June 2009

Data processing

The ionic concentration in the water is the product of geochemical reactions between the aqueous phase and the geological medium under certain environmental conditions. For evaluating the chemical evolution of water quality and the probable chemical reactions, a computational hydrogeochemical modeling was carried out using the software PHREEQC 2 (Parkhurst and Appelo, 1999).

Finally, the set of monitoring data of discharging acid drainage was analyzed by means of autocorrelation functions and cross-correlation. The former function considers the relationship between successive terms of a single time series and provides information on the duration of the

influence of an event in the system. The later function connects the sets of input and output, and indicates how they are correlated. The gap between zero and the maximum of the cross-correlation function, called delay, indicates how stress propagates thought the system.

RESULTS AND DISCUSSION

Computer modeling indicated a supersaturation of the samples of P1, P4 and PM-04 in chemical species containing iron (hematite, goethite and magnetite) and close to saturation limit of ferrihydrite. P1, P4 and PM-04 are also close to the saturation limit in relation to carbonated phase (calcite and aragonite). Non-precipitation of goethite in PM-41 and PM-43, unlike what happen in P1, P4 and PM-04, takes place at the higher pH, which favors the preferential formation of hematite (Tremocoldi, 2003). The preferential precipitation of magnetite compared to hematite takes place under reducing conditions, which is a characteristic of groundwaters.

Samples of the monitoring wells P3, PM-03, PM-40, TRINE and BNF are close to limit of saturation with respect to calcium sulfate (anhydrite or gypsum). PM-40 and P3 capture water from the bedrock of the terrain, below the BF4, have greater similarity in relation to the others. These samples are supersaturated in magnetite and close to the saturation limit in goethite and siderite. P3, PM-03, PM-40, TRINE and BNF are saturated in magnetite. This behavior highlights the trend of leach mineralogical phases containing iron, as expected in acid drainages. In addition, PM-03 and P3 samples, located side by side, are supersaturated in uranium, leading to precipitation of U_3O_8, U_4O_9 and uraninite. The sample of groundwater PM-36, located downstream of the waste rock pile did not show supersaturation in the evaluated phases. The control sample P-800 of surface water upstream of BF4, was supersaturated on hematite, goethite and magnetite.

Autocorrelation results presented similar buffer time, i.e., the duration of the influence of an event for all parameters analyzed, as showed on Table 3. Table 4 and 5 present the results for the cross-correlation. They present the response time of a phenomena (precipitation or discharge) and the signal propagation time in the system, i.e., how long the input phenomenon will affect the output phenomenon. According to the cross-correlation, the discharge on BNF (input parameter) is positively correlated to the chemical parameters (output). This implies that the increase in flow provides an increase in the concentration of U, Mn and sulfate, and a reduction of the pH (increase in H^+ concentration).

During the dry season, secondary phases are precipitated and/or adsorbed in the pores of the pile. With the onset of the rainy season, these species are leached and their peaks occur during this period. This period coincides with the seasonal dry and wet periods, explaining the formation of acid rock drainage throughout the hydrological year.

Such analysis allows us to infer on the hydraulic and geochemical behavior of the pile. After the onset of the rainy season, the pile will reflect an increased flow after 1.2 months. After three months, the pile will start to discharge the stored water in previous refills. The response of the system to the rainy season lasts about 4.8 months, i.e., nearly until the next rainy season. This explains the occurrence of discharge even during dry season. With the beginning of the discharge, the chemical species will be released after 3 months. It implies that these contaminants were leached and subsequently stored until their release in the medium. The release of contaminants

implies in a reduction of the pH. Contaminants as ferric ion is very effective to maintain low pH conditions due the low solubility of ferric hydroxide and to the release of protons by the hydrolysis reaction. It effect extends until the next rainy season.

Table 3 Autocorrelation function results.

	Buffer time (month)	**Correlation**
U	2.5	0.7
Mn	2.5	0.6

Mn	2.5	5.8	0.6
SO_4^{2-}	2.5	5.4	0.6
pH	3.0	6.8	0.7

CONCLUSIONS

Two distinct hydrochemical patterns were identified. The western region of the cell, adjacent to the mine pit, preferably oxidizes and generates more acid effluent compared to the eastern region. The transient analysis of the discharges of Mn, U and sulfate in the acid mine drainage showed a positive correlation with flow, indicating that these species are precipitated and/or adsorbed in the pore media during dry periods and have their peak discharge after the beginning of the rainy season, indicating the occurrence of a leaching process. The pH has prolonged effect over 6 months, which explains the presence of acid drainage throughout the year hydrology.

The behavior of chemical species observed in the spectral analysis of monitoring data is corroborated by the results obtained by computational modeling. Acidic effluents are presented

supersaturated or near the saturation limit for Mn containing species, U and sulfate. It is highlighted by the occurrence of Mn concentrations close to saturation limits. The leaching process and subsequent saturation of aqueous species of Mn in the water appears as a phenomenon occurred independently of the formation of acid rock drainage.

ABSTRACT

Fixation of CO_2 by brucite or serpentine is widely recognized as a passive way to reduce carbon footprint. Ultramafic rocks are rich in minerals with high potential to sequester CO_2 in ambient conditions and are sometimes associated with base metals, such as Ni. Extraction of these base metals can lead to exposure of ultramafic wastes to atmospheric conditions, such as in the case of the Dumont deposit (Royal Nickel Corporation) near Amos, Quebec, Canada. The wastes of this future open pit mine are low in sulfide content (<1 %) and rich in ultramafic minerals with significant potential to trap atmospheric CO_2. This natural process, leading to the precipitation of stable carbonates, can influence the long term drainage water quality of the wastes. The aim of this study is to predict the geochemical behavior of such wastes, as well as the impact of CO_2 sequestration on drainage water quality. The five main lithologies found in the Dumont deposit were sampled, and a combination of these lithologies was studied as waste rock, whereas a tailings sample was produced by pilot scale metallurgical testing. All samples were submitted to laboratory kinetic columns tests and to CO_2 consumption tests. The results suggest that dissolution of Magnesium silicates and precipitation of secondary Magnesium carbonates are the main geochemical processes controlling Mg, Ca, and Si concentrations in the leachates, and generating high alkalinity values. The ultramafic lithologies, which fix CO_2, show alkaline drainage, with pH values varying from 9 to 10, versus 7.0 to 8.5 for non-ultramafic samples. These results help understand the mechanisms of CO_2 sequestration by mine wastes and its impact on water quality.

Keywords: mine wastes, ultramafic rocks, carbon sequestration, kinetic columns tests, alkaline drainage

INTRODUCTION

Ultramafic rocks are considered to be good candidates as an anthropogenic carbon sink. Many studies highlight the use of ultramafic rocks with high concentrations of serpentine (lizardite, chrysotile) and brucite to react with CO_2 (Goff & Lackner, 1998; Lackner et al., 1995). There are large amounts of mafic and ultramafic rocks scattered in the earth's crust. These rocks are sometimes associated with base metals, and their extraction leads to the exposure of mine wastes at the surface. Even though the fixation of CO_2 by magnesium silicates is a slow process, the exposure of significant quantities of mining wastes with high concentrations of serpentine minerals can reduce the carbon footprint of the mining activities (Harrison et al., 2013). Carbon sequestration by mine waste is very attractive because of the quantities that are produced during mining. Furthermore, these materials are often finely ground, which increases the exposed surface area.

Existing literature on carbon sequestration by mining wastes focuses mainly on the estimation of their sequestration potential or on the evaluation of factors that potentially affect their sequestration potential, such as temperature, surface passivation, or degree of saturation (Assima et al., 2014; 2012). Many research projects also focused on techniques to accelerate the process, in order to fix more Carbon and to move to the industrial scale (Larachi et al., 2010). Fixation of CO_2 by Mg or Ca silicates, also called mineral carbonation, likely occurs in the mine tailings in the following steps: (1) dissolution of CO_2 into interstitial water; (2) acid release is consumed by silicates which release Mg^{2+} or Ca^{2+}; (3) reaction between Mg^{2+} or Ca^{2+} with HCO_3^- or CO_3^{2-} to form stables carbonates under ambient conditions (Harrison et al., 2013; Wilson et al., 2009a). Processes leading to the formation of stables carbonates can impact the quality of mine drainage. As reported by Bea et al. (2012), Carbon sequestration by ultramafic tailings at Mount Keith (Australia) leads to alkaline drainage with pH varying from 8 to 10. Wilson et al. (2009b) suggest that precipitation of nesquehonite in kimberlite processing wastes could increase their neutralization potential by 1-2 %. Rollo and Jamieson (2006) also report that dissolution of chrysotile and precipitation of Magnesium carbonates are an important process affecting pore water composition at the same site. Thus, it is important to consider the Carbon sequestration potential of ultramafic mine wastes in order to predict the drainage water quality.

The wastes studied here are those of the Dumont project of Royal Nickel Corporation, an open pit project located 25 km west of Amos in the Abitibi-Témiscamingue region, Québec, Canada. The project intends to mine and process a deposit of Nickel mineralization which contains 2 types of mineralization: Nickel sulfides (pentlandite, millerite) and an Iron-Nickel alloy (awaruite). The operation plans to treat up to 105 tons/day of ore at an average grade of 0.27 % Ni, over a lifetime of 31 years. The deposit lies within a mineralized zone of serpentinized dunite, composed mainly of serpentine, and minor minerals including magnetite, brucite, chlorite, diopside, and chrysotile. Waste rocks are composed mainly of peridotite, gabbro and basalts containing serpentine, chromite, clinopyroxene, , quartz, and plagioclase (RNC, 2012). Previous work on the Royal Nickel wastes have highlighted their ability to fix Carbon (Plante et al., 2014; Awoh et al., 2013; Pronost et al., 2011), due to high serpentine concentrations in the wastes. (Pronost et al., 2011). Eudiometer tests

show that brucite and serpentine could react with CO_2 to form stable hydrated Magnesium carbonates (Pronost et al., 2011). The carbonates formed are dypingite $Mg_5(CO_3)_4(OH)_2$-$5H_2O$) and nesquehonite $Mg(HCO_3)(OH)$-$2H_2O$) (Pronost et al., 2011). Awoh et al. (2013; 2014) developed an innovative CO_2 consumption test in order to quantify the CO_2 flux sequestered by mine wastes. Results of the various laboratory and *in situ* CO_2 consumption tests suggest that the Dumont wastes sequester CO_2 fluxes of up to 1400 g/m^2/year in typical ambient conditions. These studies have also shown that the non-ultramafic lithologies of the Dumont deposit do not consume CO_2. CO_2 consumption tests also show that a specific water content is required for optimal carbonation (Assima et al., 2012; Awoh et al., 2013). Since CO_2 sequestration involves the precipitation of secondary carbonates that may affect water quality, the aim of this work is to predict water quality of the future Dumont wastes and the impact of Carbon sequestration on the quality of the drainage water from the Dumont wastes.

MATERIALS AND METHODS

Materials characterization

Different types of waste rocks from the Dumont project were sampled for the present study: one tailings sample, one ultramafic waste rock sample, and 5 samples of the main lithologies found in the Dumont project (low grade dunite, upper peridotite, footwall ultramafic (which is dominantly peridotite)gabbro, and volcanic basalt). The tailings sample was produced in a pilot-scale plant, while the ultramafic waste rock was taken from a bulk sample at the site consisting of dunite and peridotite. The five main lithologies were sampled from representative sections of drill core.

All samples were characterized physically and chemically. The chemical characterization was performed after an acid digestion (HNO_3-Br_2-HF-HCl) followed by ICP-AES analysis of over 20 elements. A whole-rock analysis of major elements of the Dumont samples was performed by X-ray fluorescence (XRF) following a Lithium borate fusion on pulverized sample aliquots (85 % < 200 mesh) by Acme Analytical Laboratories Ltd, Vancouver, Canada. The detection limits of the chemical characterizations of the oxides ranged between 0.001 and 0.1 %. Results of major elements are presented in Table 1. These results, combined with X-ray diffraction (XRD) analysis, allow identifying and quantifying minerals present in the samples. The tailings and ultramafic lithologies (low grade dunite, upper peridotite, footwall ultramafic) contain between 34.06 % and 42.68 % MgO. The gabbro and volcanic (which are not ultramafic materials) contain 9.96 % and 6 % MgO, respectively. All wastes contain significant amounts of SiO_2between34.17 (footwall ultramafic) and 49.27 % (gabbro). While the theoretical ratio of MgO/SiO_2 in serpentine equals 1.00, it is >1.00 for the tailings, low grade dunite, upper peridotite, and footwall ultramafic samples, suggesting an excess of Mg which can be attributed to brucite, $Mg(OH)_2$. Iron is present in all samples, with Fe_2O_3 concentrations between 5.82 % and 12.62 %. The gabbro and volcanic samples also contain more Al_2O_3 (13.41 and 14.07 %, respectively) and CaO (11.97 and 9.78, respectively) compared to the other samples (Al_2O_3: 0.22-3.08 %; CaO: 0.05-0.86 %), revealing the differences in mineralogical compositions between the non-ultramafic samples of gabbro and volcanic in comparison to the other materials. The initial total carbon and sulfur contents of samples were measured by a LECO carbon/sulfur analyzer (Maxxam Analytical, QC, Ca) with a reportable detection limit of 0.05 %.

The highest concentration of carbon was detected in the volcanic sample, due to the presence of calcite (0.8 %). The tailings, waste rock, low grade dunite, upper peridotite, gabbro, and footwall ultramafic contain similar carbon concentrations (between 0.12 and 0.17 %). The highest sulfur content was measured in the tailings sample with 0.2 %, while other samples contain less than 0.08 %.

X-Ray Diffraction results coupled with oxides and trace elements analysis indicate that the matrix of ultramafic samples such as tailings, waste rock, low grade dunite, upper peridotite, and footwall ultramafic is composed mainly of serpentine ($(Mg,Fe)_3Si_2O_5(OH)_4$). Other minerals are also, present such as brucite ($Mg(OH)_2$), magnetite (Fe_3O_4), and chlorite ($(Fe,Mg,Al)_6(Si,Al)_4O_{10}(OH)_8$). The waste rock sample also contains albite ($NaAlSi_3O_8$) and quartz (SiO_2). The gabbro and volcanic contain predominantly hornblende and epidote, with lesser quartz, albite, and diospide ($CaMgSi_2O_6$). The volcanic sample contains around 5 % calcite ($CaCO_3$). There is no serpentine detected in the gabbro and volcanic samples.

Table 1 Chemical composition (major elements) of the Dumont samples

	Ultramafic Waste rock	Tailings	Gabbro	Low Grade Dunite	Upper Peridotite	Volcanic (Basalt)	Footwall ultramafic
%SiO_2	41.40	35.10	49.27	34.53	35.83	47.93	34.17

The <2 cm fraction of the samples was selected for this study, and the grain size distribution was analyzed by sieving for the fraction between 2 cm and 355 µm. The tailings and the <355 µm fraction of the other samples was analyzed with a Malvern Mastersizer S laser grain size distribution analyzer. The main characteristics of the particle size distributions are shown in Table 2. The waste rock sample contains more fines (10% <355 µm) compared to the lithology samples (less than 4 %< 355 µm) because of the difference in the sampling method. This higher fine content in the waste rock sample could lead to a higher reactivity (due to the higher specific surface) compared to the lithology samples in the present study.

Kinetic column tests

Samples from the Dumont project were submitted to laboratory kinetic column tests. Approximately 20 kg of coarse material were deposited in plexiglass columns of 14 cm in diameter and 90 cm in height, while 8 kg of tailings were deposited in a column of the same diameter (14 cm) but lower height (60 cm). The interior of the tailings column was coated with vacuum grease in order to avoid preferential flow along the column wall. A porous ceramic plate was installed at the bottom of the tailings column in order to control the suction potential at a value of 1 m below the tailings. A volumetric water content probe and a dielectric water potential probe were installed 15 cm from the bottom of the tailings in the column. A geotextile was put at the base of the other columns in order to retain the fines within the column. The columns are flushed with 2 L of deionized water every two weeks for the waste rock and lithology samples, and once per month for the tailings column. The deionized water used has a pH between 5.5 and 6 and its carbonate content is negligible. The leachates were recovered after a contact time of a few hours. The column tests were run for over one year for coarse materials and for 2 years for tailings. Thermodynamical equilibrium calculations using Vminteq version 3.0 (USEPA, 307 1999) were performed on data from kinetic column tests in order to identify the different carbonates generated during kinetic tests. CO_2 consumption tests were performed on the columns each week. Detailed results of CO_2 consumption tests are not presented here, but they reveal that the gabbro and volcanic do not consume CO_2, while all other samples do (Plante et al., 2014; Awoh et al., 2014, 2013). The calculated fluxes for the tailings column vary between 50 and 800 g/m^2/year, depending on the interpretation method used and the water content. For coarse materials, the estimated fluxes reached up to 1400 g/m^2/year.

RESULTS AND DISCUSSION

Leachates recovered after each flush were analyzed for several parameters such as acidity, alkalinity, pH, electrical conductivity, and dissolved and total metals by ICP-AES and ICP-MS, and various anions by ionic chromatography. Only pH, sulfate, Mg, Si, and Ni are presented here. The pH of the leachates stabilized quickly for all materials and do not show a transitional phase, except for column tailings. The lithologies which do not sequester carbon (gabbro and volcanic) have a pH around 8.5, while other lithologies (low grade dunite, footwall ultramafic, upper peridotite) and the waste rock have a pH between 9.0 and 10. For tailings, the pH leachate remained near neutral (between 7.0 and 8.5) during the first 200 days, before gradually increasing and stabilizing between 9.0 and 9.5.

The lower pH observed during the first cycles for the tailings can be explained by the slower diffusion of CO_2 through the tailings than through the coarser waste rock and lithology samples, leading to a slower CO_2 sequestration and, therefore, a slower effect on leachate pH. The leachates of the ultramafic materials (tailings, ultramafic waste rocks, low grade dunite, upper peridotite, footwall ultramafic) contain high Mg concentrations (around 50-100 mg/L). In these types of wastes, Mg comes from the dissolution of serpentine and/or brucite with dissolved CO_2. For gabbro and volcanic, Mg in the leachates ranges from 1 to 5 mg/L, probably from the dissolution of gangue minerals such as hornblende and chlorite. The Si concentrations in the tailings leachates (which vary from 20 to 80 mg/L) are higher than in the other leachates. For gabbro and volcanic, Si varies from 1.7 to 5.7 mg/L. The other samples only show Si in some of the last leachates (0.1-1.0 mg/L) at the end of the kinetics test. The ratio of Mg/Si concentrations are very high, which suggest an incongruent dissolution of serpentine with a preferential release of Mg over Si and/or a fastest dissolution of brucite compared to serpentine (Assima et al., 2013; Harrison et al., 2013). All columns produce alkalinity and highest values were obtained for waste rock (275-300 mg $CaCO_3$/L) compared to other lithologies (<20 mg $CaCO_3$/L). The alkalinity in the tailings leachates increase with pH and stabilize around 200 mg $CaCO_3$/L after 400 days, probably due to the gradual buildup of secondary carbonates within the tailings. The metal concentrations remain very low during the column tests. For example, the Ni concentrations are shown in Figure 1; all leachates show very low Ni concentrations not exceeding 12 µg/l, and often below the detection limit (1 µg/L).

The sulfate release rates were calculated from the cumulative leached masses for the samples leaching regular detectable sulfate concentrations (Table 3). These results indicate an increase of sulfate release rate for tailings from 0.89 g/kg/d to 1.25 mg/kg/d at 290 days. Saturation indexes calculated indicate that a variety of calcium and magnesium carbonates may precipitate (Table 4). No carbonate is suggested to precipitate in the volcanic column and before day 290 in the tailings, when pH is near neutral. It suggests that carbonate precipitation occurs at alkaline pH values for tailings column. The most common magnesium carbonates to precipitate are magnesite and hydromagnesite.

At the end of the kinetics tests, all columns were dismantled and the final carbon content was determined for the first layer of the column, the first 5 cm for waste rock, tailings and footwall ultramafic, and for the first 10 cm of the others columns. The initial and final carbon contents are shown in Table 5. All materials show an increase in total carbon content except for the gabbro. The carbon enrichment for volcanic needs further investigation, since no CO_2 consumption is observed in that lithology. According to the carbon enrichment during the kinetic tests, the Dumont wastes can fix between 4 and 15 kg of CO_2 per ton of waste exposed at the surface, although the scale-up of these results to the large scale still needs to be investigated. Also, cementation was observed in the first 5 cm of the column for all samples that consume CO_2. Examples of cemented phases found in the columns are shown in Figure 2. The precipitation of secondary magnesium carbonates probably cemented the grains in the columns. The cementation of surface mining wastes due to mineral carbonation is already reported for chrysotile mine wastes in southern Québec, Canada (Beaudoin et al., 2008; Assima et al., 2012, 2013) and for ultramafic wastes of Cassiar and Clinton Creek in the Yukon Territory and British Columbia, Canada (Wilson et al., 2009a).

CONCLUSION

Previous studies have confirmed the capacity of the Dumont wastes to sequester CO_2, and our investigations show that this process has an effect on the drainage water quality, as it leads to alkaline drainage with pH values up to 10. However, metal concentrations in the leachates remain low. The exact nature of the secondary carbonates formed will be investigated in the coming months. Cementation of the grains upon Carbon sequestration might reduce wind erosion and dust generation from the future waste rock piles and tailings ponds.

A Management Plan towards the Flooding of an Open-Cast Mine with Adjacent Underground Sections

Eelco Lukas and Danie Vermeulen

Institute for Groundwater Studies, University of the Free State, South Africa

ABSTRACT

The colliery is situated in the Mpumalanga Coalfield, north of Trichardt in the Republic of South Africa. The opencast is already rehabilitated but still acts as an entrance to the underground sections of the mine. The *Life of Mine* indicates active mining until 2035. We were tasked to develop a mine closure plan. Two surface drainage systems are present, namely the Trichardt Spruit and the Steenkool Spruit. Both these systems have been diverted locally around the opencast with the necessary permission, to maximize coal extraction and protect the environment. Several passive treatment options were tabled to minimise the post closure environmental contamination. After careful consideration it was decided to develop a mine flooding plan to exclude oxygen from the mine thereby minimising the sulfate generation inside the opencast and underground sections. To start flooding as early as possible, sections of the underground mine were identified as natural or artificial compartments to store water. The rehabilitated opencast is flooded using recharge from rainfall only. The sulfate content of the decant water is expected to decrease and only passive treatment options will be needed to improve the water quality so that the decant water may be released into the streams.

INTRODUCTION

The colliery is situated in the southern portion of the Witbank Coalfield, being part of the larger Mpumalanga Coalfields in South Africa. The coal is extracted by opencast and underground mining methods. The opencast mining was done in virgin ground, hence dewatering of existing underground workings was not needed. During the mining operations the spoils (overburden) is placed back in the pit. The spoils are levelled according to a surface plan and covered with topsoil and seeded. The opencast mining has since ceased and the rehabilitation has been completed. The underground mining, which consists of four different sections and is connected to the opencast, is by bord-and-pillar method only (**Figure 1**). The life of mine plan does not include any high-extraction and is projected until 2035 after which the mine will apply for closure. Legislation in South Africa requires that water decanting from a mining environment needs to be treated before it may be released into a stream or canal.

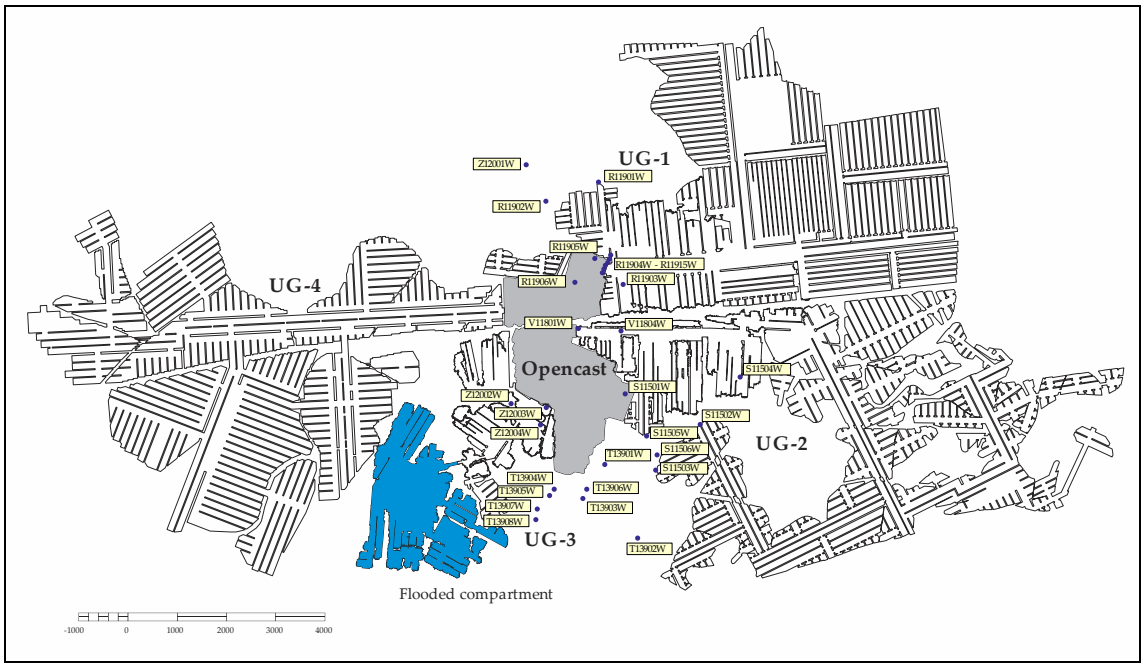

Figure 1 The opencast mine with the connected underground sections and monitoring boreholes.

METHODOLOGY

The underground workings are currently dry, except for one flooded compartment in the southern part of UG-3 (**Figure 1**). The opencast and all the underground sections have mined the same coal seam. This means that the floors of all the sections are connected. After mining has ceased the workings are allowed to be flooded. Water levels in the underground sections and opencast will rise together. The waterbody inside the workings will behave like a water table, or unconfined aquifer. Recharge in the opencast is much faster than in the underground. This means that the water level in the opencast will rise much quicker which in turn will lead to a water flow from the opencast into the underground sections. When the underground workings are completely filled, recharge to these workings will stop and only the opencast will continue to recharge. As the water table rises in the opencast sections so will the pressure in the connected underground and the waterbody in the underground will change into a confined

aquifer (the permeability of the roof is much lower than the permeability of the cavity). The water table will continue to rise until the system starts to decant. The decant position and elevation (meters above sea mean level, mamsl) was determined using the surface contours and opencast outline (**Figure 2**).

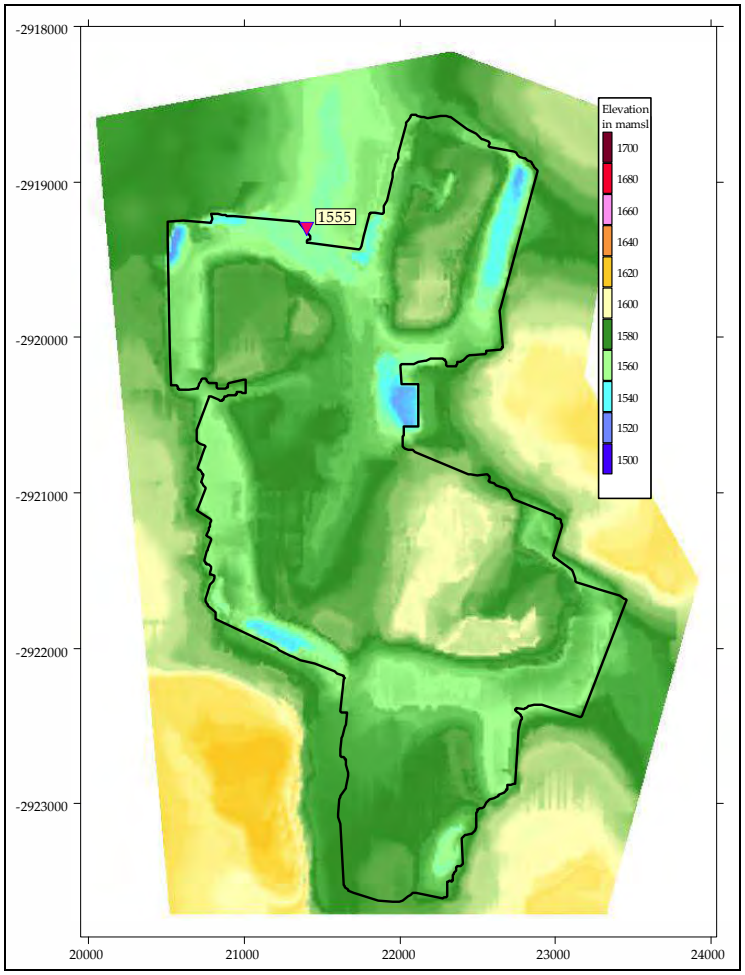

Figure 2 Opencast surface contours with decant point indicated

RESULTS AND DISCUSSION

Waterbalance

In terms of water make, the different mining methods have different recharge factors. Table 1 shows the recharge factors used in the Mpumalanga Area (Vermeulen, 2003). A fixed mining height of 4.60 m and the pillar-plan were used to determine the extraction factors for the four connected underground sections.

A stage-volume curve depicts the relationship between a water level elevation and the volume of water inside the opencast or underground workings. The water level is assumed to be horizontal. Using a stage-volume curve for the rehabilitated opencast pit with a void space of 25 % in the backfilled spoils, a volume can be determined at decant level. A management level

at 1 550 mamsl, five meters below the decant elevation, is suggested. This results in a 9 400 Mℓ buffer to be utilized in very wet seasons (**Figure 3**).

Table 1 Recharge values per mining methode

Mining method	Recharge as a percentage of the average rainfall
Bord-and-pillar	1 – 3%
Stooping	6 – 13%
Longwall and shortwall	15 – 20%
Opencast	20 – 30%

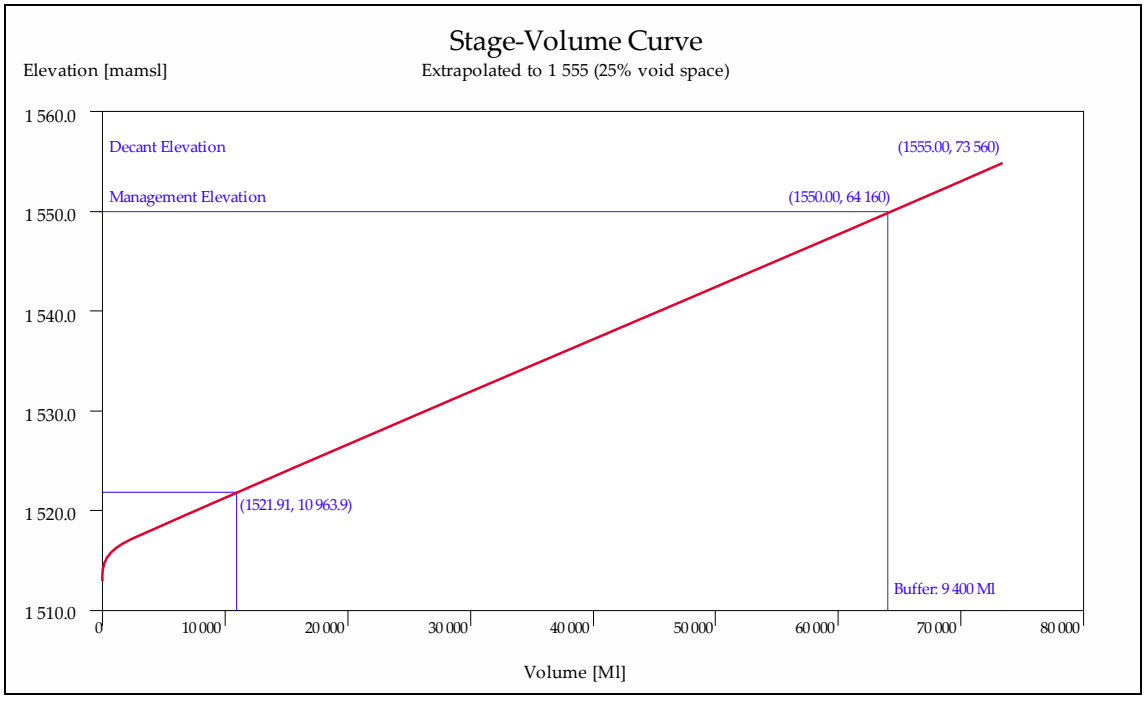

Figure 3 Stage-volume curve for the rehabilitated opencast

The stage-volume curve appears to be a mainly linear because the opencast does not have benches and the walls are almost vertical. The storage capacities for the separate workings were calculated using the outline pillar plan and a fixed mining height of 4.60 m. The opencast is currently not completely dry. Using two boreholes in the northern part of the pit, a water level elevation of 1 521.91 mamsl was determined (Table 2).

Table 2 Water storage capacity for separate working at the colliery

UG Section	Area (ha)	Mining Height (m)	Extraction factor (-)	Capacity (Mℓ)	Remaining Capacity (Mℓ)
UG-1	3 000	4.60	53.5	73 840	73 840
UG-2	2 848	4.60	53.5	70 051	70 051
UG-3	932	4.60	53.0	22 176	9 933
UG-4	3 173	4.60	55.0	80 279	80 279
OC @1550	780	-	25.0	64 160	53 196

Another factor that influences the inflow of water is the depth of mining. Natural permeability usually decreases with depth. This is because calcium carbonate, which is the binding material between the grains of sand (sandstone) and mud (shale), has to some degree been leached by circulating groundwater from the top 40 m of sediments. An empirical relationship between recharge and mining depth has been established through years of observation in the collieries as shown in Table 3 (Hodgson and Krantz, 1998).

Table 3 Bord-and-pillar recharge-values per depth of mining

Depth of mining (m)	Percentage recharge for average rainfall
10	3 – 10
20	2.5 – 5
30	2 – 3
40	1.5 – 2
>60	1 – 1.5

The depth of the underground workings at this colliery varies between 34 and 150 meters below ground level (**Figure 4**) and an average recharge rate of 1.5 % is suggested. Using the recharge rate the area of each section, a water make per section can be calculated, as well as the time it will take to flood the underground sections.

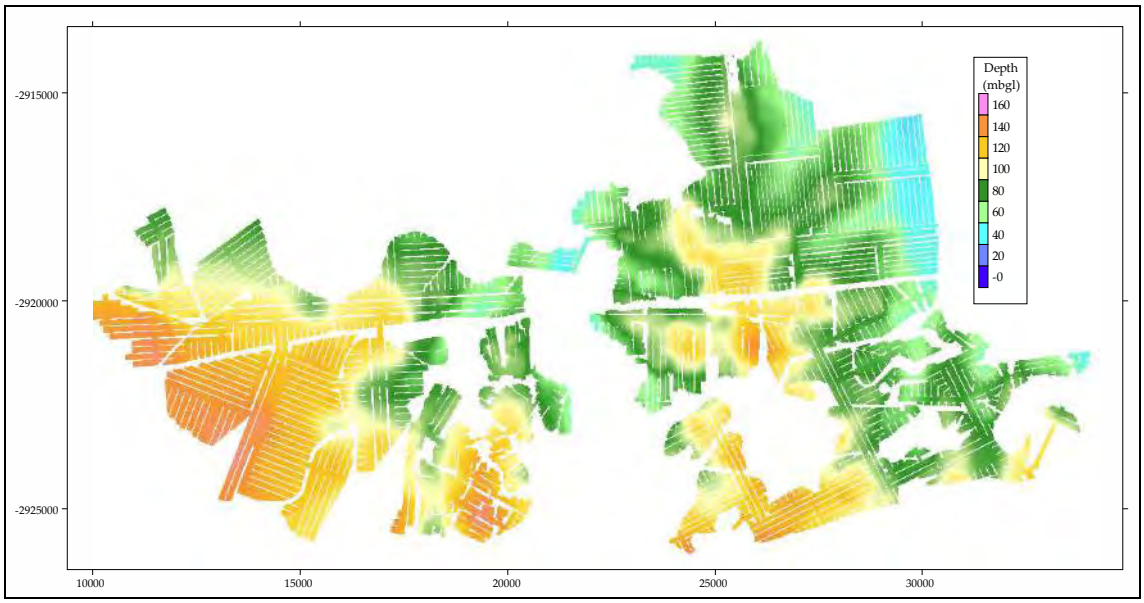

Figure 4 Depth of the coal floor in the current and future underground sections of the colliery

The recharge in the opencast is much higher than the recharge in the underground. Observations over the last twenty years have led to the values in Table 4 (Hodgson and Krantz, 1998). For the entire opencast a recharge value of 20 % is applied. Apart from the mining geometry, the other most important factor controlling water flow in a mine is the coal floor contours. As far as possible the provided peg data and mining height was used to generate a coal floor contour. Where gaps in the data exist, the coal floor was interpolated from exploration borehole information. The result is illustrated in **Figure 5**.

Table 4 Recharge values for opencast pits

Water source	Water into opencast [% rainfall]	Suggested average [% rainfall]
Rain onto ramps and voids	20 – 100	70
Rain onto not rehabilitated spoils	30 – 80	60
Rain run-off from levelled spoils	3 – 7	5
Rain seepage into levelled spoils	15 – 30	20
Rain run-off from rehabilitated spoils	5 – 15	10
Rain seepage into rehabilitated spoils	5 – 10	8
	[% of total pit water]	[% of total pit water]
Surface run-off from pit surroundings	5 – 15	6
Groundwater seepage	2 – 15	10

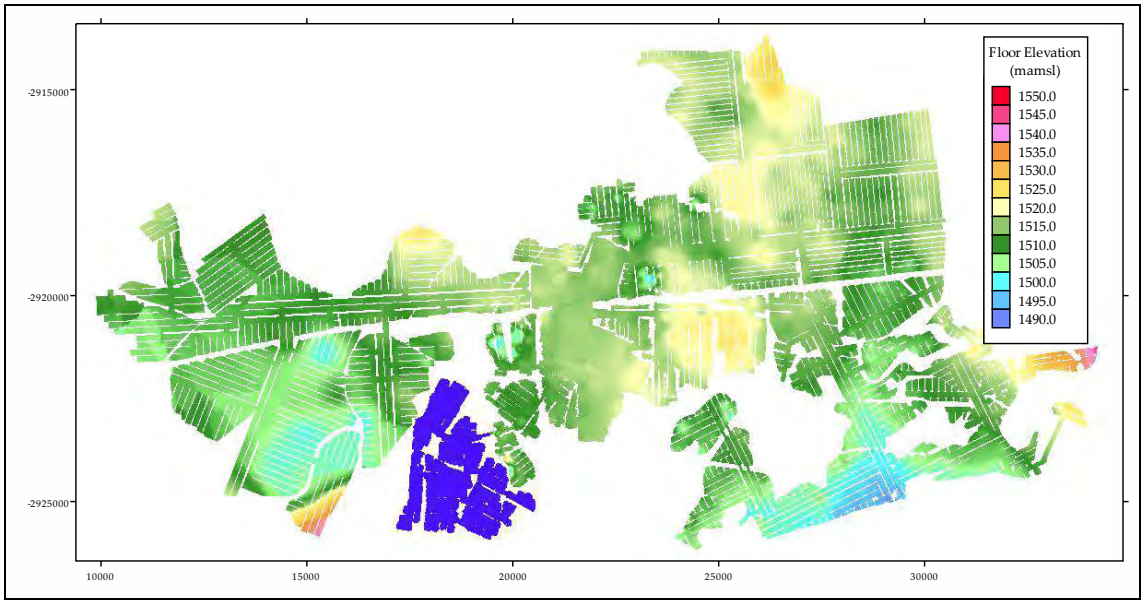

Figure 5 Coal floor contours for the current and future opencast and underground workings

Table 5 Recharge and time to fill values for each section

Section	Capacity Mℓ	Area ha	Rainfall m/a	Recharge %	Recharge Mℓ/a	Recharge m3/d	Time to fill years
UG-1	70 030	2 848	0.7	1.5	299	820	234
UG-2	73 840	3 000	0.7	1.5	315	863	234
UG-3 (Flooded)	0	534	0.7	1.5	0	0	0
UG-3	9 900	399	0.7	1.5	42	115	236
UG-4	80 280	3 173	0.7	1.5	333	912	241
OC @1550	53 196	780	0.7	20	1 092	2 992	49
TOTAL	**287 246**	**10 734**			**2 081**	**5 702**	

UG-3 is divided into a southern and northern part by the presence of a dolerite dyke. A downthrow of 10 m occurs on the southern part. The southern part has been flooded and does no longer partake in the water balance due to the fact that the artificial aquifer has changed from a water table to a confined aquifer.

The capacity of the opencast is calculated at the management elevation of 1 550.00 mamsl. As the opencast will recharge much faster than the connected underground, water will flow from the opencast into the underground sections. This will help the underground to fill up much faster and a total time of **139** years is calculated for the opencast and underground to be flooded to the management elevation of 1 550 mamsl. The management elevation is much higher than the highest points of the roof contours in each of the underground sections hence the underground will be flooded long before the whole system will start to decant. This also implies that when the water in the opencast is at its management elevation, water in the underground is under pressure and the water make in these sections will cease, resulting in a total water make, for the whole system, that is equal to the recharge of the opencast (1 092 Mℓ /a or 3 Mℓ /d).

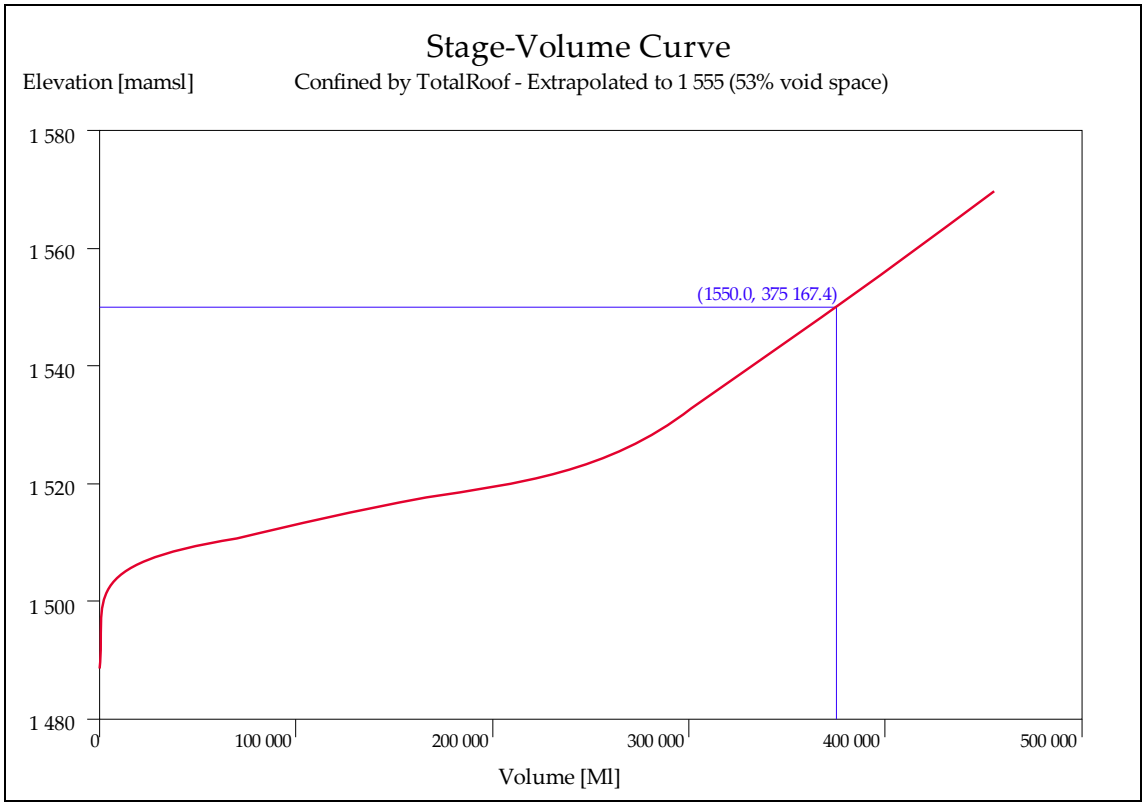

Figure 6 Stage-Volume curve for the combined opencast and underground workings

The recharge factor used in the calculations is the net gain of water in the pit. The gain of water is made up of the actual recharge minus evapotranspiration.

The colliery is situated in the quaternary Sub-Catchment A71H and has an annual evaporation of 1 550 mm (WRC Report: Surface Water Resources of South Africa, 1990).

To prevent future decant the complete water make of the opencast needs to be evaporated. A flooded area of 1 092 000 m^3 / 1.55 m = 70 ha is needed. This is above and beyond the existing final voids that have a combined wet footprint of 30 ha. A total flooded area (evaporation dams and final voids) of 100 ha is needed. Table 6 shows the flooded area on the surface of the rehabilitated opencast at different water level elevations together with the daily evaporation and the net recharge. The text at the decant elevation is in bold and the elevations above the

decant elevation are in red. Only at an elevation of 1 561 mamsl the flooded area is large enough to evaporate more than the water make, resulting in a negative recharge. (**Figure 7** & **Figure 8**)

Table 6 In-pit water level elevations with the size of the flooded areas

Elevation mamsl	Volume in Pit Ml	Flooded Area ha	Evaporating m³/d	Net Recharge m³/d
1 550	2 363	32.2	1 367	2 992

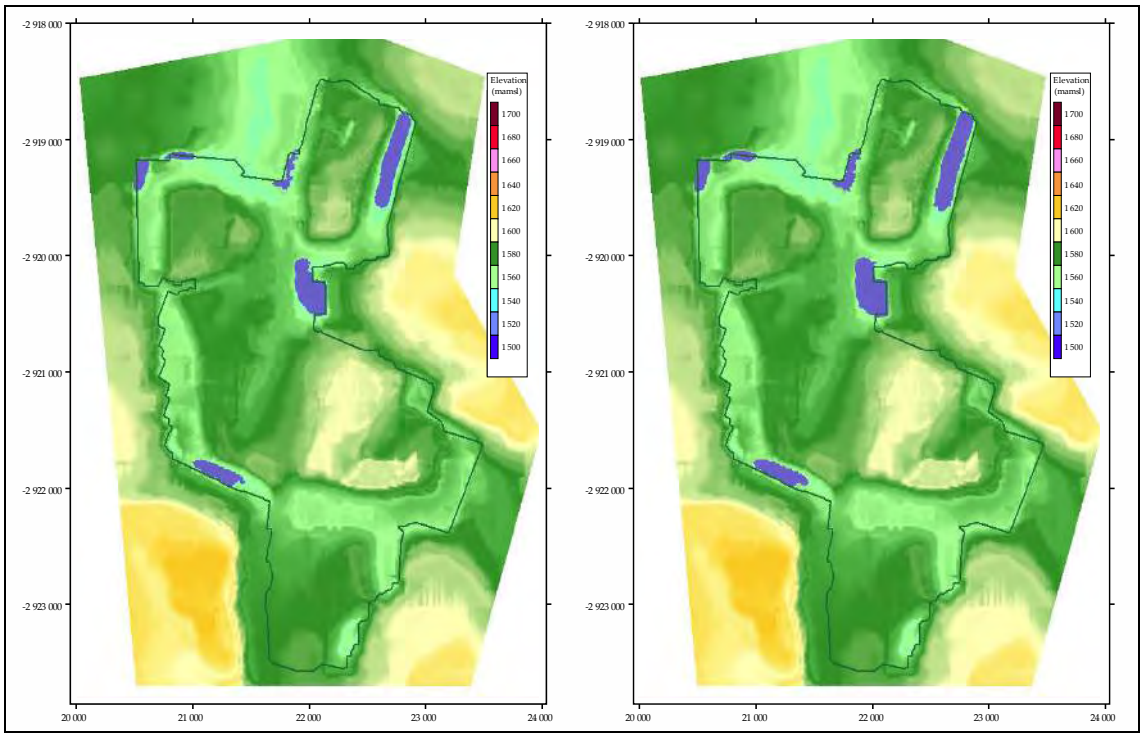

Figure 7 Flooded areas in the rehabilitated opencast - WL elevations at 1 550 & 1 555 mamsl

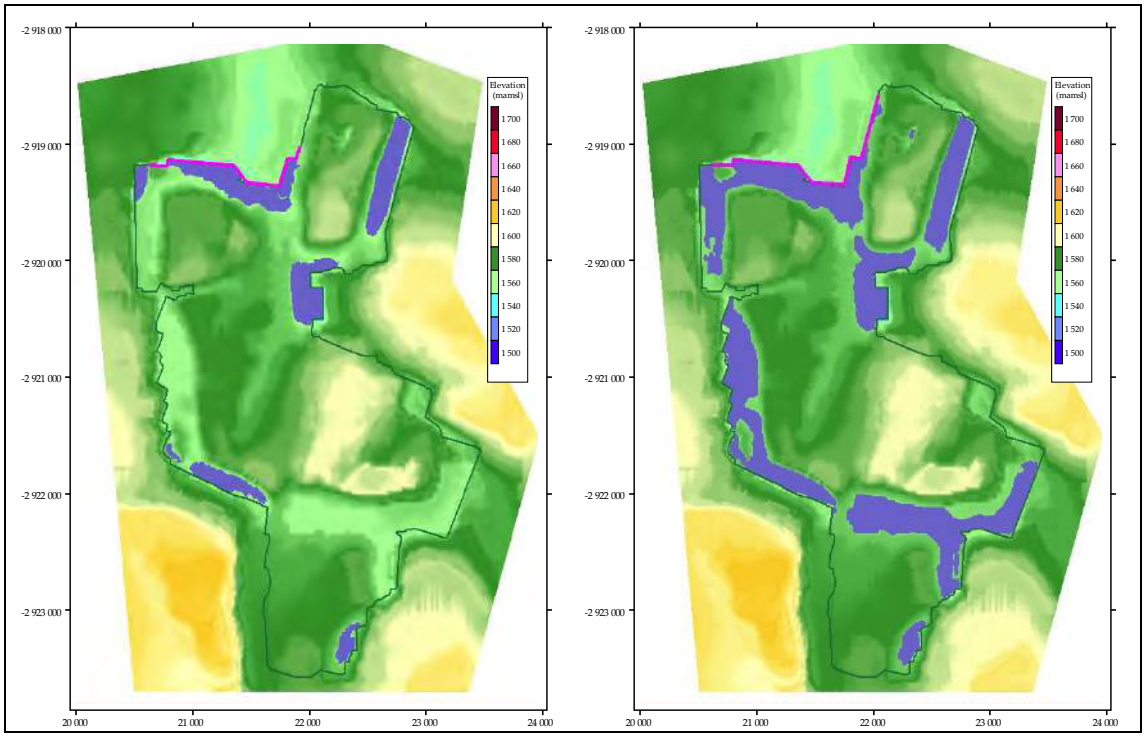

Figure 8 Flooded areas in the rehabilitated opencast - WL elevations at 1 560 & 1 565 mamsl

Sulfate generation

The remaining pillars in the underground as well as the spoils in the opencast will have a fair amount of pyrite. This in combination with the recharge water and oxygen will result in a sulfate generation that will continue until either the pyrite or the oxygen is depleted. The sulfate concentrations recorded during the last few years are erratic to say the least (**Figure 9**).

The expected long-term salinity of the opencast pit water can be calculated from the regional reaction rate within opencasts **7 kg/ha/d SO_4**. (Hodgson and Krantz, 1998). This rate appears to be fairly constant despite differences in degree of spoils saturation, age of spoils or regional impacts. It is therefore possible that the observed rates, as derived from flow and concentration calibration, reflect a maximum sulfate concentration with a consistent recharge. The maximum sulfate concentration is determined by the gypsum solubility (Usher, 2003). Hodgson has suggested that gypsum precipitation will play a role under low flow conditions (Hodgson, 2000). The sulfate generation in the underground is expected to be **1.2 kg/ha/d** (Vermeulen and Usher, 2006).

After mining has ceased the workings are allowed to be flooded. When the water level reach an elevation of 1 532 mamsl all the underground section, except for two little high parts in UG-2 and UG-4 will be flooded. The water volume will be 262 447 Mℓ and with a total recharge of 5.70 Mℓ/d (see Table 5) it will take 126 years to reach this stage.

The sulfate generated on a daily basis can be calculated:

For the opencast:	780 ha x 7 kg/ha/d	= 5 460 kg/d
For the underground:	9 420 ha x 1.2 kg/ha/d	= 11 304 kg/d
The average sulfate concentration:	16 764 kg/d ÷ 5 700 m^3/d	= 2.94 kg/m^3 (g/ℓ)

The opencast will continue to recharge with a 1092 Mℓ/d (see Table 5) with an expected sulfate concentration of: 5 460 kg/d ÷ 2 992 m^3/d = 1.82 kg/m^3 (g/ℓ)

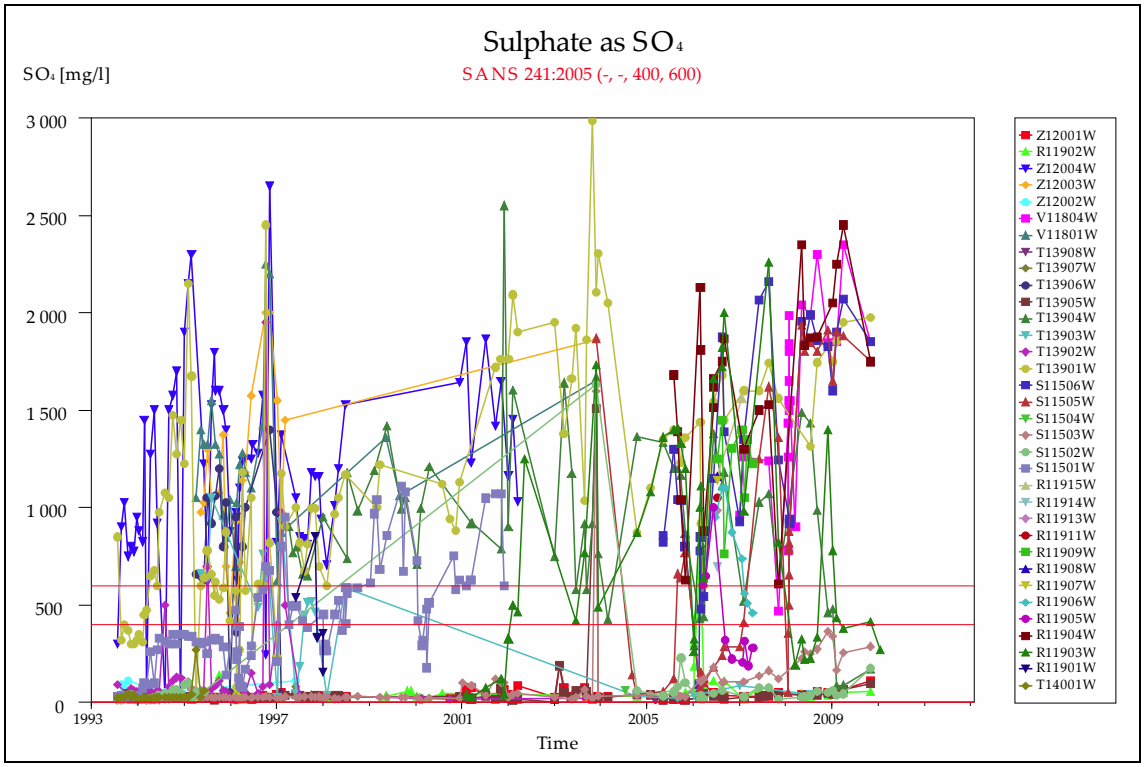

Figure 9 Recorded sulfate concentration at the colliery

CONCLUSION & RECOMMENDATIONS

To evaporate the excess water in the boundary of the opencast, three options may be considered:

1. Lower the current rehabilitated surface of the opencast, or at least some parts thereof in such a way that the flooded area at management level (1 550 mamsl) is 100 ha in size.
2. Raise the decant height to an elevation of 1 565 mamsl, a berm needs to be constructed at the northern part of the opencast allowing the water level to rise to 1 561 mamsl without the possibility of decanting. The berm needed will have to be 2.1 km long and 10 m high at places.

3. 
4. **Figure 7** rightmost picture shows the partly flooded surface of the opencast pit with the position of the dyke displayed in magenta.
5. A combination of the above options.

Response to Increasing Rainfall and High Rainfall Events at Wheal Jane, Cornwall, UK

Lee Wyatt, Arabella Moorhouse and Ian Watson
Environment Department, The Coal Authority, United Kingdom

ABSTRACT

After the closure of Wheal Jane mine in 1991, and the associated mine water rebound, highly contaminated acidic mine water overflowed from the mine and discharged at surface. This caused a major pollution incident affecting the Fal Estuary and resulted in emergency pumping being undertaken at Wheal Jane to prevent re-occurrence. Investigations by the Environment Agency into future options, resulted in the treatment plant being constructed, becoming operational in 2000.

Management of the Wheal Jane plant was transferred to the Coal Authority in 2011 as a result of its expertise in managing coal mine waters. Prior to 2011, the primary objective focused on operating and maintaining the plant in order to comply with the permitted discharge limits; with limited emphasis placed on other factors such as regional context. The approach undertaken by the Authority is to maintain compliance with the permit, whilst endeavoring to make efficiency savings. Part of this strategy includes the assessment of treatment methodology, the regional context and long-term water management.

Two high rainfall events have occurred since 2011, which have necessitated the requirement for additional emergency pumping; thus stressing the treatment plant. These events, although atypical, are part of an on-going trend of increased pumping requirements to control water levels, particularly during winter months. It is unclear if climate change causes these observed changes. To aid management and understanding of these events and identify any trends, the Authority has undertaken assessments of rainfall, water levels, abstraction rates and hydrochemistry. The results show variable time delays in response to rainfall, changes in key metal parameters, and different regional trends in groundwater levels. These results indicate that a number of different pathways for water entering Wheal Jane are present. A dynamic strategy is therefore required, to manage any future high rainfall events or increases in annual rainfall.

Keywords: mine water, treatment, operation, rainfall, metal mine

INTRODUCTION AND HISTORY

Wheal Jane mine is located within a complex of interconnected mines in Cornwall, southwest England (Figure 1) and is a former tin mine (that also includes other ores for copper and zinc), which was worked from at least the early 18th Century until 1991, when the mine was abandoned. After the mine closed, de-watering pumping ceased and the water levels rose in the workings. Contingency plans were implemented to control the foreseen rises in contaminated mine water, which could result in a pollution incident. Despite this however, in January 1992, the plan was suspended, which resulted in a build-up of mine water underground (Hamilton, 1993). Consequently, in the same month the contaminated mine water started discharging at surface, releasing approximately 40 000 m^3 of water in to the River Carnon (a tributary of the River Fal) over a few hours with an iron concentration of 1 800 mg/L (Hamilton, 1993).

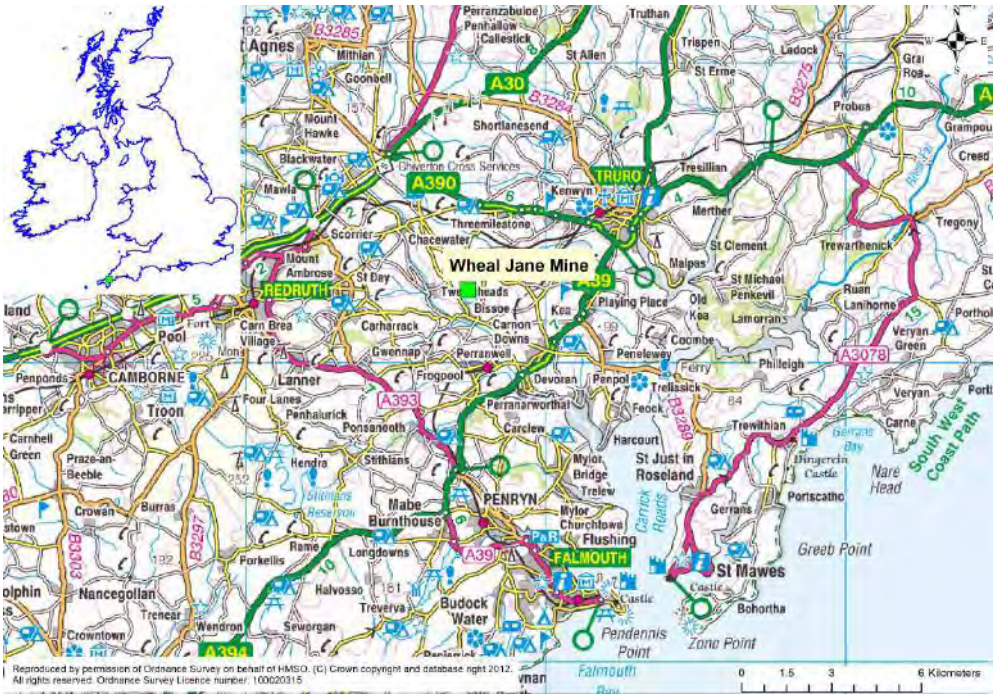

Figure 1 Location map for Wheal Jane mine and surrounding area

In the subsequent years, options for remediation of the mine water were considered, with a pilot passive treatment scheme being built in 1994, to undertake research in to long-term solutions. In 2000, the existing active (chemical treatment) plant was constructed and became operational. This plant remediates water pumped from Wheal Jane No.2 Shaft, using a high-density sludge approach, including aeration, pH adjustment (by lime dosing) and a clarifying (including polymer dosing) unit (Coulton *et al.*, 2003). Scheme capacity was originally designed for a flow of 440 L/s (Brown, Barley & Wood, 2000) with an environmental discharge consent of 350 L/s; this was later revised to the current discharge rate of 460 L/s. It should be noted that the discharge from the plant also includes a minor flow (*c.* 20 L/s) originating from the drain of the tailings lagoon.

GEOLOGY

Southwest England is dominated by late Carboniferous to early Permian Cornubian Granites, which intruded into predominantly Devonian-aged strata dominated by mudstones and siltstones, with occasional coarser-grained horizons; (Dines, 1956). A variety of different metal ores are found within the Cornish orefields including ores for tin, copper, lead, zinc and iron. These orebodies are typically zoned, following the order in which the minerals precipitated out of solution with increasing distance from the igneous intrusions. Typically tin-ores were the first to form, followed by copper-ore, zinc-ore, lead-ore and finally iron-rich minerals (Dines, 1956). At Wheal Jane the main mineralized lodes (or veins) occur in a ENE-WSW direction and recorded 19th Century returns are documented for tin, copper, lead, silver and zinc, with significant amounts of pyrite combined with smaller quantities of arsenic, ochre and iron-ore also being noted (Dines, 1956). These records suggest that a mineral assemblage containing ores such as cassiterite (tin-ore), chalcopyrite (copper-ore), arsenopyrite (source of arsenic contamination), sphalerite (zinc-ore), galena (lead-ore and also the source of silver) and pyrite (source of sulfur) are found at Wheal Jane. Assuming the ore deposit mined at Wheal Jane follows a similar zoning pattern to that found in other areas of the region, the cassiterite and chalcopyrite-rich sections of the mine will be concentrated in the deeper workings (i.e. nearer the emanative center, (Dines, 1956)), with the sphalerite-galena dominated assemblage situated in the shallower regions. Returns of ochre and iron-ore (situated in weathered gossans) (Dines, 1956), suggest that the ore body at Wheal Jane also contains a significant amount of pyrite. It is this mix of sulfide minerals which produces the acid mine drainage that occurs at Wheal Jane mine.

MINING CONTEXT

Wheal Jane Mine is located toward the southeast extent of a mining block including a series of interconnected abandoned mines, mine workings and drainage adits. Wheal Jane mine and its workings are connected to a number of other mines at depth and to at least three shallow drainage adits (Figure 2); including Janes Adit, Nangiles Adit and County Adit (or Great County Adit). The extent to which the river and streams in the area flow over shallow mine workings (lodes) and drainage adits, suggest that surface water ingress into the mine workings is common; in the catchment, this has been estimated at approximately 270 L/s (Wyatt *et al.*, 2013).

HIGH RAINFALL SETTING

In the southwest of England, the prevailing wind direction is from the southwest, resulting in Atlantic storms frequently buffeting the region, particularly over the autumn and winter months; although severe weather events can occur at any time of year. Some of these storm events can be localized in nature, being restricted to smaller individual catchment areas. For the purposes of this paper, rainfall data for the Wheal Jane area have been obtained from a number of locations within the catchment, spanning a variety of time periods.

Background rainfall

To undertake assessments of recent rainfall figures against the long-term background trends for the southwest of England, data from the rainfall gauge at Camborne (situated 14 km west of Wheal Jane Mine) was used to provide information commencing from 1979 to the present (Met Office,

2014). In addition to the rainfall gauge at Camborne, a separate gauge was installed in 2004 at Wheal Jane. A summary of these data are shown in Table 1.

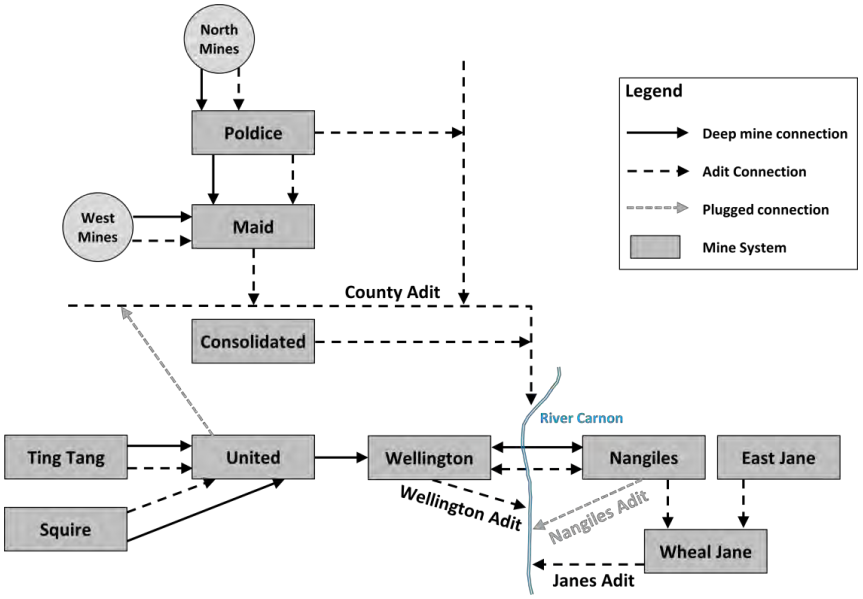

Figure 2 Conceptual diagram for Wheal Jane mine and connected mine (after Wyatt *et al.*, 2013)

Unprecedented high rainfall event in the UK

The time period between October 2013 and February 2014 resulted in exceptionally high rainfall throughout the UK, with the winter of 2014 (December 2013 to February 2014) being the wettest recorded (since 1766) in England and Wales (CEH, 2014a). Rainfall was especially high during the winter in southwest England with all months from December 2013 to February 2014 having higher than average rainfall. In December 2013, rainfall in the southwest of England was over 25% higher than the monthly average (CEH, 2013); in January 2014, the total rainfall was 63% (nearly two-thirds) higher than the monthly average (CEH, 2014b), whereas in February, double the monthly rainfall fell over the course of the month (CEH, 2014a).

Table 1 Summary table of rainfall for Camborne (C) and Wheal Jane (WJ) rainfall gauges (winter rainfall is 1st December to 28th February data)

Data set	Mean (mm)	Maximum (mm)	Period of Max Rainfall
C monthly rainfall 1979 to 2010	89	242	November 2002
C monthly rainfall 2010 to 2014	85	218	January 2014
WJ monthly rainfall 2004 to 2010	102	321	October 2005
WJ monthly rainfall 2010 to 2014	126	347	February 2014
C winter rainfall 1978 to 2010	348	561	1989/1990
C winter rainfall 2010 to 2014	345	584	2013/2014
WJ winter rainfall 2004 to 2010	305	501	2006/2007
WJ winter rainfall 2010 to 2014	467	876	February 2014

For the purpose of investigating the high rainfall events at Wheal Jane, comparisons of winter rainfall (*i.e.* 1st December to 28th February) have been assessed for both Camborne and Wheal Jane (see Table 1). Table 1 shows that the winter rainfall between 2010 and 2014, is higher than for the previous years; the winter of 2014 saw the highest volume of rainfall at Wheal Jane recorded. Furthermore, the weather patterns and uneven distribution of rainfall in the southwest of England (*i.e.* storm events) during this time period also resulted in the winter 2014 rainfall being significantly higher at Wheal Jane compared to that recorded at Camborne for the same time period (*i.e.* 876 mm at Wheal Jane compared to 584 mm at Camborne).

RESULTS

To manage the treatment plant effectively at Wheal Jane, regular measurements of water level, abstraction rates and chemical analysis are collated at Wheal Jane mine site; more recently regional monitoring of water levels around Wheal Jane has also been undertaken. The results from this wider monitoring program, in conjunction with rainfall and river stage data, have been used to analyze the Wheal Jane mine system and its surrounding environment.

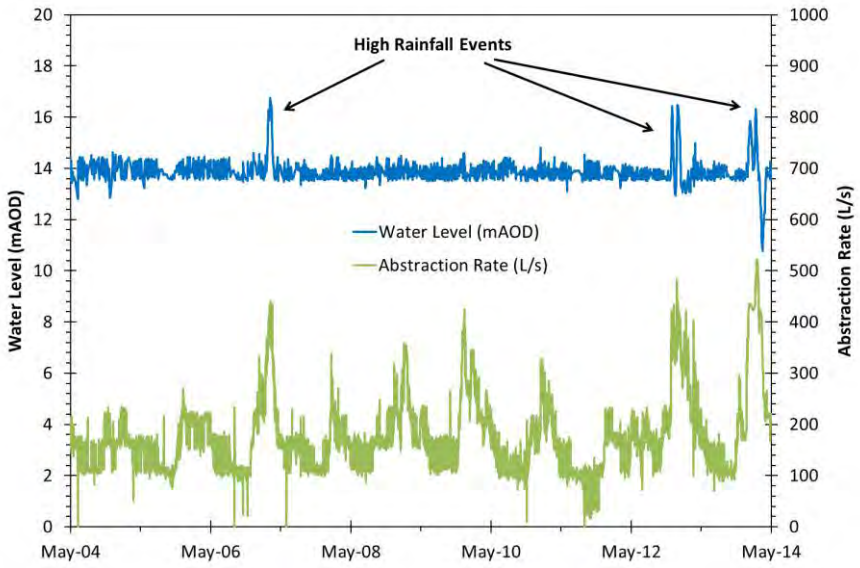

Figure 3 Plot of water level and abstraction rate at Wheal Jane

Water levels, abstraction rates and rainfall

Mine water levels have been measured on a daily basis concurrently with abstraction rates since the treatment plant became operational in 2000. A reasonably good correlation can be made between the data from the pumping shaft at Wheal Jane and the level of mine water in the shaft. Since 2011, datalogging systems have provided water level and pumping data at regular 15 minute intervals.

Results from the water level and abstraction rate data (Figure 3) show that under normal conditions, the pumping rate at Wheal Jane can be altered to maintain the water below an upper control level (i.e. 14.5 m above Ordnance Datum (AOD)); although on occasions the amount of

water in the mine workings is too great for the pumps; hence there are peaks in water level. Since 2004, the volume pumped and the number of pumps installed has increased; the pumping rate has increased from c. 300 L/s (six pumps) to the current position of c. 400 L/s (eight pumps), with an additional two emergency pumps (additional c. 100 L/s) kept on standby. Since 2004, when the current control bands were implemented, there have been three instances where pumping has been insufficient to control the water level within this designated operational band due to high rainfall events.

Chemistry

Routine daily measurements of key parameters are taken of the pumped mine water and treated effluent. Throughout some of the high-rainfall / high-water level events there have been some changes in the mine water quality observed. The results of selected parameters are summarized in Table 2. Figure 4 shows selected mine water chemistry data against water level since 2004. The chemistry data for the pumped mine water shows a trend of decreasing concentrations for some of the parameters over time; this is part of the 'first-flush' trend which has been on-going since 1991 (Wyatt *et al*., 2013).

Iron, calcium, sulfate and arsenic

Figure 4 shows that prior to 2007, the variation in the iron concentration over any 12 month period was greater compared to the differences demonstrated post 2007, as concentrations of iron have decreased over time. The trends for arsenic and sulfate (not displayed on Figure 4) follow the same pattern as iron, as do the seasonal variations shown by the calcium concentrations. Figure 4 shows that there is a reduction in concentration of iron and calcium during high rainfall events, which is echoed by reductions in concentrations of sulfate and arsenic (Table 2).

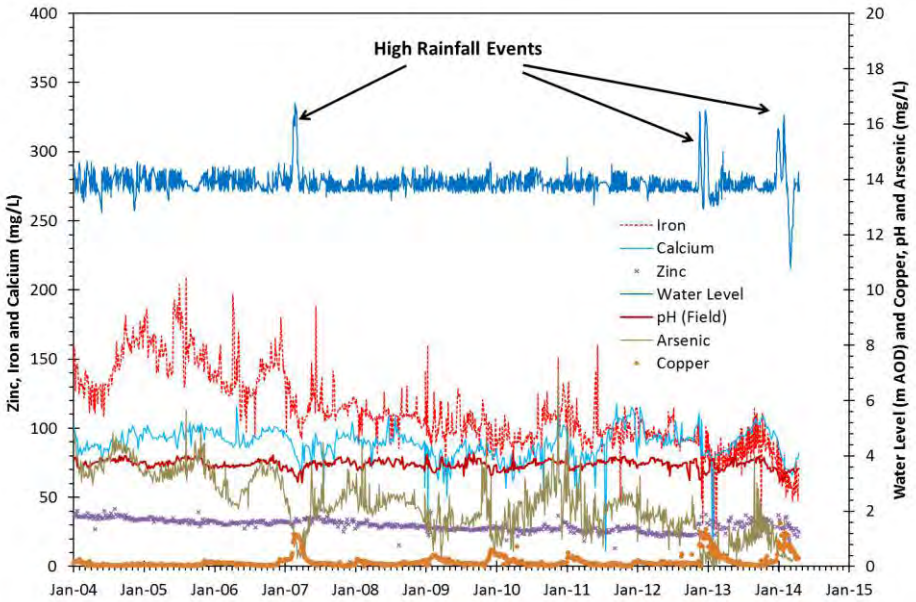

Figure 4 Plot of water level and selected chemistry parameters for the pumped water at Wheal Jane

Copper, pH and cadmium

Copper, pH and cadmium all show similar trends with respect to high rainfall and seasonal variations; with higher concentrations (decrease in pH) corresponding with high water levels and winter periods. However, the high water level peaks in cadmium are not as pronounced as copper.

Zinc, aluminum, manganese and nickel

Trends in zinc, aluminum, manganese and nickel concentrations do not appear to show any direct correlation with high rainfall or high water level events, and variations in concentrations throughout a season or during these events is very minimal or not present.

Table 2 Summary table of selected chemistry data for peak of each event and typical winter values

Parameter	Typical winter	2007 event	2012/2013 event	2014 event
Iron (Fe)	107 mg/L	118 mg/L	76 mg/L	70 mg/L
Zinc (Zn)	28 mg/L	32 mg/L	30 mg/L	31 mg/L
Sulfate (SO_4) *	624 mg/L / 457 mg/L	499 mg/L	401 mg/L	357 mg/L
Aluminum (Al)	10.6 mg/L	12.1 mg/L	9.6 mg/L	8.7 mg/L
Manganese (Mn)	3.7 mg/L	3.5 mg/L	3.3 mg/L	3.0 mg/L
Calcium (Ca)	91 mg/L	82 mg/L	87 mg/L	82 mg/L
Copper (Cu)	135 µg/L	1 044 µg/L	1 026 µg/L	863 µg/L
Nickel (Ni)	249 µg/L	267 µg/L	169 µg/L	177 µg/L
Cadmium (Cd)	15 µg/L	33 µg/L	41 µg/L	26 µg/L
Arsenic (As)	2,155 µg/L	932 µg/L	283 µg/L	443 µg/L
pH (in-situ)	3.7	3.3	3.3	3.2

* typical sulfate winter values are pre / post 2007 concentrations

DATA ANALYSIS

Analysis of the results presented above indicate a number of patterns and trends, these may represent different scenarios of the mine system during high rainfall events and high water levels.

Analysis of the rainfall data against water level (Figure 5) show that although the high water levels do correspond with high monthly rainfall, there are similar high monthly rainfall periods, which have not resulted in elevated water level. However, based on a seven day cumulative total rainfall (Figure 5) the peaks in water level do correspond more closely with the highest rainfall peaks (*e.g.* 5th to 6th February 2014). More detailed analysis of the rainfall data and water level data indicates that there is often a delay in response to rainfall, with the water level peaking approximately five to 10 days after a high rainfall event; although towards the end of the 2014 extreme event, this delay was only a few hours.

These data show that the Wheal Jane system is sensitive to rainfall; although the differences in water level responses suggest that there may be a variety of situations which affect the water flow paths and / or the residence of water in the mine workings. Given the complexity between the underground mine workings, available storage, rainfall volume, extent of saturated strata, surface conditions, river water levels and possible connections between surface and near-surface water to

the mine workings; the exact reasons for the different responses is complex and poorly understood. However, during the extreme rainfall event in 2014, which included a prolonged period of high rainfall, it could be seen that under fully saturated conditions, any rainfall impacted Wheal Jane almost instantaneously. Furthermore, evidence from previous high rainfall events indicate that as the ground becomes more saturated, the response time between rainfall and water make (*i.e.* water level and abstraction rate) generally becomes less.

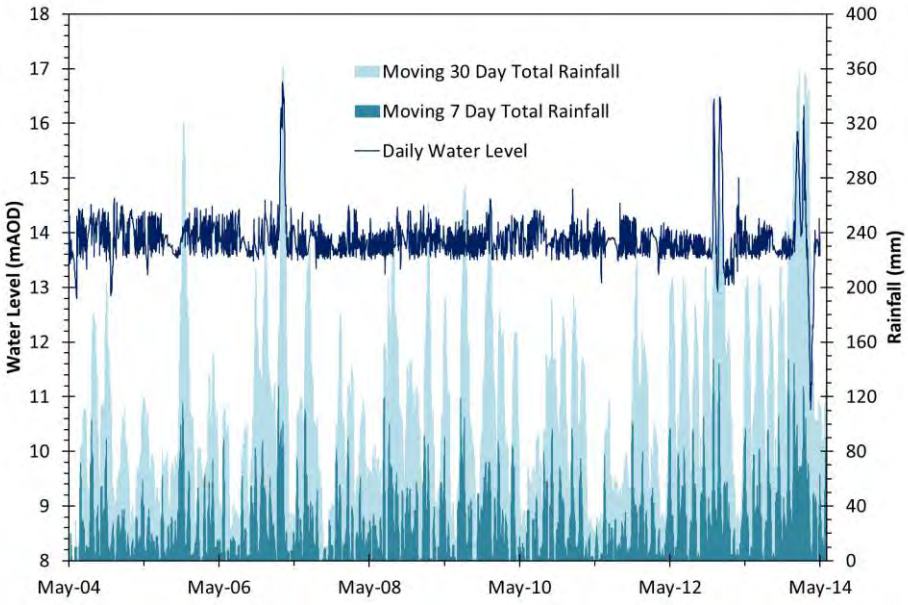

Figure 5 Plot of water level and rainfall as 30 day moving total

Chemistry

Throughout high rainfall events and high water level scenarios, there are changes in the mine water chemistry. Concentrations of some key metals and other parameters rise (*i.e.* Cu and Cd), some fall (*i.e.* As, Ca, SO_4, pH and Fe), whilst others remain steady (*i.e.* Ni, Zn, Al and Mn). These patterns in chemistry, although complex, suggest a different source of water during periods of high water level. Increases in certain metals, indicate that this water may not be all 'clean' shallow groundwater or surface water; moreover the results imply that water is passing through shallower mine workings (which are usually dry). However, from the geology and mineralization of the area, the copper ore (chalcopyrite) is often present in deeper workings, whereas the zinc ore (sphalerite) is commonly found in shallower workings; this trend is the opposite of those observed in the high water level scenarios. A possible explanation for this would be that secondary mineralization rich in Cu and Cd, potentially found in usually dry mine workings, tailing ponds and ore processing waste areas contribute a larger proportion of flow to the mine workings during these 'wet' periods.

To assess which mineral phases are saturated under normal and high flow conditions, the geochemical model PHREEQCi has been used. During normal flow conditions, iron and aluminum-rich phases such as gibbsite (SI=0.34), goethite (SI=1.82), alunite (SI=4.66) and hematite (SI=5.65) are supersaturated. In contrast, during high flow conditions the mineral phases are all under-saturated. This geochemical difference necessitates an increased level of treatment during high flow

conditions; i.e. extra alkali dosing to counter a lower initial pH. This increased operational demand is exacerbated by the increased flows occurring concurrently with worse water quality.

OPERATIONAL MANAGEMENT

At Wheal Jane, the primary purpose of the pumping and treatment is to prevent uncontrolled discharges of polluted mine water. Typically this is achieved through altering the pumping rate to maintain the water level within a control band (*i.e.* 13.5 mAOD to 14.5 mAOD). However, since the CA was awarded the management of Wheal Jane in 2011, key drivers have been to make efficiency savings whilst investigating alternative operational strategies (Wyatt *et al*., 2013).

The two most recent events have resulted in additional emergency pumping being required to prevent outbreak of mine water to the river; the latest event being in 2014 also resulted in the requirement to purchase additional pumps. However, this method of using emergency pumps (provided by the fire service) resulted in undesirable increases to the costs of managing Wheal Jane. These high rainfall events, in conjunction with the current conceptual model of the mining hydrogeology system, has led to some changes and recommended alterations to the management of Wheal Jane, especially during high rainfall / high water level events, which include:

- Purchase of additional pumps (in 2013) plus emergency pump and second back-up pump (in 2014) to give a total pumping capacity of *c.* 550 L/s; some 150 L/s greater than the rate in 2012.
- Drawdown test undertaken to assess the possibility of lowering the water level and acquire additional storage capacity in the mine workings ahead of predicted high rainfall events. This test also allowed assessments of any chemistry changes to be understood and specifically to confirm any improvements in water quality.
- Analysis of Wheal Jane mining and hydrogeological context to assess the impacts from pumping and to assess the influence on the surrounding environment on Wheal Jane. Required to confirm if changing the pumping control level will impact the surrounding area.
- Development of a high water level management strategy, including determination of any thresholds and triggers to develop a simple pragmatic system to manage the water level.

Investigation in to utilizing a controlled overflow (*i.e.* via Janes Adit) during high rainfall events; anticipated to be <50 L/s for <1 % of the time.

High water level management

A simple pragmatic system to manage the proposed water level is summarized below:

- Use up to six pumps to hold water level below 14.5 mAOD in normal conditions
- If water level rises, use all available pumps to lower water level to 11 mAOD
- Pump sufficient quantities of water to hold the level between 11 mAOD and 11.5 mAOD
- Continue to hold the water level at this band until only four pumps are required

Based on historical pumping data, this trigger level approach described above would only be implemented for up to 5 % of the time. Hence, such a trigger approach should not result in unwarranted extra pumping costs for an unacceptable number of false alarms.

SUMMARY AND CONCLUSIONS

Following work and investigations undertaken by the CA since 2011 in to various hydrogeological features of the Wheal Jane system, a variety of aspects have been observed, which include:

- Relatively quick response at Wheal Jane to high rainfall events suggests inputs from shallow groundwater and / or surface water. Thus, likely implying direct mining connections to the shallow drainage systems (*i.e.* County Adit) or to the surface (*i.e*. open stope workings)
- A quick response to rainfall suggests little available storage within the Wheal Jane mine system; especially in winter months when the ground storage is lower. To prevent risks of uncontrolled discharges to surface during high rainfall events, a lower water level could be maintained in drier periods for a lesser costs than at certain times in the winter
- High rainfall events which have high water levels, lead to a different hydrochemistry of the pumped mine water. This could reflect the influence of shallow water inputs, and / or different mineralogy in shallower mine workings
- A different approach in the management of high water levels could be implemented to create additional storage ahead of anticipated wet periods, this could also significantly reduce or remove the need for costly emergency pumping

The option of a controlled overflow reduces the current risks, however further investigations regarding flow and chemistry are required. In the medium to long-term and based on natural improvements to hydrochemistry of the mine water, this option (possibly with passive treatment) would be highly beneficial

Simulation of Hydrological Processes in the Dump Slope of a Mining Pit for Landslide Forecasting

Jinxing Guo[1], René Blankenburg[2] and Peter-Wolfgang Graeber[1]

1. *Institute of Waste management and Contaminated Site Treatment, Technical University of Dresden, Germany*
2. *Ingenieurbuero fur Grundwasser - IBGW® Leipzig, Germany*

ABSTRACT

Dump slope in the open-cast mining pit is always a safety issue, as it can experience catastrophic destruction due to the slope failure caused by various factors, such as atmospheric conditions (especially precipitation), vegetation and so on. The precipitation has direct influence on the water content change with the infiltration water into the unsaturated slope especially during the heavy rainfall event. The significant effects of vegetation on the slope stability can be essentially contribute to two major aspects, water movement via the soil-plant-atmosphere continuum and soil reinforcement by the root system. The aim of this study is to investigate the hydrological regime in the dump slopes and the influence of the saturation degree on the stability of dump slopes under the consideration of precipitation and vegetation with the program PCSiWaPro® (by Technical University of Dresden).

Physical model tests of a sand slope at TU Dresden showed that it was the partial saturated condition that had already caused mechanical instabilities. Using the simulation program PCSiWaPro®, the distribution of the water saturation in the partial saturated slope area under transient boundary conditions can be simulated. It is based on solving the RICHARD's Equation in two spatial dimensions using the finite element method. The integration of a weather generator into PCSiWaPro® allows a transient flow calculation with respect to atmospheric conditions (precipitation, evaporation, daily mean temperature and sunshine duration) and removal of water by plant roots and leaves. With PCSiWaPro® a case study in an open-cast mining pit in Saxony (Germany) has been carried out to simulate the hydrological process in the dump slope especially for the unsaturated zone; then with the simulation results, the stability analysis models could be applied to verify how detailed water content and vegetation influence the stability of the dump slope.

Keywords: dump slope, water content, saturation, stability analysis,

INTRODUCTION

This study area locates between Leipzig and Bitterfeld with the City of Delitzsch in the center which has been shaped by the lignite mining activities for more than one century. Mining activities are always essential for the production of necessary minerals and then for the development of the modern society. However they also bring us lots of serious environmental and ecological problems, among which the dump slope landslide in the mining pit is one of the main concerns. Constantly appearing causes have a great weight on the issue of slope stability, like the heavy rainfall event and the change of the ground water level.

Surface erosion (surface runoff) and increase of water saturation in the dump slope body are the main causes of instability risk (Bonelli, 2013). There was an early assumption that the landslides and suffusion phenomenon can arise only in the fully saturated soil areas on the air side; however AIGNER (2004) indicated from a physical experiment (shown in Figure 1) that this can occur even in the partially saturated soil area of the slope. The surface erosion is relatively easy to be detected and avoided, while the soil moisture increase risk cannot be easily identified. Therefore, these geological structures are more sensitive and dangerous due to the flow from the ground water and rainfall water infiltration into the unsaturated zones (Bonelli, 2013).

Figure 1 A physical model slope with slides on the air side (Aigner, 2004)

In those unsaturated slope areas, various factors could influence the water balance and then the stability, for example, soil materials, geometry, atmospheric conditions (e.g. precipitation), and even vegetation (Tien H. Wu, 2013) (see Figure 2). The precipitation has direct influence on the water content change with the infiltration water into the unsaturated slope and then changes groundwater movement regime (especially in an extreme rainfall event). The significant influence of vegetation on slope stability can essentially be attributed to two major aspects: water movement via the soil–plant–atmosphere continuum (SPAC) (Coppin, Barker & Richards, 1990) and soil reinforcement by the root system (Gray, 1995). Vegetation is a major component of SPAC, responsible for the suction force of water against gravity. The absorbed soil water will subsequently be removed through the transpiration process into the atmosphere. Ultimately, this water cycle system would result in less saturated and more stable slopes. Concurrently, vegetation also contributes to mass stability by increasing the soil shear strength through root reinforcement (Gray, 1995). The frequency of slope failures tends to increase when vegetation is cut down and their roots decay (Abe, 1997).

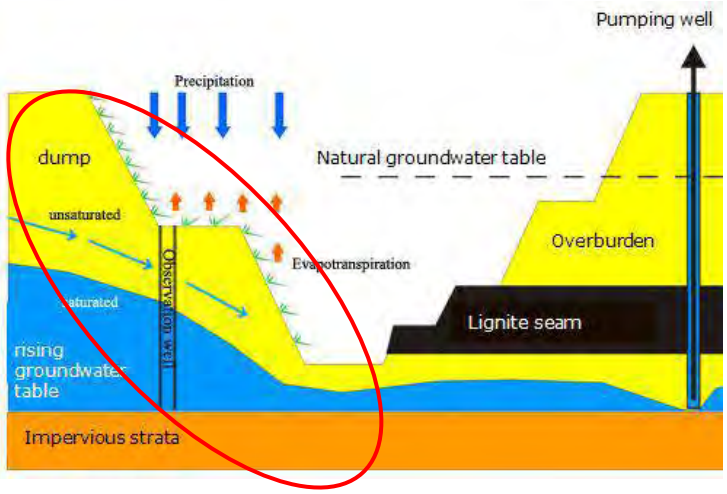

Figure 2 A simplified structure of the dump site

HYDROLOGICAL PROCESS SIMULATION PROGRAM

The hydrological process could be simulated by the Program PCSiWaPro® (developed at the Technical University Dresden, Institute of Waste Management and Contaminated Site Treatment) which could describe the distribution of water saturation under transient boundary conditions (Graeber et al., 2006). With PCSiWaPro® a 2D model of the dam could be built, incorporating information of geometry, soil properties, climate parameters and geohydraulic as well as time-dependent boundary conditions. To determine the effects of the factors mentioned above on the through-flow, water saturation and the geomechanical instabilities in the partially saturated region of the dump slope, the seepage line as the border between the fully saturated and partially saturated zones was used for validating the simulation results.

Theoretical Background of PCSiWaPro®

PCSiWaPro® simulates water flow and contaminant transport processes in variably saturated soils, under both steady-state as well as transient boundary conditions. The flow model can be described by the RICHARDS equation (equation 1).

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial x_i}\left[K\left(K_{ij}^{A} \frac{\partial h}{\partial x_j} + K_{iz}^{A} \right) \right] - S \qquad (1)$$

The equation contains the volumetric water content θ, pressure head *h*, spatial coordinates *xi* (x_1 = x and x_2 = z for vertically-plane simulation), time *t*, and K_{ij}^{A} as components of the dimensionless tensor of anisotropy K. S is a source/sink term, which can be partly characterized by the volume of water that is removed from the soil by plant roots. The effects described by this strongly nonlinear partial differential equation are subject to hysteresis, especially the relationship between water content and pressure head. This relationship can be described by the VAN-GENUCHTEN-LUCKNER equation (2).

$$\theta = \theta_r + \frac{\phi - \theta_{r,w} - \theta_{r,l}}{\left[1 + (\alpha h_c)^n\right]^{1-\frac{1}{n}}} \quad (2)$$

Φ is the porosity of the soil; h_c characterizes the pressure head difference between the wetting (water) and non-wetting phase (air); α (scale factor) and n (slope) are empirical VAN-GENUCHTEN parameters (Kemmesies, 1995). The simulation tool PCSiWaPro® implements this relationship and solves the RICHARDS equation in two vertically-plane dimensions with transient boundary conditions, using the numerical finite element approach. For the solution of the linear system of equation originating from discretizing the RICHARDS equation, an iterative preconditioned conjugate gradient solver is used.

Advantage of the Program PCSiWaPro®

There are some advantages of the program PCSiWaPro® in the field of the 2D simulation of hydrological processes. First of all, in PCSiWaPro® four kinds of Pedotransfer functions (Vereecken H. et al., 1989; Weynants, Vereecken & Javaux, 2009; Teepe, Dilling & Beese, 2003; Woesten, Pachepsky & Rawls, 2001) have been applied for the estimation of VAN GENUCHTEN-LUCKNER parameters α and n based of the corn-size-distribution-curves in the program operation interface shown in Figure 3 below.

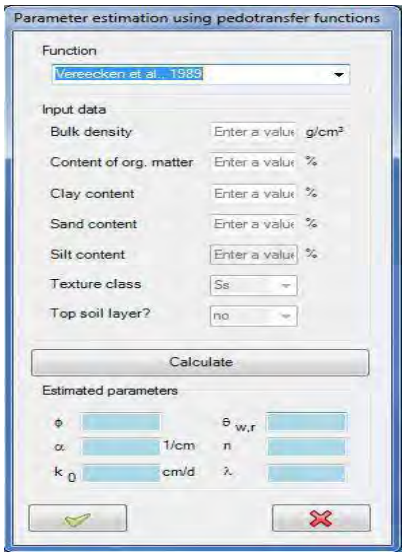

Figure 3 Operation interface of parameter estimation using pedotransfer function in PCSiWaPro®

Secondly, a further advantage of PCSiWaPro® is the coupling of a weather generator whose input data basis is real climatic data with the time frequency of one day, such as precipitation, daily average temperature and sunshine duration from the public weather data of the German Weather Service (DWD) (Figure 4); this generator allows for the generation of transient infiltration fronts with a temporal resolution up until 30 minutes with respect to those atmospheric conditions and removal of water by plant roots. In addition, it can be applied for the unknown location based on the method of the spatial interpolation and the method of the inverse distance with the geographic

coordinate of the surrounding climate stations. With these advantages, a much better resolution of the hydrological process simulation could be achieved in the dump slope either during a dry season or during a rainfall event. For example, variation of water content distribution in the slope could be simulated and predicted hourly especially during a wet season for the risk management of the possible landslide. However, when transferring this program to other countries (e.g. Poland, China, and Japan), the DWD data in this weather generator is no more suitable; instead, the local weather service data needs to be transferred to PCSiWaPro® in order to get high resolution time series for the local hydrological simulation work.

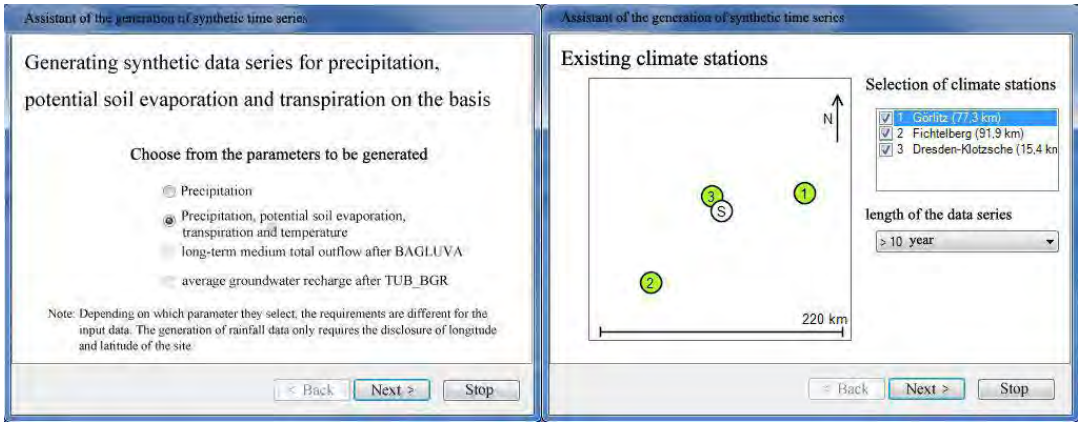

Figure 4 Operation interfaces of the weather generator for an example in the Dresden area

Thirdly, PCSiWaPro is coupled with soil parameter and chemical data bases for the estimation of the VAN GENUCHTEN-LUCKNER soil parameters and the transport parameters, respectively.

Lastly, PCSiWaPro® could provide us a strong calibration system between the simulation results and measured values from any observation point in the dump slope; with the pre-input of the measured data, this program carries out detailed calculation for different kind of values (e.g. pressure head, water content, concentration). This calibration system could also be taken as a test for the applicability and availability of the program PCSiWaPro® in our study area.

STABILITY ANALYSIS MODEL

Slope stability problems of the dump slope are among the most commonly encountered problems in geotechnical engineering. Numerous scientists conducted a large amount of research in this field and several numerical methods were developed for the slope stability analysis. The typical methods are Infinite Slope Equation, Ordinary Method of Slices, JANBU'S Simplified Method, MORGENSTERN-PRICE method and so on. Due to the close relationship between the water content (or saturation) and slope stability, the infinite slope equation is one of the most applicable equations to be used together with water flow simulation in unsaturated slope bodies (Hammond C. et al., 1992; Biondi G. et al., 2000); and it assumes identical conditions occur on any vertical section of the slope. The objective of the analysis is to produce estimates of the probability of infinite slope failure in form of the conventional factor of safety (Fs) which is defined as the ratio of shear strength to shear stress for a one-dimensional infinite slope under both saturated and

unsaturated conditions (Griffiths, Huang & Gordon, 2011; Duncan & Wright, 2005; Hammond et al., 1992); equation 3 and 4 are given for the Fs analysis within the root system as,

$$Fs_{(z)} = \frac{\tan\phi'}{\tan\beta} + \frac{2(c'+c_r)}{rz\sin 2\beta} + \frac{S_e}{rz}(u_a - u_w)(\tan\beta + \cot\beta)\tan\phi' \quad (3)$$

$$Fs_{(z)} = \frac{\tan\emptyset'}{\tan\beta} + \frac{2(c' + c_r)}{\gamma z \sin 2\beta} + \frac{S_e}{\gamma z}(u_a - u_w)(\tan\beta + \cot\beta)\tan\emptyset'$$

$$S_e = \frac{\theta - \theta_r}{\theta_s - \theta_r} \qquad S_e = \frac{\theta - \theta_r}{\theta_s - \theta_r} \quad (4)$$

where u_w is the pore water pressure; u_a is the pore air pressure; S_e is the saturation; θ is the volumetric water content; θ_r is the residual volumetric water content; θ_s is the saturated volumetric water content; $(u_a - u_w)$ is soil matric suction; z is vertical depth below the ground surface; Ø' is the angle of internal friction; c' is the soil cohesion; β is the slope angle and γ is the total soil and water unit weight (Lu & Godt, 2008); c_r is the root reinforcement (Tien H. Wu, 2013).

From the VAN GENUCHTEN-LUCKNER equation, the relationship between water content and matrix suction can be easily achieved, as shown below (equation 5):

$$u_a - u_w = \frac{\left[\left(\frac{1}{S_e}\right)^{\frac{n}{n-1}} - 1\right]^{\frac{1}{n}}}{\alpha} \quad (5)$$

α is scaling factor; n is slope factor. α and n could be achieved by the pedotransfer functions in PCSiWaPro®.

The root reinforcement c' should be neglected in equation 3 when the slope depth is below the root area. Generally, when the Fs value of a dump slope is reduced to less than one unit, landslides could be predicted and the necessary prevention is in need to reduce the landslide risk.

In the above three equations (3, 4 and 5), the values of all those parameters could be easily achieved from the local geo-data base except the volumetric water content θ which is variable depending on the local hydrological and atmospheric conditions. However, θ could be calculated or predicted by the program PCSiWaPro®.

DISCUSSION OF SIMULATION RESULTS

A real dump slope model has been selected from the mining area near the city of Leipzig for the practical application of the program PCSiWaPro® whose simulation results would play one of the key roles on the stability analysis. This study structure is totally 300m wide and 94m high with horizontally layered dump soils (e.g. 20m depth of clay layer in the middle with the hydraulic conductivity k_f of 10^{-8} m/s, 11m depth of sandy cover with the k_f value of $1.3 \cdot 10^{-5}$ m/s over the clay

layer) and sandy slope with the k_f value of $4.5 \cdot 10^{-5}$ m/s. Additional basic data, like groundwater water level change, have been obtained from the local agency and the company IBGW Leipzig.

After setup of the model in the program PCSiWaPro®, a simulation period of five years from Jan. 2000 to Jan. 2005 was selected. On the dump slope, atmospheric boundary condition has been defined, which means this slope would have additional input of rainfall water; after the formation of this dump slope, a constant groundwater level of 88m was detected during this simulation period, which supports the determination of the boundary condition of constant potential head on the left side of this model.

In order to better investigate the contribution of precipitation to the increase of water saturation in the slope and groundwater table, a simulation without input of rainfall water has been shown beforehand in Figure 5 which displays the saturation condition in different soil layers in this slope for the day of 30th June 2004. In the zoomed figure, the moderate increase of groundwater surface could be explained by the increasing capillary rise of water in the slope sand from the saturated clay soil which exhibits much higher water retention due to the much smaller particle size. Accordingly in Figure 6 the different blue colors below the groundwater surface indicate the different saturated water content of different dump materials; due to the larger porosity, the clay material with the darker blue color shows the higher saturated water content (0.52) compared with the sandy slope showing the lower water content (0.4). In addition, in PCSiWaPro® the implemented mesh generator for calculation depending on the finite element method uses the "Boundary Representation Modelling Technique" and therefore requires the specification of the model boundaries; in this simulation the structure of the model was discretized with medium finer (0.5 m) meshes, which results in a good representation of water content distribution. However the serrated lines between two different water content and water saturation layers could be even more smoothed with finer model structure meshes (e.g. 0.1 m).

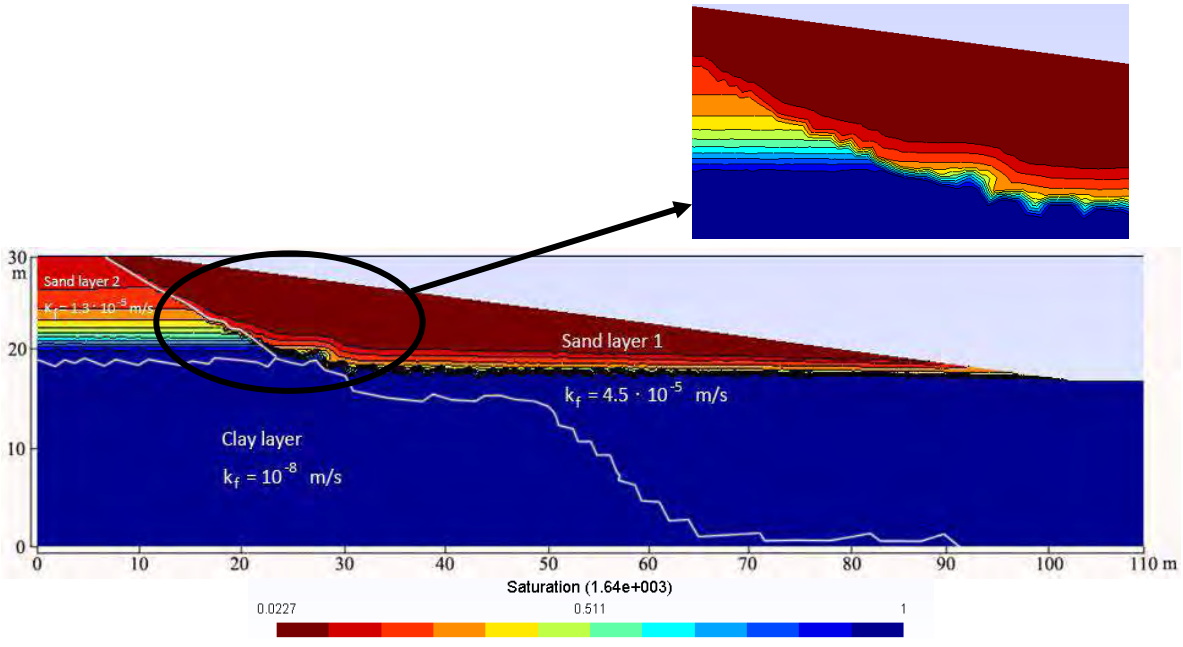

Figure 5 Water saturation simulation without input of precipitation on June 30th, 2004 (the white lines are the borders of different soil layers with different hydraulic conductivity)

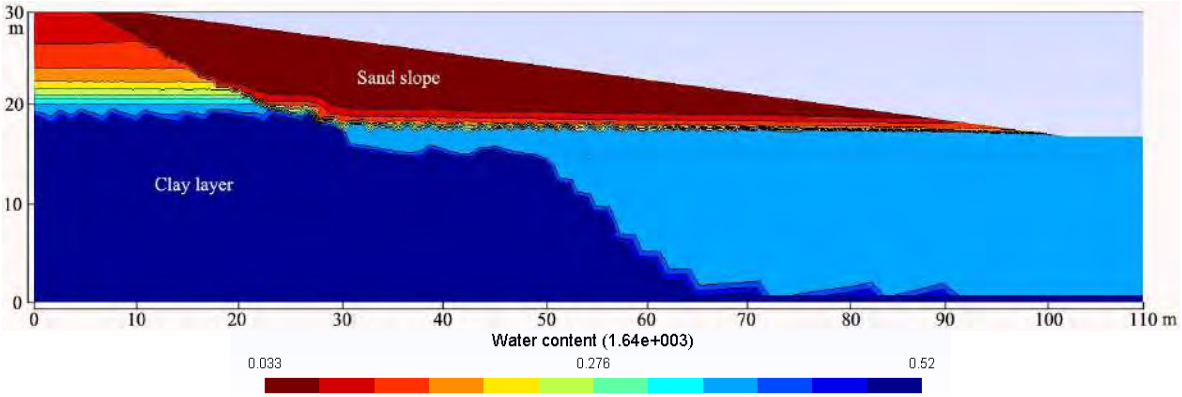

Figure 6 Water content simulation results without input of precipitation on June 30th, 2004

Figure 7 shows the precipitation data output from the weather generator in PCSiWaPro® for a typical year in the study area. As can been seen in this graph, the rainfall event mainly occurred in the summer between June and September, especially in the mid-June, early July and early September. In addition, although the rainfall season came every year from the mid-June, the ground-water level showed no change between the year of 2000 and 2005, which was mainly due to the manmade operation of pumping discharge from the groundwater during the mining activities in order to prevent the possible overload groundwater storage especially in the rainfall season and to prevent the possible geological and environmental disasters.

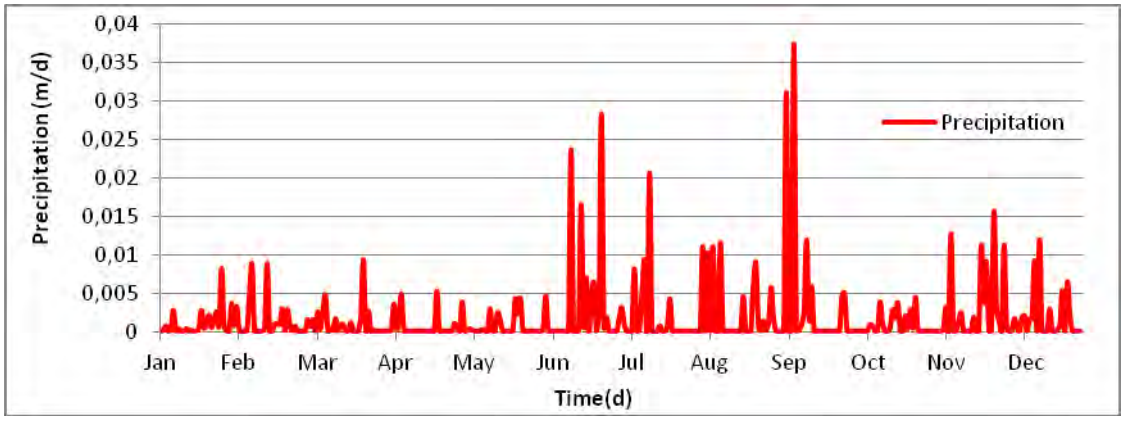

Figure 7 Typical daily precipitation data for one year in this area from the weather generator in PCSiWaPro®

Depending on the advantage of weather generator, the simulation result of water content was illustrated in Figure 8 for 30th June 2004 (during the rainfall season) considering both the groundwater flow and rainfall water infiltration. Rainfall water provided an additional flow into

the top and the right sand slope embankment, thereby increasing water content in this unsaturated slope. In addition, the rainfall water reaching the groundwater table in the slope has also performed as a complementary for the groundwater recharge.

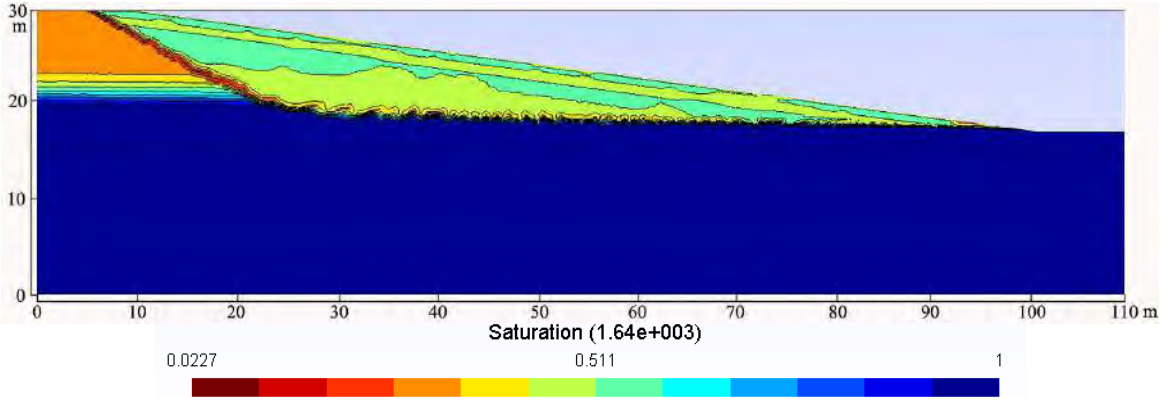

Figure 8 Simulation of water saturation distribution with input of precipitation on June 30th, 2004

In addition, due to the constant groundwater table after the year 2000, a stable value was achieved for the water level measurement from an observation well in this dump slope. A comparison between the measured and simulated water level has been carried out. The accordance between the measured and the computed values using the program PCSiWaPro® was good for our study area. However only a little bit deviation (0.3m) found in the comparison could be explained by the fact that our simulation was mainly based on the average values of those different dump soil parameters (e.g. average porosity, hydraulic conductivity); however the accuracy of the simulation could be improved with more field and laboratory investigation for soil parameters of the different dump slope soils.

CONCLUSIONS

1) The experiment results from the physical slope model in the laboratory indicated clearly that ground water flow had been already detected in the highly partial-saturated slope body; and due to the increasing of water saturation, the stability of this unsaturated slope was influenced with an already-happening surficial landslide.
2) With the Program PCSiWaPro®, water content and saturation distribution in the slope zone could be simulated and predicted dynamically within the whole study period, which is the preliminary work for stability analysis by the infinite slope model.
3) This study has also tested and calibrated the availability of PCSiWaPro® to simulate the groundwater level variation in an observation well within a continuous period.
4) The agreement between the measured groundwater level and the computed one using the program PCSiWaPro® was good for our study area; however there was a little deviation between those two values. These deviations could be caused by poorly estimated soil parameters (e.g. porosity, hydraulic conductivity).
5) With the simulation results, the stability analysis has been carried out and certified that this dump slope was stable (the minimum Fs value is 3, and the detailed calculation is not exhibited here); although the precipitation has contributed a lot for the decrease of the slope

stability, due to the manmade operation the groundwater table in this dump slope was always kept stably low between the year of 2000 and 2004, which resulted in a safe slope.

ABSTRACT

South Africa is faced with the legacy of environmental impacts due to gold mining activities which have taken place over 120 years in the Witwatersrand region. Over time, as economically exploitable gold ores have been depleted, progressive cessation of mining operations has taken place. Gold mining has caused considerable changes to the surface and subsurface water flow pathways. This is due to the influence of historical surface operations, shallow sub-surface mining and deep underground mine excavations. The generation of acid mine drainage as a result of the oxidation of pyrite and other metal sulphides associated with the gold ores has caused acidic mine water with a lowered pH, elevated levels of sulphate, and elevated concentrations of mobile toxic metals. The management of the acid mine drainage poses a major challenge. A vital question is: Who is responsible for the resultant environmental management and clean-up?

The approach adopted for the study is one that involves an integrated modeling methodology. The following elements and techniques are included: source identification, geochemical, solute mass and transport modeling, geochemical speciation and kinetic modeling. Use is made of environmental cost accounting so that the scientific source identification and apportionment findings can be expressed in terms of monetary values. The current study seeks to scientifically quantify the environmental risks associated with existing and historical gold mining activities, identify the parties whose activities are responsible for impairment of water resources, and to translate these in terms of responsible parties' respective contributions according to the "polluter pays" principle.

Keywords: Source Apportionment, Integrated Modeling Approach

INTRODUCTION

South Africa is faced with the legacy of environmental impacts due to gold mining activities which have taken place over 120 years in the Witwatersrand gold mining region. Over time, as economically exploitable gold ores have been depleted and progressive cessation of mining operations have taken place. Gold mining over this period has caused considerable changes to the surface and subsurface water flow pathways. This is due to the influence of historical surface operations, shallow sub-surface mining and deep underground mine excavations. The generation of acid mine drainage as a result of the oxidation of pyrite and other metal sulphides associated with the gold ores has caused acidic mine water with lowered pH, elevated levels of sulphate, and elevated concentrations of mobile toxic metals.

The management of the acid mine drainage poses a major challenge and a vital question is: Who is to responsible for the resultant environmental management and clean-up? The source apportionment methodology is underlain by an integrated modeling approach. The impact of identified pollution sources are simulated and quantified at selected downstream points.

BACKGROUND

The South African Inter-Ministerial Committee (IMC) on Acid Mine Drainage (AMD), comprising the Ministers of Mineral Resources, Water Affairs, Science and Technology, and the Minister in the Presidency: National Planning Commission, appointed a team of experts to report on the assessment and reappraisal of the situation with respect to acid mine drainage, focusing on the Witwatersrand goldfields (Inter-Ministerial Committee, 2010).

AMD has been reported in the Western, Central and Eastern Basins (South Africa) were identified as priority areas. These areas require immediate action due to the lack of adequate measures to manage and control the problems related to AMD. The urgency of implementing intervention measures is necessary before problems become more critical. Another concern is the proximity of these problems to densely populated areas.

Pumping of groundwater from Grootvlei Mine in the Eastern Basin ceased in 2011 and mine flooding commenced. The mine historically maintained the mine water level in this basin at a depth of ~700 mbgl by pumping 75–108 Ml/d. Treatment of the mine water has not occurred for some time and an early casualty of the situation is Blesbokspruit, including a Ramsar-listed wetland (Inter-Ministerial Committee, 2010).

The South African government is compelled to provide long-term water treatment facilities for the decanting mine water. Treatment plants could include desalinization, through one of several treatment methods involving chemical precipitation, membranes (such as reverse osmosis), ion exchange or biological sulphate removal. All methods produce clean, potable water, but are costly and produce waste products of their own (Pratt, 2011). Associated cost recovery of treatment plants will have to be conducted through the “polluter pays” principle and therefore it is necessary to formulate a source apportionment methodology.

Study Area

The study area is located in the Gauteng Province of South Africa and covers the East Rand area, including the towns of Boksburg, Germiston, Brakpan, Benoni, Heidelberg, Springs and Nigel. In Mining terms the area is referred to as the East Rand Basin. Mining in the Eastern Rand portion of the Witwatersrand Goldfields started in about 1888 at the Nigel Mines and in 1892 at Van Ryn Estates, slightly later than the mines on the Central Rand. The mine lease areas in the basin cover about 768 km^2 as shown in Figure 1. It is important to note that the East Rand Basin is geographically, hydrologically and hydrogeologically different from the other Witwatersrand mined basins (Scott, 1995).

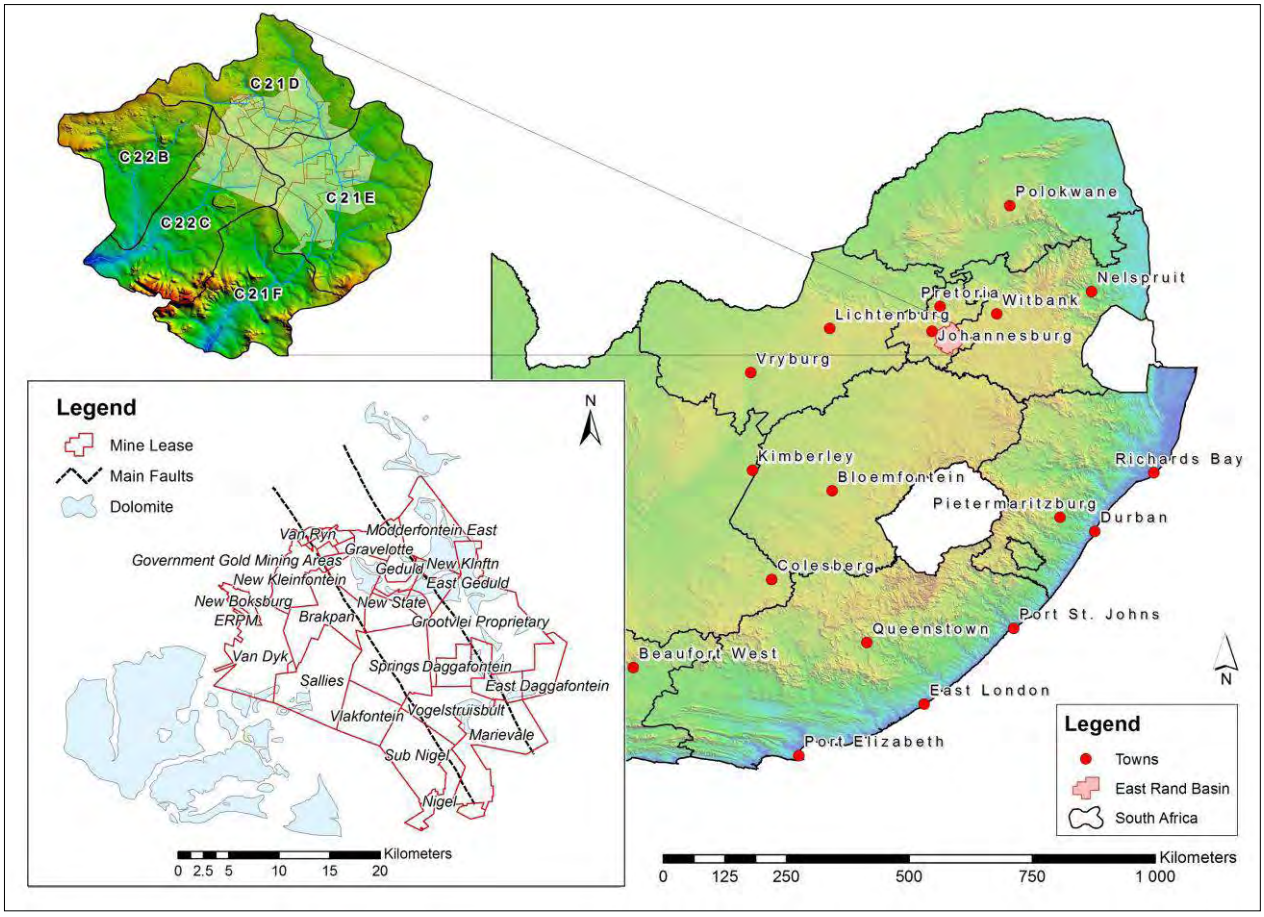

Figure 1 Locality map of the East Rand Basin

The surface catchment area considered comprises of five quaternary catchments (Figure 1): C21D, C21E, C21F, C22B and C22C. A summary of average hydrological values for each of the quaternary catchments are presented in Table 1. The two major drainage systems associated with the aforementioned catchments are the Blesbokspruit and the Natal/Rietspruit.

Table 1 Summary of average hydrological values for the study area (Middleton & Bailey (2005)

Quaternary	River	Catchment Area (km²)	MAP (mm/a)	MAR (mm/a)	MAE (mm/a)	Recharge (%MAP)
C21D	Blesbokspruit	446	698	36	1625	5.7
C21E	Blesbokspruit	628	691	35	1625	5.1
C21F	Blesbokspruit	426	704	38	1625	6.2
C22B	Natalspruit	392	692	32	1630	5.9
C22C	Rietspruit	465	684	31	1625	6.3

MAP – mean annual precipitation, MAR – mean annual rainfall, MAE – mean annual evaporation

Historic Mining

Mainly gold was mined in the area with selected coal deposits (mined via opencast pits). The gold reefs targeted were the Main, Kimberley and the Black Reef. The spatial extend of these mined-out reefs as well as a vertical profile is shown in Figure 2. Note the water level in the profile represents the shallow regional groundwater level and does not reflect the water level associated with the mine workings.

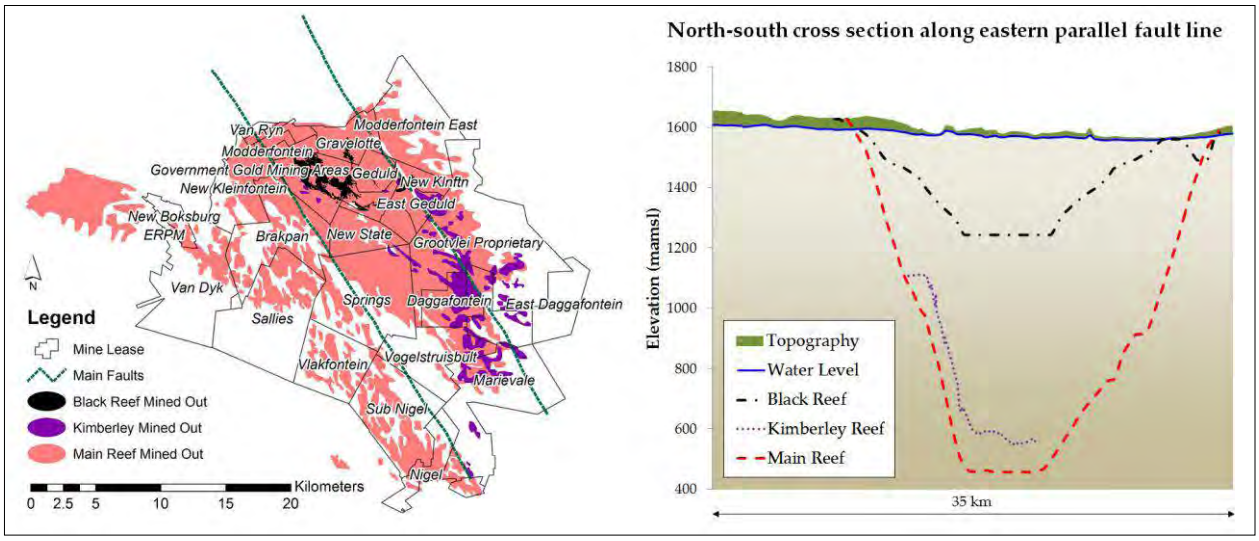

Figure 2 Mined out reefs of the East Rand Basin

METHODOLOGY

The source apportionment methodology relies on an integrated modeling approach between mine flooding, a regional groundwater model and a surface water model. Prioritization of sites and associated monitoring forms the bases of the aforementioned models. The methodology is discussed in more detail in the sections that follow.

Prioritization

A spatial approach was used to prioritize the different site types based on a site weighting given to each site. A regional model grid was used for this purpose and a layer was created for each site type e.g. tailing storage facilities (TSF), mines shafts, subsidence, dolomites, etc. A total of 13 different site types were used in the prioritization, where the resultant layer features were assigned a value of one. A zero value was assigned in the absence of these features. The priority for each grid cell was calculated as follows:

$$Priority = \left(\sum_{1}^{n} S_n W_n \right) \times DRASTIC \quad (1)$$

where n represents the number of sites types, S_n is the site value for the grid cell (zero or one) and W_n is the relative weight associated with the site type. The *DRASTIC* index (DWAF, 2006) is an index expressing the aquifer vulnerability between 1 and 200, where an index value of 200 expresses the highest aquifer vulnerability to possible groundwater pollution. Weights (W_n) applied in the prioritization is presented in Table 2. Note no weighting was assigned to the Dolomitic areas as these already form part of the DRASTIC index used.

Table 2 Summary of relative weights applied to site types in calculating priority

Site Type	W_n
Embankment	1
Pans	2
Dams, Reservoirs, Wetlands	3
Diggings, Excavations, Lineaments	5
Open Cast, Mine Shafts, TSF, Subsidence, Waste Water Treatment Works	10

The normalized prioritization map for the East Rand Basin is shown in Figure 3 together with selected pollution sources. Note that there are areas outside the mine lease area that received high prioritization. For the purpose of this study, the focus was on the prioritized areas within the mine lease area.

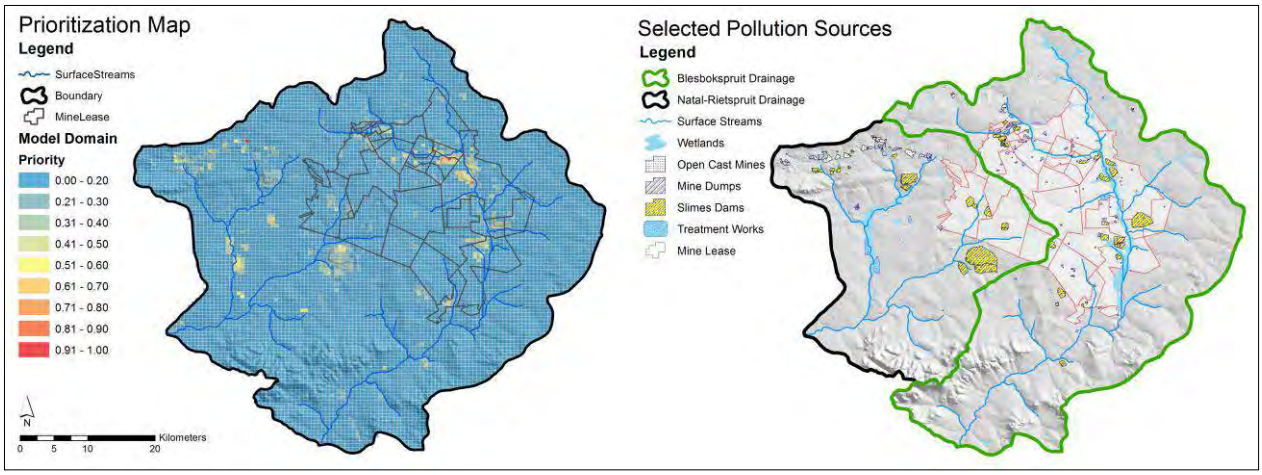

Figure 3 Normalized prioritization map and selected pollution sources of the East Rand Basin

Monitoring

A monitoring network for both the surface and groundwater had to be established due to the fact that all mining operations, with the exception of the reworking of selected tailings storage facilities (TSFs), ceased and no active monitoring was taking place. Historic datasets and reports were consulted to select monitoring points that coincide as far as possible with historic monitoring points. Physical access to sites and appropriateness of sites dictated the location of monitoring points. The final monitoring networks for both surface and groundwater are shown in Figure 4.

It is clear from the groundwater monitoring network that numerous boreholes were drilled into the dolomites for water supply. The groundwater monitoring network focused on the immediate mine lease area and only few boreholes were found that formed part of the monitoring network.

Only a single weir exists within the mine lease boundary which has data from 1977 to 2004 after which monitoring of the flow gauge stopped. Surface flow measurements were conducted through surveying cross sections and measuring stage and flow velocity. The existence of large areas comprising of wetlands (Figure 3), specifically in the Blesbokspruit, posed challenges in flow measurements as the wetland acts as a buffer to flow. Often zero flow velocities were recorded within the wetland itself.

Three sampling campaigns were conducted during the course of the study, which included both a wet and a dry season. Each sampling campaign recorded surface flow and quality as well as groundwater levels and quality.

Mine flooding water levels with selected water quality measurements were being monitored at selected mine shafts by the South African Government and this data were used to calibrate the mine flooding model.

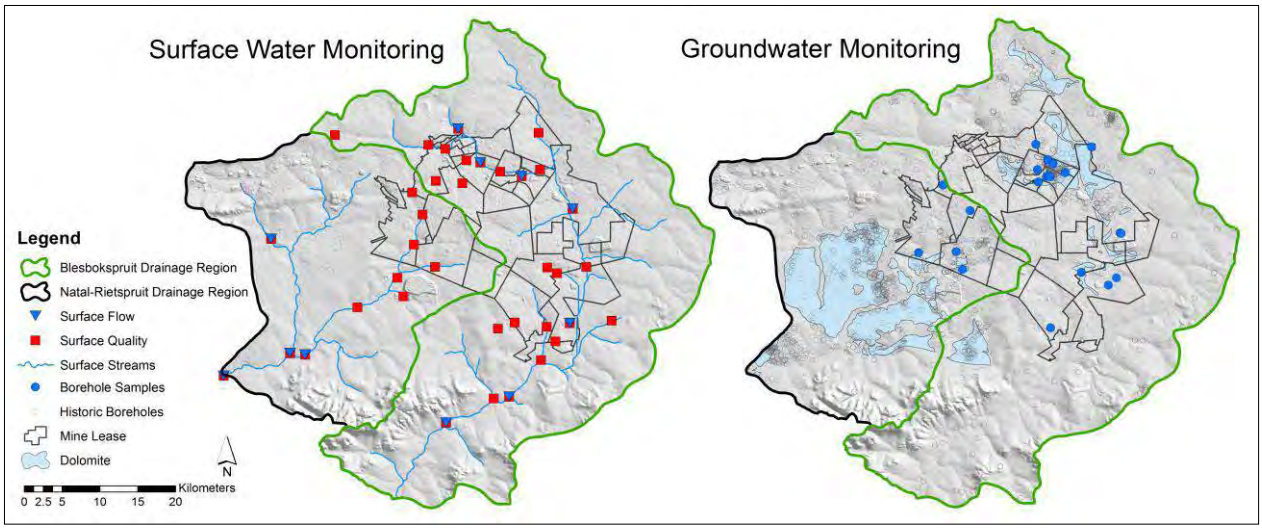

Figure 4 Surface and groundwater monitoring network

Source Term Determination

Material was sampled from the TSFs by making use of an auger. Samples were taken from the weathered and un-weathered zones. In storage facilities where the material is being reworked, samples were taken of the freshly exposed material. Samples were also taken from waste rock dumps.

In order to estimate the source terms that may impact on the study area, the risk sources were clustered based on their respective mineralogy. Geochemical models were developed for the various clusters types. Physical parameters of the heap that included geometry, particle size distribution, and saturation and oxygen concentration profiles formed part of the input to the geochemical models. In addition to this, the pore water composition was obtained through static leaching of the sampled materials. Humidity leach cell tests were performed in order to calibrate the numerical geochemical models.

A total of 18 TSFs and 12 waste rock dumps within the study area were sampled. A total of 9 source terms were determined for the nine cluster types determined for the TSFs and 8 source terms were determined for the waste rock dump clusters.

The spatial distribution of the TSFs and waste rock dumps are shown in Figure 3.

Model Concept

The mine hydrology, hydrogeology and surface hydrology of the area were modeled through the use of a surface run-off model, a regional groundwater model and a mine flooding model correspondingly. All three the aforementioned models are inter-connected to account for the total water balance and produce an aggregated system response. A graphic representation of the model framework is shown in Figure 5.

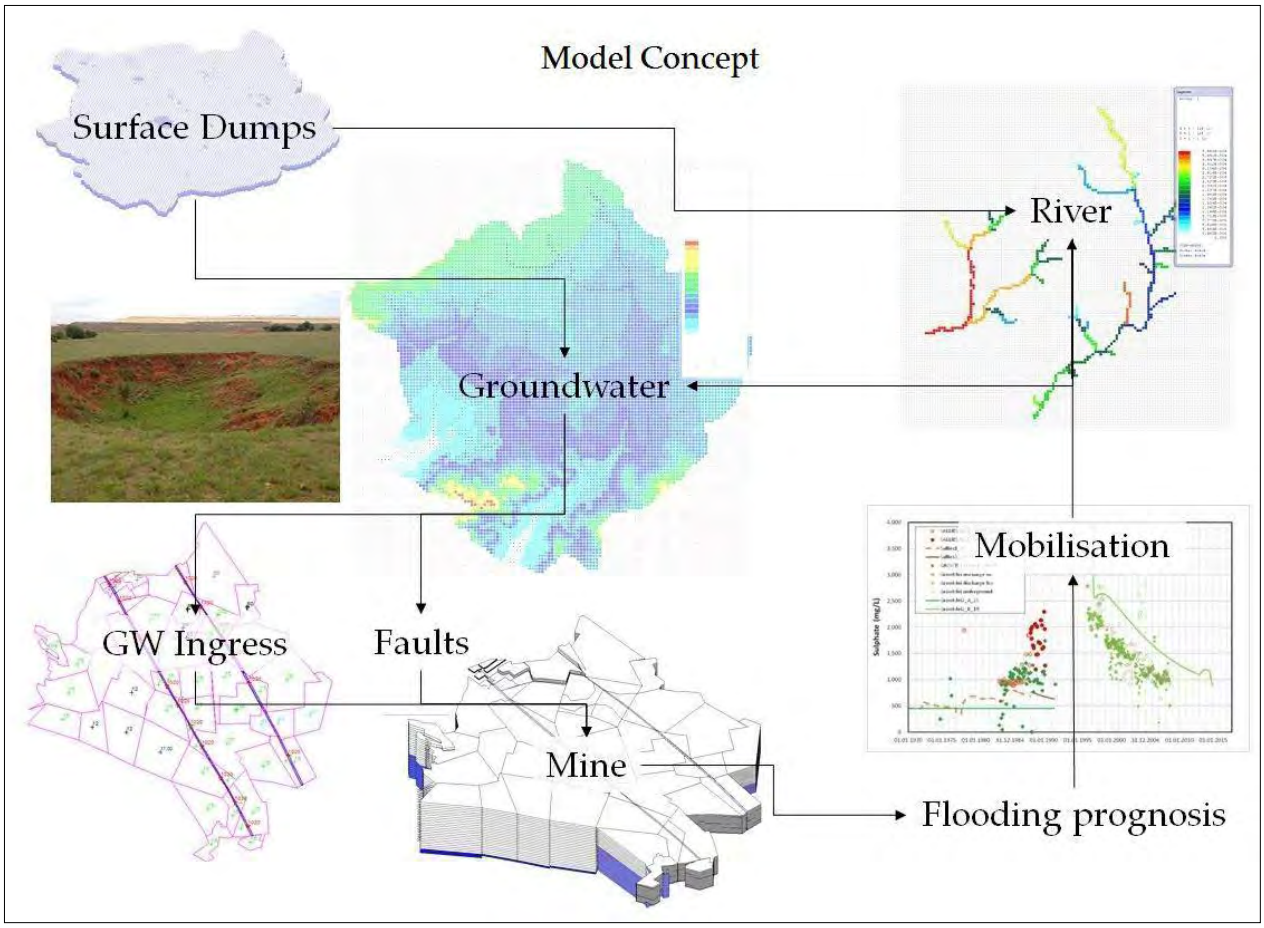

Figure 5 Source apportionment through an integrated modeling approach

The mine flooding model accounts for the two major fault lines running through the mine lease area (Figure 2) as well as areas of high ingress e.g. subsidence (Figure 5). The mine model is overlain by a multi-layer regional groundwater model onto which the surface pollution sources are added. The groundwater model grid size was chosen to ensure all TSFs and waste rock dumps were incorporated into the model.

The interface between the surface and groundwater model allows for surface-groundwater interaction which includes the decanting of mine water into the surface streams. The mine water decant to the streams can either be through surface runoff or via the shallow aquifer.

The source terms for the TSFs and waste rock dumps were included in the groundwater model.

Reactive mass transport modeling was applied in the mine flooding model and typical SO_4 results at the Grootvlei Shaft are shown in Figure 6.

In terms of the mass transport, the system was simplified to only consider sulfate as a conservative ion to track the pollution emanating from the various TSFs and waste rock dumps. The other major anion and cation movement can be modeled by making use of the associate geochemical modeling.

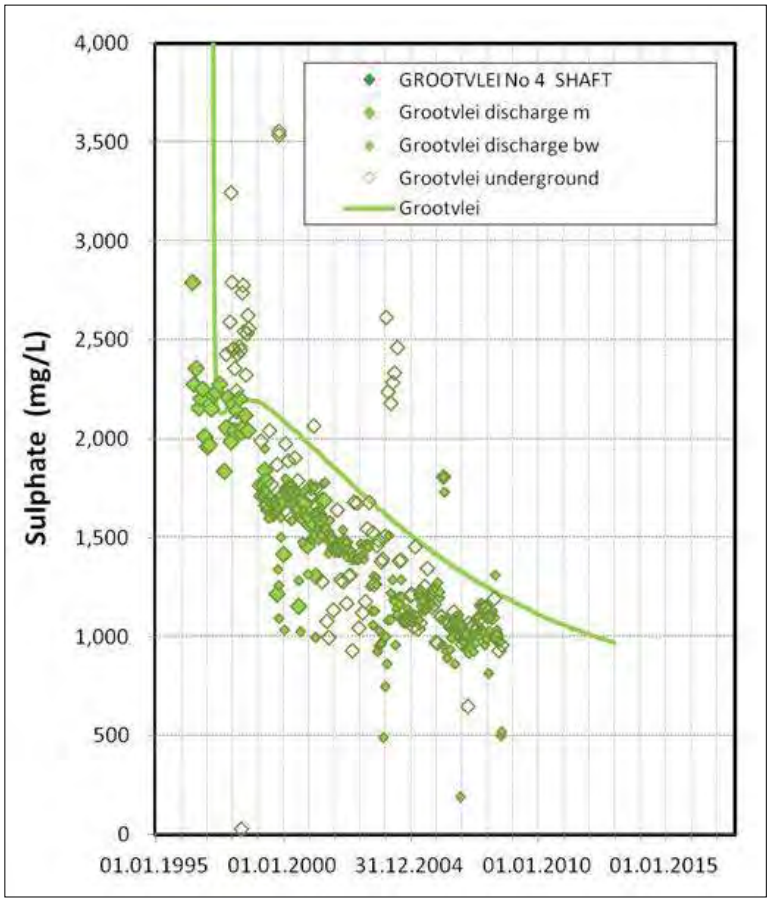

Figure 6 Model surface calibration points

Although the mine flooding model and the regional groundwater is calibrated individually, the surface water model calibration is representative of the integrated model calibration (Figure 7). The source apportionment is carried out at specified surface water points and the surface runoff model serves as a "water tree" routing all the contributions of pollution sources that report to surface water features downstream.

The groundwater model reports to the surface streams through surface-groundwater interaction and the mine flooding model reports to the surface streams through surface decant if it takes place.

The mine flooding model is also connected to the regional groundwater model and subsurface decant into the surrounding aquifer is accounted for where shafts are not hydraulically disconnected from the aquifer.

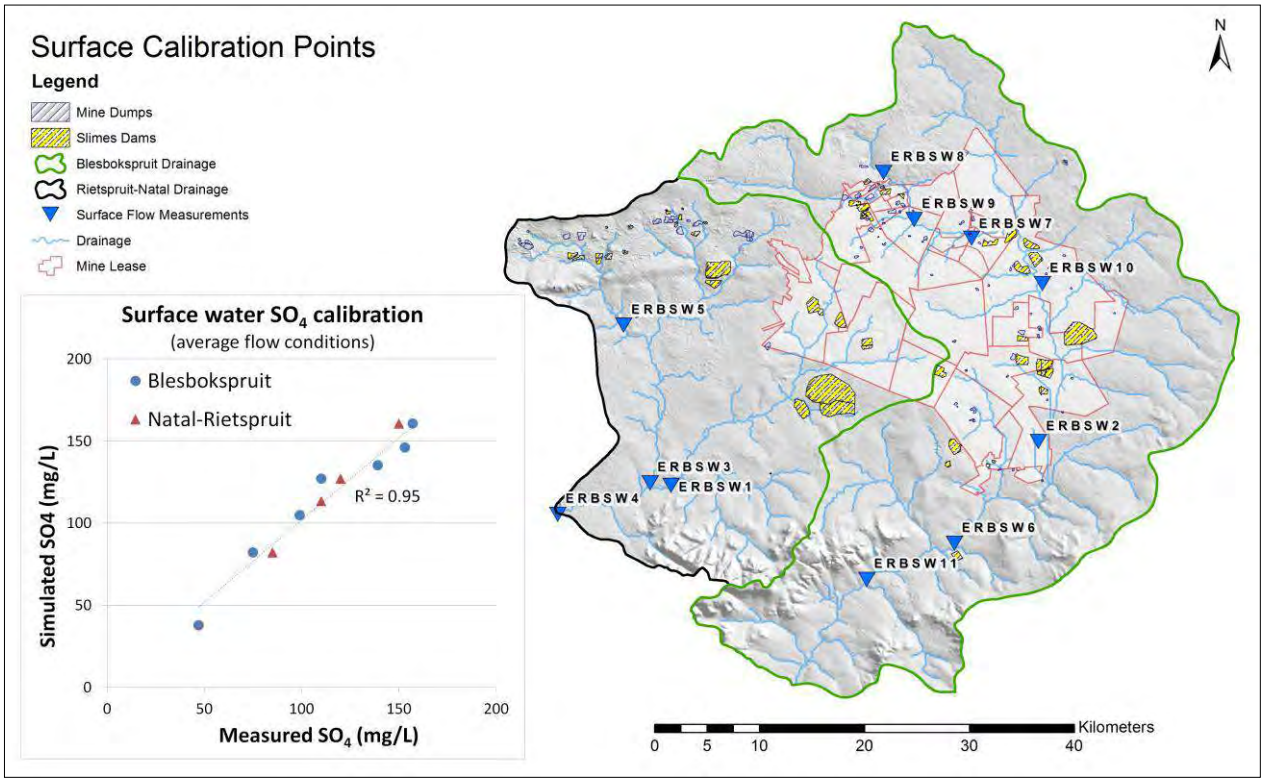

Figure 7 Integrated model surface calibration points and associated calibration

The surface water model only accounts for conservative mass transport as the surface water translates into a complex system with raw sewage (Figure 8) discharged into the water course due to faulty infrastructure or waste water treatment works running above designed capacity. Furthermore large wetlands (Figure 9) exist throughout the Blesbokspruit buffering flow and altering water chemistry.

Figure 8 Raw sewage discharged into the Blesbokspruit

Figure 9 Wetland in the Blesbokspruit

Mine Flooding Model

The mine flooding simulation was conducted using the DMT BoxModel. The BoxModel is a 3D finite volume program for modeling the flow of groundwater and mine water, heat transport and multi-component mass transport including sorption, microbial degradation and the reactions with minerals. A special feature is the highly flexible discretization, to model geological structures such as layers and faults as well as structural mining elements and mine excavations (DMT, 2011). The BoxModel also allows for interfacing to a regional groundwater model.

Regional Groundwater Model

MODFLOW was selected as choice of regional groundwater model for the study area. MODFLOW is the USGS's three-dimensional (3D) finite-difference groundwater model. MODFLOW is considered an international standard for simulating and predicting groundwater conditions and groundwater/surface-water interactions (Harbaugh, 2005).

Surface Water Model

The EPA SWMM (Storm Water Management Model) was used as primary rainfall-runoff model. The model is a dynamic and used for single event or long-term (continuous) simulation of runoff quantity and quality from primarily urban areas. The runoff component of SWMM operates on a collection of sub-catchment areas that receive precipitation and generate runoff and pollutant loads (Rossman, LA 2010). In general SWMM is not applicable to large-scale, non-urban watersheds, but Nakamura and Villagra (2009) has shown successful application of SWMM to a natural catchment. Calibration parameters from SWMM were used to setup the secondary surface water model which forms part of the DMT BoxModel.

Source Apportionment

The technical component of the source apportionment was conducted through the use of the interconnected model representing the study area. The effect of various sources described by the model could be quantified at specific points of interest through the use of a what-if analysis. The pollution sources in question are disconnected from the model and the net effect of the detached pollution sources is recorded at points of interest.

The financial modeling based on the interconnected model relies heavily on the confidence of the model output, which is difficult to quantify considering future scenarios. The status quo confidence of the model output is related to the calibration state of the model and associated data.

The legal part of the source apportionment, which falls outside the scope of this paper, is far more challenging than the technical part due to legacy mining concerns.

DISCUSSION

The interconnected modeling approach allows for a what-if analysis to quantify the impact of various pollution sources at specified points in the network.

A challenge in model output confidence exists for the East Rand Basin as the monitoring network established only reflect the system response for a single hydrological year. Very little historic monitoring data are available to validate the model calibration.

The change of water character entering the wetland areas is contributed to the existence of Sulphate Reducing Bacteria (SRB). The surface water model employed does not explicitly account for wetlands or the effect of SRB's and this mechanism is simulated with a "treatment plant" within the surface water model. A study is currently being carried out to characterize the wetland response function particularly for the use in the surface water model.

CONCLUSION

Source apportionment in a complex mining environment requires the use of an integrated modeling approach. Model confidence on both current and future scenarios is important for the purposes of financial modeling which is the final step in the apportionment study. Continued monitoring would be required to validate the model response before final apportionment studies can be carried out.

ABSTRACT

The mining exploitation of metallic sulphides in the Carolina district, together with the activities associated to the mineral treatment, when maintained through centuries due to the wealth of the ores, generate important accumulations of wastes in structures of different kind of tailing dams and ponds, for instance.

The objective of this study is, on the one hand, to check the applicability of geophysical prospecting internal structure of deposits of wastes on the other hand, the study also aims to apply such techniques to deduce some hydrological features of this waste deposits, a circumstance which must fit with their hydrogeological setting and with the results obtained of the hydrochemical survey of the selected site.

La Aquisgrana dam two profiles of 96 electrodes with the same configuration were made. Both were oriented in the NE-SW direction and were 285 m in length with spacing of 3 m between the electrodes. The profiles covered the dam from one end to the other to characterize the residue and the contact with the substrate. ERI has allowed us to obtain a model of the studied structure and has also permitted the selection of the best place to position borehole to control geochemical quality, which coincides with the preferential infiltration zones, the site where the water level and physico-chemical parameters are periodically measured.

Ten Years Later: The Ronneburg Waste Rock Relocation Project in the Light of Performance Monitoring and Sustainability Analysis

Michael Paul and Silvia Jahn
Division for Engineering and Radiation Protection, Wismut GmbH, Germany

ABSTRACT

A key project of the WISMUT remediation program, which is dedicated to the closure and remediation of the former East German uranium industry, is the Lichtenberg open pit remediation project at the former Ronneburg mine site (Thuringia, Germany). The project comprised the geochemically controlled relocation of about 133 Mm^3 of waste rock and associated contaminated material to the worked-out Lichtenberg open pit. Relocation started in 1990 and ceased in 2008. By 2014, cover construction and re-vegetation of the Lichtenberg backfill are complete at about 214 ha (95% of the total area), 100 ha have been reforested. Ongoing performance monitoring aims to measure the overall environmental impact and to prove successful implementation of the remedial work. Regular inspections confirm the physical stability of the 1.6 m thick two-layer soil cover. Re-vegetation is characterized by the establishment of 18 plant communities based on a 'controlled succession approach'. So far, the main root zone covers the uppermost 0.7 m of the soil profile. Water balance monitoring of the cover is carried out at five monitoring stations. For a mean hydrological year (710 mm precipitation) runoff rates were as follows: surface runoff 0…2 %, interflow 3…9 %, infiltration 8…13%. Further decrease of the infiltration rate is expected with progressive forest development. The mean radon exhalation rate through the soil cover is about 0.12 $Bq/(m^2s)$. Gas monitoring confirms the expected decrease of the oxygen concentrations vs. depth, with oxygen concentrations < 1% in depths below 3.5 m. Groundwater quality downstream the backfill area is characterized by significant pollution with uranium, heavy metals and sulfate, which partly results from the relocated waste material but mainly from flooding of the Ronneburg underground mine. In consequence, groundwater collection and treatment will be necessary for at least another two to three decades to come.

CHAPTER 15

MINE WATER GEOCHEMISTRY

Minewall Stations and Mass Loadings at an Epithermal High Sulfidation Deposit – What, No Scaling?

Claudio Andrade[1] and Keith Mountjoy[2]

1. *Barrick Gold Corporation, Canada*
2. *Klohn Crippen Berger, Peru*

ABSTRACT

A geochemical study was completed to determine in-situ loading rates from pit wall alteration types on a mass per unit area basis using Minewall wash stations. Surface water quality samples were also collected to determine the aqueous geochemical signature from acid rock drainage and metal leaching of the open pit and waste rock dumps. Secondary mineral precipitates were collected and analyzed to provide insight into metal controls. The study provided information for use in predictive water quality modeling of current and future pit and waste rock dump water quality.

Study results show that pit and waste rock dump water quality can be described as a Ca-Fe-Al-H-SO_4 system in an advanced state of pyrite oxidation and acid sulfate flushing. Surface water quality samples indicate there is a noticeable dry-wet cycle that stores and releases secondary acidic minerals of wide ranging solubilities. X-Ray Diffraction analyses identified alunite(?), calcite, gypsum, chalcanthite, paracoquimbite, coquimbite, ferricopiapite, zincocopiapite, bronchantite, antlerite, and posnjakite that can potentially store and release a host of major and trace ions.

Minewall loading rates are up to 100 to 1000 times higher than humidity cell loading rates on a mass per mass basis, and likely originating from both primary mineral weathering (sulfide oxidation) and secondary mineral dissolution. It is likely that the degree of secondary mineral storage and release changes throughout the year in response to dry- (storage) wet-season (release), compared to primary mineral weathering loading contributions. Implications of these Minewall station loading rates are that they do not require scaling factors for use in water quality modeling to avoid effectively underestimating modeling estimates.

Keywords: Minewall, epithermal, modeling, loading rates, water quality

INTRODUCTION

The ore deposit of interest is an economic Au-Ag high sulfidation epithermal type. The mine is an open pit heap leach operation and has been operating since the late 1990s. The mine classifies material in terms of alteration types summarized in Table 1 and Figure 1.

Table 2 summarizes the paragenetic minerals identified relevant to ARD-ML as sources of acidity and metal loadings to waste rock materials contact water quality. These minerals are termed as primary minerals in this study.

Table 2 Selected paragenetic minerals important to ARD-ML processes

Selected paragenetic minerals	Ideal formula
Alunite	$KAl_3(SO_4)_2(OH)_6$
Pyrite	FeS_2
Sphalerite	(Zn,Fe)S
Bismuthinite-stibnite	$Bi_2S_3 – Sb_2S_3$
Enargite	Cu_3AsS_4
Galena	PbS
Tennantite	$(Cu,Fe)_{12}As_4S_{13}$
Covellite	CuS
Native sulfur	S
Schwertmannite	$Fe^{3+}_{16}O_{16}(OH)_{12}(SO_4)_2$
Lepidocrocite	FeO(OH)
Goethite	FeO(OH)

The objectives of this study were to:

- Quantify site specific *in situ* loading rates of the various alterations types found on the open pit wall on a unit area basis [i.e., mass / (area * time)]
- Characterize surface water quality sampled directly downstream of the major mine components including pit walls and waste rock dumps
- Identify and quantify the secondary minerals controlling metal solubility, and
- Suggest modeling approaches to estimate closure water quality for mitigation purposes.

METHODOLOGY

International industry standard methods were employed throughout the desktop, laboratory and field scale studies consistent with MEND (2009) guidelines, the GARD Guide (INAP 2009) and Morin and Hutt (1997). Three types of sampling were carried out: surface waters, solid-phase secondary mineral precipitates and mine wall station leachate sampling within and directly downstream of the waste rock dumps (WRD) and pit walls. Analytical testing for the aqueous-phase was carried out at Certimin S.A., Lima (formerly CIMM) while solid-phase analyses were carried out at Mineral Services in North Vancouver, British Columbia, Canada.

Surface Waters

Surface water samples were collected within and directly downstream of the waste rock dumps and pits. The following parameters were measured or analyzed: pH (lab and field), electrical conductivity (lab and field), lab REDOX, acidity, sulfate, dissolved oxygen, alkalinity (carbonate, bicarbonate), cyanide (total, WAD), nitrogen (nitrate, nitrite, ammonia), fluoride, chloride, phosphate-phosphorus, total suspended solids, total dissolved solids, turbidity, and a 54 total and dissolved metals suite. Samples were collected in the field, split for total and dissolved metals analyses, preserved with standard high purity nitric acid after passed through standard 0.45 µm filters. Holding times were typically 24-48 hrs.

Secondary Mineralogy

Secondary mineral precipitates were identified in the field and collected for advanced mineralogical analyses. The objectives of the analyses was to identity and quantify the secondary weathering phases and associated metals of interest including Al, Fe, S, As, Cd, Cu, Pb, Sb, Zn and Hg. The mineralogical analyses consisted of X-Ray Diffraction with Rietveld-refinement, optical petrography, and scanning electron microscopy.

Thermodynamic Modeling

The geochemical thermodynamic modeling software Geochemist's Workbench (GWB) was used to model surface waters to determine potential secondary mineral controls on water quality (Bethke, 2008). Note that the data base thermo_minteq.dat was used for all modeling runs.

Minewall Stations

Established methodologies (Castendyk and Eary, 2009) for the prediction of closure pit lake water quality include mass-water balance approaches in parallel with thermodynamic geochemical modeling and water balance calculations. A prerequisite includes the quantification of elemental loading rates, typically sourced from standard humidity cells or larger-scale field kinetic tests (MEND, 2009) on a mass per unit mass basis over time [e.g., mg/(kg * week)]). Note that field based approaches are preferred for predictive water quality assessments as they include secondary mineral solubility controls under site-specific conditions of aged materials at advanced oxidation conditions (i.e., microbially mediated with pyrite oxidation by Fe^{3+}). Conversely, laboratory humidity cells are designed to estimate primary oxidation rates using a high liquid-to-solid leachate ratio (MEND, 2009) and are often the only source of elemental loading rate data available for predictive water quality modeling but require scaling from laboratory conditions to expected site-specific field conditions.

Another approach is the quantification of loadings rates on a mass per unit surface area basis [e.g., mg/(m^2*week)]. This later method, referred to as the Minewall approach, is a site-specific method and has been used successfully to bracket loading rates without the use of scaling factors (Morwijk Enterprises, 1995; Morin and Hutt, 2004). The method is particularly useful for active mines where reactive pit wall material is exposed and available for relatively easy leachate sampling. The method is designed for pit lake water quality predictions required for mine closure assessments.

Five Minewall stations were constructed on the main alteration types. Photo 1 shows an example station after construction. Between sampling events, a cover was placed over the station to allow:

- Mineral reactions to proceed aided only by humidity as the sole source of water, and

- Secondary minerals to precipitate and prevent flushing or hydraulic disturbance.

It is expected that the reactivity of a particular alteration type varies at different scales (mm to meters) and temporally as new materials is exposed on pit wall, however the size of the Minewall window (~1m), good understanding of typical alteration mineralogy and selection in the field results in reasonable representative sampling. Site-specific field-based calculations of material loading rates and reaction progress over time was subsequently generated.

Photo 1 Typical Minewall station prior to leachate collection (left) and with cover between sampling events (right). Note that the upper horizontal structure of the Minewall measures ~50cm for scale.

Minewall stations were sampled weekly for the first month and then monthly for eight months thereafter between November 7, 2011 and July 7, 2012. Sampling consists of gently flushing one litre of distilled water over the face of the exposed material and collecting the leachate in a clean HDPE sample bottle for analyses. Approximately 0.75 L of leachate was collected per sampling event. The following parameters were measured or analyzed: pH (lab), electrical conductivity (lab), REDOX, acidity, alkalinity, sulfate, and a 52 element total and dissolved suite. Full Minewall construction and sampling methodology can be found in Morin and Hutt (2004). Samples were collected in the field, split for total and dissolved metals analyses, preserved with standard high purity nitric acid after passed through standard 0.45 μm filters. Holding times were typically 24-48 hrs.

RESULTS AND DISCUSSION

Surface Water Quality (WQ)

These waste materials are highly acid generating; similar to other deposits types around the world, such as Pueblo Viejo, Dominican Republic and Summitville, Colorado. Waste rock dump and pit wall contact waters can be described by the Ca-Fe-Al-H-SO_4 system (Figure 1). The measured acidity over time indicates that there is a noticeable increase as the wet season begins, typically October or November. The mechanism for this temporal difference is due to the dissolution and flushing of soluble secondary acidic minerals, which have precipitated in the preceding dry season via evapo-concentration. This is a common climate driven process observed at other acidic mine sites controlling WQ (Nordstrom and Alpers, 1999). Such waters are often characterized by a Ficklin plot where the acidic system results in high dissolved trace metal concentrations, and in this case is an excellent predictive tool to determine bulk trace metal concentrations Figure 2. The pH shows a narrow acidic range less than pH 3.0 and can be considered to have high metals and high acidity originating from epithermal high sulfidation quartz alunite acid sulfate mine components (Plumlee et al, 1999).

Note that water treatment at site includes HDS + RO technology to meet national WQ regulations for users downstream. ARD has been calculated to continue and persist for several decades to hundreds of years after closure.

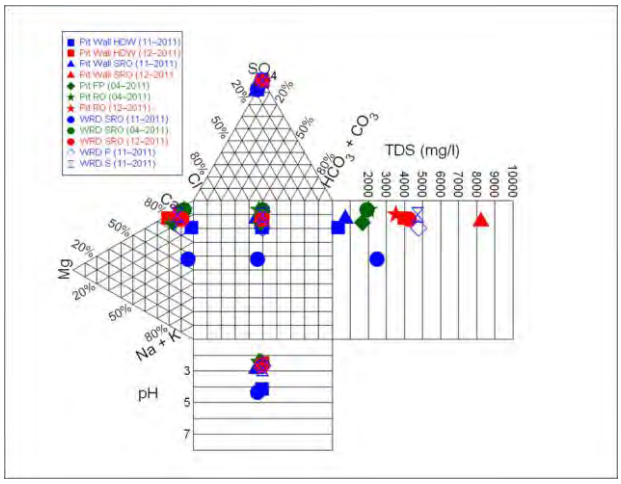

Figure 1 Durov diagram of waste rock dump and pit wall contact waters

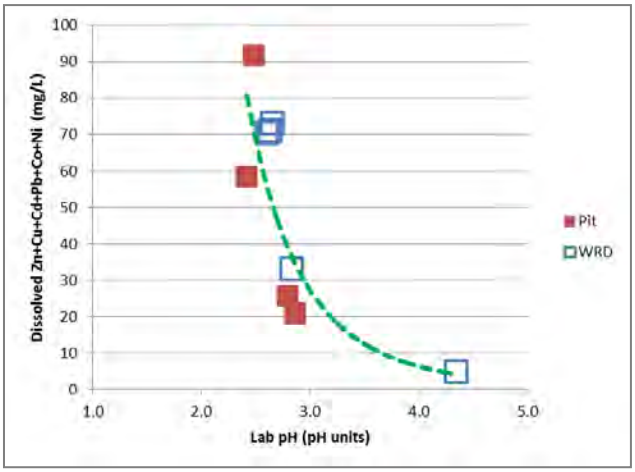

Figure 2 Ficklin Plot of waste rock dump and pit wall contact waters.

Thermodynamic Modeling

Sulfide oxidation and acid sulfate dissolution at Pierina are the main geochemical process impacting WQ. The paragenetic sequence of secondary Fe-SO4 minerals after pyrite oxidation has been documented by Bandy (1938), Buurman (1975) and Nordstrom and Alpers (1999) and is summarized by Jambor et al. (2000; Table 1). The mineral evolution can be regarded as an initial precipitation of hydrated Fe-SO4 minerals followed by progressive (de)hydration as the mineral crystal lattice matures. In an open system, such as WRDs and pits, the (de)hydration cycle will typically follow the seasonal climate trends (precipitation and evaporation). However, the entire or partial suite of hydrates may be present as moisture content or vapour pressure varies at the micro-scale within/on the WRD and pit wall materials.

Table 1 Paragenetic Secondary Mineral Sequence after Pyrite Oxidation (modified from Jambor et al, 2000)

Stage	Mineral	Formula
Early	Pyrite	FeS_2
	Melanterite	$FeSO_4 \cdot 7H_2O$
	Siderotil	$FeSO_4 \cdot 5H_2O$
	Rozenite	$FeSO_4 \cdot 4H_2O$
	Szmolnokite	$FeSO_4 \cdot H_2O$
	Copiapite	$Fe^{2+}Fe^{3+}_4(SO_4)_6(OH)_2 \cdot 20H_2O$
	Romerite	$Fe^{2+}Fe^{3+}_2(SO_4)_4 \cdot 14H_2O$
	Coquimbite	$Fe^{3+}_2(SO_4)_3 \cdot 9H_2O$
	Kornelite	$Fe^{3+}_2(SO_4)_3 \cdot 7H_2O$
	Rhomboclase	$(H_3O)Fe^{3+}(SO_4)_2 \cdot 3H_2O$
	Parabuttlerite/Voltaite	$K_2Fe^{2+}_5Fe^{3+}_4(SO_4)_2 \cdot 18H_2O$
Late	Jarosite/Halotrichite/Bilinite	$Fe^{2+}(Al,Fe^{3+})_2(SO_4)_4 \cdot 22H_2O$

Results of thermodynamic modeling of WRD and pit WQ are presented in Figure 3 through Figure 6. Modeling indicates dissolved Ca, K, Al and SO_4 may be controlled in the form of gypsum ($CaSO_4 \cdot 2H_2O$) and alunite precipitation [$(K, Na)_2Al_6(SO_4)_4(OH)_{12}$]. Additional potential controls on dissolved Cu and SO_4 include bronchanite [$Cu_4SO_4(OH)_6$] and antlerite [$Cu_3SO_4(OH)_4$], however the pH of the system would have to approach neutral conditions for bronchanite stability.

Other secondary minerals that may be theoretically controlling WRD and pit WQ are ferrihydrite [$Fe(OH)_3$], K-jarosite [$Fe^{2+}(Al,Fe^{3+})_2(SO_4)_4 \cdot 22H_2O$] and melanterite ($FeSO_4 \cdot 7H_2O$). Ferrihydrite is important as it is a common host for metal sorption in the aqueous systems (Dzombak and Morel, 1990). The latter two minerals are important as they bracket an important and common family of hydrated Fe-SO_4 minerals found in acid environments (Nordstrom and Alpers, 1999 and Jamieson et al, 2005) and may be additional controls on trace metals such as Zn.

Secondary Mineralogy

Secondary mineral precipitates can be found at the centimetre to 10s of meter scale. Six of ten samples collected showed distinct morphological differences or were from distinct environmental locations (i.e., WRD and pit vs. Leach Pad) and were submitted for mineralogical analyses.

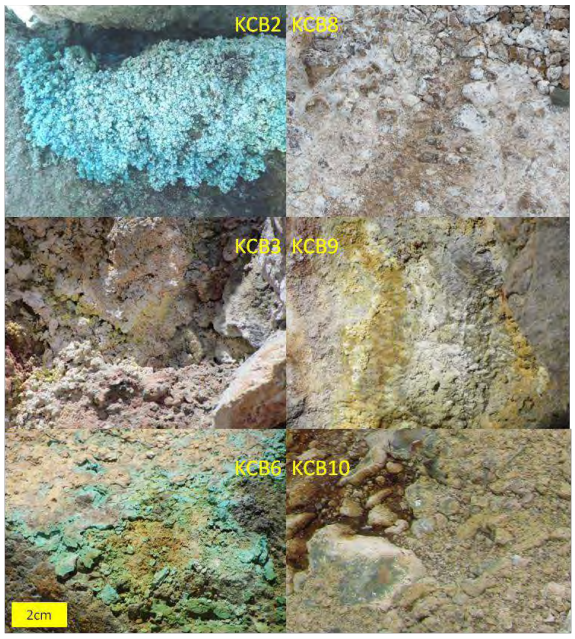

Figure 7 Secondary mineral sample locations

Table 2 summarizes the secondary minerals identified by XRD with Rietveld refinement. Note that primary alunite is present in several distinct morphologies and is ubiquitous. Furthermore, alunite is kinetically slow to precipitate at standard temperature and pressure likely requiring high ionic strengths in solution to overcome this barrier (Alpers et al, 1994). However, alunite has been observed in low P&T digenetic environments (Wray, 2011; Prietzel and Mayer, 2005; Goldbery, 1980 and Goldbery, 1978). The formation of alunite can be described as a result of the alteration of K-rich clays, such as kaolinte and/or illite in acidic environments. Although sample collection focussed on secondary minerals, "entrainment" of primary alunite in sample collection cannot be ruled out.

An unexpected result of the XRD analysis was the presence of calcite in the 6KCB sample. Calcite is extremely soluble in acidic conditions, such as those found within the pit and WRD environments. Analytical misinterpretation has been ruled out as this mineral was identified petrographically on several occasions. Carbonate is typically found as rims on lithic fragments and is thought to be either from the original paragenetic sequence or less likely, as a secondary precipitate forming at ambient conditions in the pit. In addition, calcite may be present at the core of particles, either through original paragenetic mineral encapsulation or subsequent secondary mineral armouring and unavailable for reactions. Neither of these possibilities can be ruled out at this time, and may be moot as there is nil buffering capacity evident in the highly acidic pit and WRD aqueous environment. However, the identification of bronchanite via XRD coupled with the theoretical thermodynamic modeling provides supporting evidence and a potential geochemical pathway for slightly acidic to near-neutral pH micro-environments. However, the pH of the pit on a macro-scale remains highly acidic.

Calcium, Cu, Fe, Zn and S attenuating mechanisms are evident through ideal crystal lattice structure formulas. This is especially important for the Cu-SO_4 phases where Cu contributes as much as 4 moles to the weight of the ideal minerals found at station 6KCB. Additional important trace elements associated by either substitution/co-precipitation into the lattice or sorption onto the

mineral include Cu, Co, Mn, S, Al, Si, Na, Pb, Mn. Note that no micro/nano mineralogical techniques were done to investigate these mechanisms and quantify concentrations.

Table 2 Secondary minerals identified by XRD with Rietveld refinement.

Selected Minerals	Ideal Formula	2KCB	3KCB	6KCB	8KCB	9KCB	10KCB
				Weight %			
Pyrite	FeS_2	2.6		4.2		5.7	3
Covellite?	CuS				0.2		
Alunite	$K_2Al_6(SO_4)_4(OH)_{12}$	6.9	6.3	7.6	1.2	9.8	1.4
Gypsum	$CaSO_4 \cdot 2H_2O$	0.5		35.3	1.1	19.5	13.5
Chalcanthite	$CuSO_4 \cdot 5H_2O$	78.1					
Paracoquimbite	$Fe_2(SO_4)_3 \cdot 9H_2O$		28.7 (Al, Si, Na)				
Coquimbite	$Fe_2(SO_4)_3 \cdot 9H_2O$		2.2				
Ferricopiapite	$Fe^{2+}_{0.66}Fe^{3+}_4(SO_4)_6O(OH) \cdot 20H_2O$		47.2 (Al, Si)				
Zincocopiapite	$ZnFe_4(SO_4)_6O(OH) \cdot 18H_2O$					11.7	
Calcite	$CaCO_3$			7.0(Cu, Co, Mn, S, Al, Si, Na)	0.5		
Bronchantite	$Cu_4(SO_4)(OH)_6$			14.1 (Al, Si, Fe)			
Antlerite	$Cu_3(SO_4)(OH)_4$			9.2 (Al, Si, Fe)			
Posnjakite?	$Cu_4(SO_4)(OH)_6 \cdot H_2O$			0.6 (Al, Si, Fe)			
Amorphous (SEM)	(Fe, Mn, Pb) - (hydr)oxide Fe – (hydr)oxide with As, Zn, P, Al						

Notes: Elements in parentheses identified in/on mineral structure by SEM.

Secondary minerals are both sinks and sources of the above mentioned elements. They are sinks as the dry season approaches and pit and WRD waters experience evapo-concentration and secondary mineral precipitation. Conversely, secondary minerals are sources of elemental loadings to surface waters as the wet season approaches and minerals dissolve due to their moderate to high solubility.

Mass Loadings per Unit Area

Minewall loading rates (Figure 8 to Figure 10), based on unit surface areas, were compared with humidity cell loading rates and show *in situ* field rates are potentially 100-1000 times higher than lab-based rates. This agrees with an extensive comparison of Minewall and humidity cell data done by Morin and Hutt (2004). The Minewall loading rates are believed to be originating from both primary mineral weathering rates (pyrite oxidation) as well as secondary mineral dissolution. The relative magnitude of each was not determined; however, it is likely that secondary dissolution contributions oscillate throughout the year being greater during the onset of the wet season compared to primary minerals weathering loading contributions. The humidity cells contained drill core reject (80% passing <2 mm) that was acid generating (Figure 8) and show initial high first flushes, but much lower than Minewall station average acid loading rates. Note that humidity cell material particles are assumed to have cubic surface areas as a reasonably conservative estimate (as opposed to a sphere) for each mesh size particle analysis and respective surface area calculations.

The above observations have important scaling implications to modeling. Scaling is defined as the factors used to estimate the climatic and physical factors in the field that require accounting for when loading rates are derived from laboratory-based kinetic experiments (e.g., humidity cells). Minewall stations are designed to produce site-specific in situ loading rates, meaning that climate and physical scaling factor products are equal to one. The Minewall station leachates are thus assumed to be at quasi-equilibrium (Morin and Hutt, 2007), meaning that the following factors are at a scale large enough not to require additional adjustments:

Mass – generally it is difficult to convert exposed Minewall station material to a mass basis, as the depth/thickness of mass contributing to active leaching cannot be accurately estimated. For example, if we assume a uniform 2.7 t/m^3 density of the minerals exposed at the QA Minewall station and either a 0.002 m or 0.01 m active leaching depth, the resulting calculations would yield 0.46 kg and 2.3 kg of active mass contributing to leaching, respectively. Field observations indicate that an estimated volume of <10% to 15% of the total flushing solution (~1 L) is initially taken up (i.e., sponge effect) by the wall material. Therefore, field observations would suggest that the depth of the active mineral layer is on the order of millimetres instead of cm. This estimate varies for the different alteration types (i.e., the AR material has a relatively higher sponge effect than the QA material), however the absolute differences between alteration types is not believed to impact concepts or interpretations materially. Note that inundation of large proportions of pit wall areas (i.e., pit lake formation) can result in water penetrating the wall to a significant depth as the pit lake develops and perhaps nullifying the small-scale observations at the Minewall station. Another important observation is that the ARG material shows continually increasing dissolved constituents and is likely associated with its friable nature. The advanced hydrothermal alteration inherent in the ARG material and subsequent chemical weathering at ambient conditions degrades this material physically into a fine-grained "muck" quickly after initial mining exposure. The potential suspended solids content is in the 1 g/m^2 to 10 g/m^2 range for all alteration types.

Area – at the Minewall station, the scale is believed to represent the alteration type average per unit area. In other words, alteration surface area in one part of the pit is equal to alteration surface area in another part of the pit (i.e., no scaling roughness factors according to fractures).

Surface Area Roughness – surface area roughness and/or fracturing is estimated to control loading rate estimates on a mass per unit area by 2-3 factors at most. This will not affect selection of base cases or upper bound loading rates for predictive WQ modeling.

Solid:Liquid ratio – over a one week period in April and November 2011, 5 L and 2 L of precipitation would have fallen on an average Minewall station surface area of 0.11 m^2, assuming

the Minewall surface was planar. In reality, the Minewall stations are inclined and if we assume a slope of 1:2.5 the resulting planar area of the average Minewall station would capture 2.2 L and 0.8 L for the month of April and November, respectively. In practicality, this is considered the same as the 1 L flushing and 0.75 L collection volumes during Minewall station sampling in the first month.

Reaction rates – reaction rates are assumed to be optimal (i.e., pH <3.5 and advanced enough that Fe^{3+} is the primary electron acceptor in pyrite oxidation likely mediated by microbial activity as shown in Equations 1). Note that no Fe speciation or microbial identification was carried out in this study; however, the low pH, high dissolved Fe, SO_4 and acidity in WQ samples and age of the pit wall material suggests this assumption is valid.

$$Fe^{2+}_{(aq)} + 0.25O_{2(aq)} + H^{+}_{(aq)} \rightarrow Fe^{3+}_{(aq)} + 0.5H_2O_{(l)}$$

$$FeS_{2(s)} + 14Fe^{3+}_{(aq)} + 8H_2O_{(l)} \rightarrow 15Fe^{2+}_{(aq)} + 2SO_4^{2-}{}_{(aq)} + 16H^{+}_{(aq)}$$

Equations 1 Ferrous Oxidation (upper) and Advanced Pyrite Oxidation (lower)

Conversely, humidity cell scaling factors typically -scale down loading rates for grain size based on the fact that the humidity cell is testing 80% <2 mm and is often assumed to typically represent 5% to 25% of the waste and pit wall grain size. Additionally, this is only one of several scaling factors that are applied to loading rates (Morin, 2013) translating into a typical factor product of 0.1-0.001. This effectively decreases the applied loadings rates and could underestimate WQ predictions. Note that the humidity cells operated for 25 and 60 weeks to near stable rates. The comparison between lab and field data strongly suggests the Minewall station data should be used for future pit inundation, flushing and pit lake predictions for closure WQ and mitigation assessments.

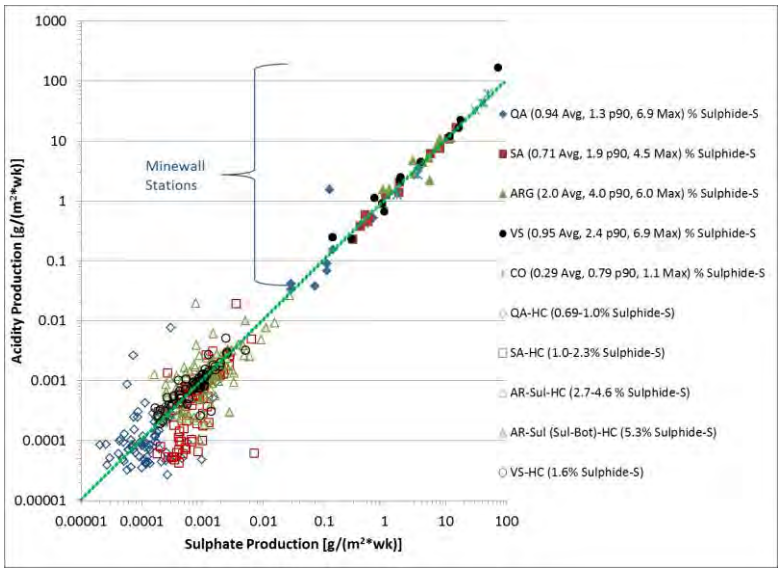

Figure 9 Minewall station and humidity cell leachate acidity versus sulfate loading rates.

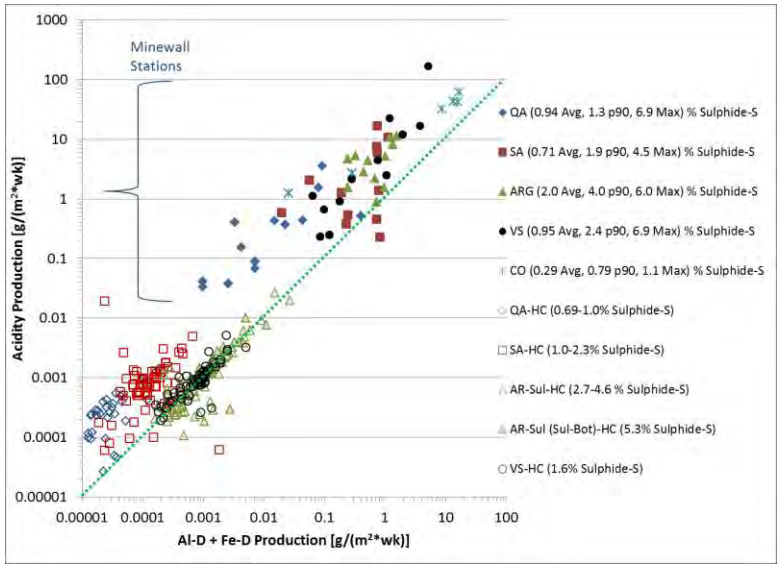

Figure 10 Minewall station and humidity cell leachate acidity versus Al-D + Fe-D loading rates.

CONCLUSION

Epithermal high sulfidation acid sulfate geology produces leachate water high in metal and acidity, consistent with other deposits of the same type. Field leaching studies were initiated on representative alteration types on aged pit walls at the meter scale known as Minewalls. Loading rates are up to 100 to 1000 times higher than humidity cell loading rates on a mass per unit area basis with both primary and secondary minerals contributing to loadings on a seasonal basis. Minerals of interest included pyrite, calcite, chalcanthite, paracoquimbite, coquimbite, ferricopiapite, zincocopiapite, bronchantite, antlerite, and posnjakite and possibly alunite. Minewall

station loading rates do not require scaling factors for use in water quality modeling and will avoid effectively underestimating estimates.

ACKNOWLEDGEMENTS

The authors wish to thank Alexandra Mauler-Steinmann for excellent and timely delivery of mineralogy reporting. Engaging discussions with Drummond "Dusty" Earley III were much appreciated. Data collection was facilitated by various dedicated and enthusiastic mine site and Klohn Crippen Berger personnel.

Establishing an Total Dissolved Solids: Electrical Conductivity Ratio for Mine Waters

Christian Wolkersdorfer[1] and Elena Hubert[2]

2. *Technische Universität Bergakademie Freiberg, Germany*

ABSTRACT

Total dissolved solids (TDS) expresses the sum of all dissolved ions in water. In a given water, the TDS content in mg/L and electrical conductivity κ_{25} at 25 °C in µS/cm are related to each other by the equation $TDS = \kappa_{25} \times f$, where f is a constant, commonly referred to be in the range of 0.55 – 0.9. Mine water with elevated TDS contents rapidly causes scaling or corrosion, as high TDS values are often associated with lower pH-values. TDS is also used to calculate the potential amount of sludge in mine water treatment, which makes TDS a crucial parameter.

For accurate TDS determinations, filtered water samples are oven dried and the mass of the residue is the TDS-content. As this procedure is time consuming, the TDS is commonly estimated from EC measurements using the above equation and laboratory and field conductometers are manufactured with a programmable conversion factor. Normally TDS is reported without further considering the conversion factor or its way of measurement.

In this paper, we describe TDS/EC conversion factors for 45 South African, mining impacted waters. It can be shown that the conversion factor ranges from 0.25 to 1.34 with a mean of 0.86 and a standard deviation of 0.19. No correlation with other on-site parameters was found, though there is a tendency to higher conversion factors at lower pH-values and higher electrical conductivities.

Based on our work we conclude that prior to using the TDS/EC conversion equation, the conversion factor for the single mine water, not only site specific but also time depended, must be determined in the lab and the conductometer be programmed with this conversion factor. In addition, the conversion factor 0.65 recommended in the South African Water Quality Guidelines should no longer be used for mining impacted water.

Keywords: mine water, South Africa, electrical conductivity, total dissolved solids (TDS)

INTRODUCTION

When electrolytes or salts are dissolved in aqueous solutions their ions dissociate and increase both the amounts of dissolved solids in the solution and their conductivity (Hölting and Coldewey, 2013). Consequently, both parameters are relevant in characterizing the chemistry of aqueous solutions. Electrical conductivity (EC) and total dissolved solids (TDS) are commonly analysed in water samples to provide an indication for the waters' mineralization or salinity. Both parameters are related to each other, as each charged ion of the dissolved constituents contributes to the conductivity of the aqueous solution. EC measurements are therefore commonly used for estimating the TDS (Gustafson and Behrman, 1939).

Electrical conductivity is measured with a probe that determines the resistivity of the aqueous solution. Because the resistivity is the reciprocal of the conductance, the conductivity of the aqueous solution can be calculated based on the resistivity measurement (American Public Health Association et al., 2005, Hölting and Coldewey, 2013):

$$G = \kappa \frac{A_c}{l_c}$$

where G is the conductance in S, κ the electrical conductivity in S/cm, A_c the cross section of the conductor in m² and l_c the characteristic length in m. The electrical conductivity κ is calculated as follows:

$$\kappa = \frac{l}{A \cdot R}$$

where κ is the electrical conductivity in S/cm, l the distance between the electrodes in cm, A the cross section of the electrodes in cm² and R the electrical resistance in $\Omega = \frac{1}{S}$.

Because the electrical conductivity is temperature dependent (Smith, 1962), the measured value has to be temperature compensated, usually to 25 °C.

TDS is determined analytically by evaporating the aqueous solution and measuring the weight of the dry residue (Hem, 1985). Accurate determination of the total dissolved solids for filtered or unfiltered samples is achieved by evaporating the aqueous solution at predetermined temperatures, which are in the range of 105 to 110 °C and at 180 °C (American Public Health Association et al., 2005). When comparing the sum of all analysed ions and molecules with the analytically determined TDS, the latter frequently exceeds the sum of ions, as not all water constituents are usually included in the analysis (Howard, 1933).

Problems with this method occur when water contains considerable amounts of sulphate, as the minerals that precipitate during evaporation of the water are Ca, Mg or Na sulphates which contain water in their crystal structure (Howard, 1933). Even at a temperature of 180 °C, not all of the crystal water is released from the crystal and consequently, the determined TDS is greater than the sum of all analysed ions in the aqueous solution.

It can be shown that EC and TDS are related with each other by the following equation

$$\mathrm{TDS} = \kappa_{25} \cdot f \quad [\mathrm{mg/L}]$$

where TDS are the total dissolved solids in mg/L, κ_{25} the temperature compensated electrical conductivity in µS/cm at 25 °C and *f* a conversion factor in (10 g m)/(L S). Commonly, the value of this factor is given to be in the range of 0.55 – 0.9 (American Public Health Association et al., 2005, Wolkersdorfer, 2008) and many probes are pre-set to a factor in this range. If the water contains elevated concentrations of SiO_2, this relationship is no longer accurate and corrections for SiO_2 need to be applied (Day and Nightingale, 1984).

However, there are cases where those values can't be used to precisely calculate the TDS and as each aqueous solution contains different ions the factor *f* changes with the water's chemistry. Ali et al. (2012), for example, determined factors between 0.41 and 2.01 for industrial waste water in Korea and based on the data of Atekwana et al. (2004) for a contaminated aquifer in Michigan/USA a conversion factor of 0.50 to 1.21 can be calculated. For South African rivers, van Niekerk et al. (2014) determined factors between 0.48 and 0.86 (n = 144 643) and based on the data of Day and Nightingale (1984) the ratio for SiO_2-rich waters in California is between 0.56 and 0.82, while Weiner (2010) provides a range of 0.55 to 0.7 for surface and ground waters and 0.5 for seawater. Department of Water Affairs and Forestry (1996) recommends a single conversion factor of 0.65 for South African waters, while Hobbs (2013) inconsistently used 0.7 or 0.77 while he determined a factor of 0.73 from 1045 EC measurements and TDS lab analysis. In a personal communication, Hobbs reports TDS/EC ratios of 0.46 to 1.29 for a variety of surface, ground and waste waters with an average of 0.83 (n = 16).

Because high TDS values are often associated with lower pH-values, water with elevated TDS concentrations rapidly causes scaling or corrosion. Besides, TDS is used to calculate the potential amount of sludge in mine water treatment. Consequently, the effective and low cost evaluation of TDS becomes a crucial parameter. In this paper, we present first results of determining the TDS/EC-ratio for 45 South African mine water samples taken at various locations in the Witwatersrand gold fields, the Mpumalanga coal mines and various other locations in Gauteng, Mpumalanga and Limpopo.

METHODOLOGY

Unfiltered and unacidified water samples at 45 locations in the South African provinces Gauteng, Mpumalanga and Limpopo were taken in 1-L-PE bottles (Figure 1). On-site, the parameters temperature (Hach CDC401), pH (Hach PHC201), redox-potential (Hach MTC101), electrical conductivity (Hach CDC401) and oxygen saturation (Hach LDO101) connected to a Hach HQ40d were determined. pH was calibrated at the start of each sampling day with pH 4, 7, and 10 standard solutions. Electrical conductivity was calibrated with a 1413 µS/cm 0.01 M KCl standard solution. Samples were kept in a cooler box with cooling elements and stored in a cooling room at TUT until further analysis. Sample aliquots were allowed to warm to room temperature before each lab analysis.

TDS was determined in the lab using standard method 2540 (American Public Health Association et al., 2005) after filtering the sample through a 0.45 µm cellulose nitrate membrane filter. All samples were analysed in duplicates and if necessary in triplicates when the deviation of the duplicates was too high.

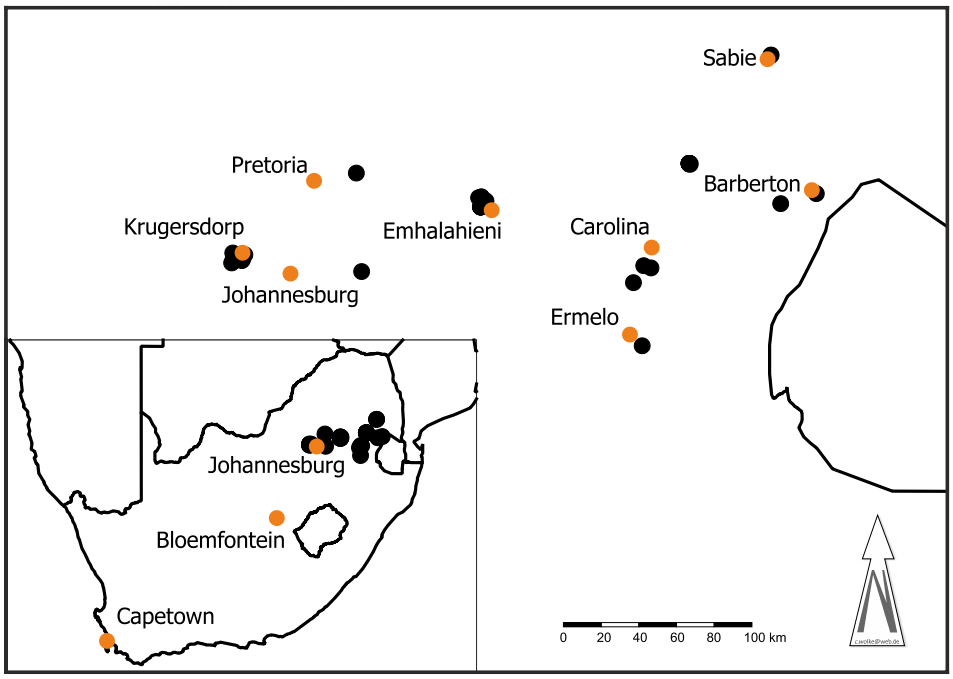

Figure 1 Map of the sampling locations (dark dots) within Nord-Eastern South Africa.

Electrical conductivity was measured in the lab with a daily calibrated EC probe (Hach CDC401) attached to a Hach HQ40d. All data was temperature corrected to 25 °C with a compensation factor individually determined for each sample from measurements of the EC while heating a cooled sample aliquot. This temperature correction factor ranged between 1.16 and 2.16 % with an average of 1.92 %. After measuring the EC and determining the TDS, the conversion factor was determined according to this equation:

$$f = \frac{\mathrm{TDS}}{\kappa_{25}}$$

where f is the correlation factor for EC and TDS in (10 g m)/(L S), TDS is the total dissolved solids in mg/L and κ_{25} the temperature compensated electrical conductivity in µS/cm at 25 °C. Then the averages of the correlation factors f determined for one sample by duplicate or triplicate measurements were calculated.

Both, the geological setting and the climatic conditions of the sampled sites vary. Geologically, the sites are located in the Karoo Supergroup (eMmalahleni, Carolina, Ermelo), the Transvaal Supergroup (Sabie, Krugersdorp, Edendale) and the Barberton Greenstone Belt (Barberton). Climatically, all the sites are within the humid subtropical climate zone (Köppen Climate Classification) with hot, rainy summers and cool dry winters and precipitation between 600 and 800 mm/a (Johnson et al., 2006, Lynch, 2004).

Results And Discussion

Field pH of the 45 samples ranged between 2.45 and 7.85 and the electrical conductivity between 45 and 16 369 µS/cm with average values of 3.92 and 5 091 µS/cm, respectively (Table 1). As can be

seen, most pH-values are in the range of the iron buffer, some in the aluminium buffer and those at higher pH-values in the carbonate buffer range (Figure 2).

Consequently, the water samples represent a wide range of mining impacted waters in South Africa from the low pH-values indicative for AMD, high pH-values for well buffered mine water and one surface water sample. As expected, the general trend of all samples is that lower pH-values often relate to higher electrical conductivities (Figure 2). Exceptions from the general trend are samples from the abandoned Transvaal and Delagoa Bay Colliery near eMalahleni, which show an exceptionally high electrical conductivity. Reason for this behaviour is that this mine was closed several decades ago, is very close to the surface, the coal was mined underground as well as strip mined and the pyrite oxidation is consequently higher than in the flooded mines with low pH-values. A similar situation occurred in the case of the Yorkshire № 1 and the Shoff mines in the US were the up-dip and strip mined Shoff mine also shows higher contamination loads than the down dip Yorkshire № 1 mine (Mentz et al., 1975).

Lab determined TDS ranged between 50 and 13 984 mg/L with an average of 4 279 mg/L and a standard deviation of 4 422 mg/L (Table 1). Using those analytically determined total dissolved solids concentrations, the calculated TDS/EC ratio is in the range of 0.25 to 1.34 with an average of 0.86 and a standard deviation of 0.19 (Figure 3). This result is unexpected as an e-mail poll revealed that most South African mine water researchers (n = 38) either use the factor 0.65 from Department of Water Affairs and Forestry (1996) or the factory programmed factor of the EC meters.

To identify which other on-site parameter can be used to estimate the TDS, statistical investigations were conducted. Yet, no dependency on another on-site parameter could be found for the 45 analysed samples. Most of the TDS/EC factors increase with increasing TDS of the sample, but the abandoned tailings dam and the Transvaal and Delagoa Bay Colliery samples deviate from this general trend (Figure 3).

Table 1 Field and lab parameters of the analysed mine water samples. Average of the pH calculated from the $\{H^+\}$ activity. TDS from lab analyses.

	pH, –	κ_{25}, µS/cm	TDS, mg/L
n	45	45	45
Minimum	2.45	67	50
Maximum	7.85	16 369	13 948
Median	3.76	3 059	2 832
Average	3.92	4 769	4 279
σ	1.93	5 091	4 422
σ, %	40	107	103

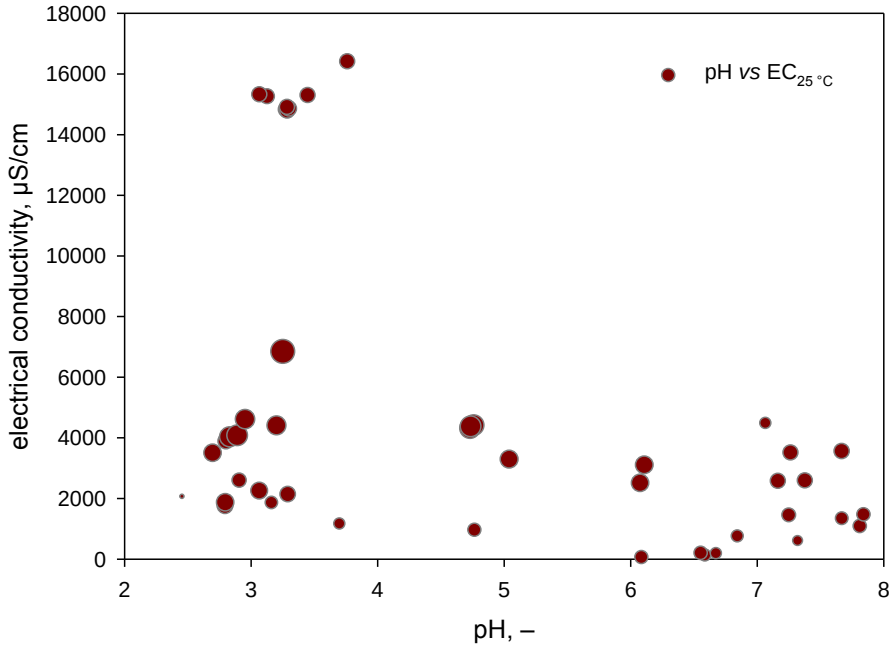

Figure 2 Scatter plot of the measured pH-values and electrical conductivities of all samples. The radius of the circles represents the TDS/EC ratio, $n = 45$.

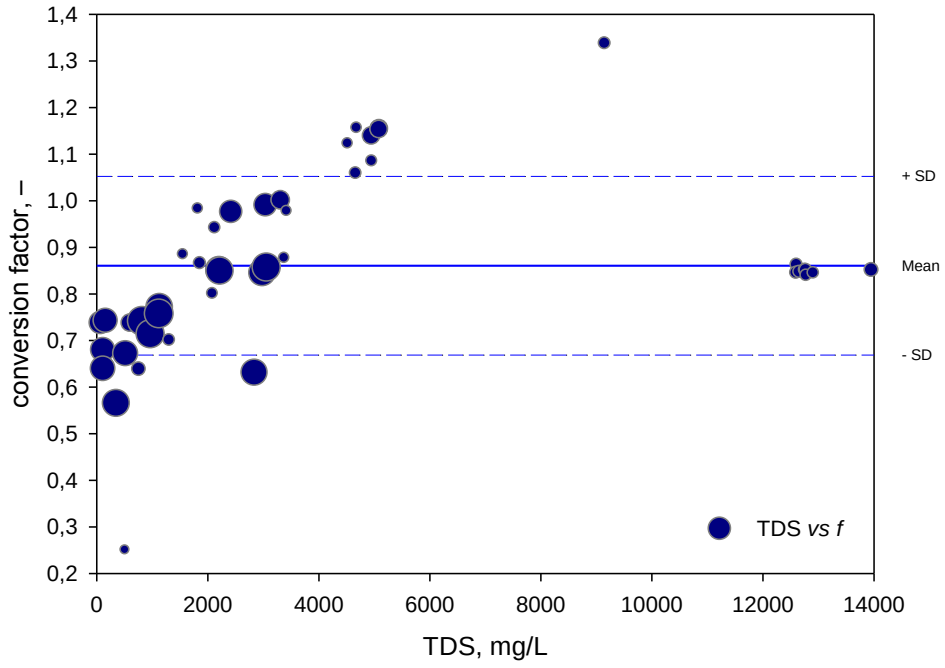

Figure 3 Scatter plot of the lab determined TDS and the TDS/EC ratios. The radius of the circles is proportional to the pH-value of the sample; $n = 45$.

CONCLUSIONS AND RECOMMENDATIONS

As can be seen from the above data, it is not possible to use a single conversion factor from EC to TDS to estimate the total dissolved solids of a mine water sample. The range of the ratio is too high to use it as a reliable tool for TDS estimations. Consequently, prior to using the TDS/EC conversion equation, the conversion factor for the single mine water, which might change with local, diel or seasonal variations, must be determined in the lab and the conductometer be programmed with this conversion factor. Together with the results, the applied conversion factors should be mentioned. In addition, the conversion factor 0.65 recommended in the South African Water Quality Guidelines (Department of Water Affairs and Forestry, 1996) should no longer be used for mining impacted water and the guidelines might need to be updated in this regard.

Future work will investigate a larger set of samples and will include chemical analyses as well. This shall determine how the TDS can be more reliably estimated from the EC without its lengthy lab determination.

ACKNOWLEDGEMENTS

We thank our colleagues at Tshwane University of Technology (TUT) who provided us with equipment and facilities for analysing the water samples and our colleagues at various mines and governmental institutions who provided us with locations, water samples and data. This work was financed by a SARChI (South African Research Chair Initiative) research grant of the NRF (National Research Foundation). Special thanks to Henk Coetzee who introduced us to the "heavily toxic" mine water situation in South Africa.

A more comprehensive paper with all the relevant data is currently under review in the Journal Water SA in will be available during the year 2015.

3. *Geochimica, USA*

ABSTRACT

A geochemical assessment of a lined tailings deposit from an operating gold mine located in a semiarid climate was performed for this study. A total of 58 samples were collected, including surface and deep tailings as well as fresh tailings from the carbon-in-leach circuit. Several analyses were performed on these samples, including the modified acid-base accounting, NAG test, chemical and mineralogical characterization. Kinetic tests were also performed on two samples of fresh tailings. Both mineralogical characterization and the acid-base accounting showed that the neutralization potential in the tailings is at least two times higher than the acidification potential, confirming the current, slightly alkaline conditions of the reservoir, with pH value always higher than 7. The alkalinity trends monitored and gypsum detected in the mineralogical composition (1.3%) of the tailings collected in the reservoir suggest that acid neutralization and precipitation of sulphate salts are occurring. In the oxidizing environment within the tailings, the arsenic concentrations varied from below detection limit to 0.081 mg/L, always with a slightly alkaline pH. This concentration range can be related with the dissolution of amorphous ferric arsenate. The arsenic concentrations monitored in a slightly reducing environment (Eh=-12V) are much higher than the concentrations identified in the oxidizing environment. The Eh, pH, and dissolved iron concentrations (average 3 mg/L) suggest that the arsenic is being released by the reduction of Fe^{3+} to Fe^{2+}. Based on the results from this work, it was possible to establish a conceptual model of arsenic behavior in oxidizing and slightly reducing environments within the tailings, as well as recommend actions for a stable closure of the tailings dam to prevent the arsenic release in the long term to the environment.

INTRODUCTION

In the semiarid climate of Brazil, a gold mine is operating since 1984. In 1988 the underground mining of sulphide ores started and since then, the tailings generated from processing this material (CIP circuit) are being deposited in a tailings dam.

The deposit has two of the ore occurrence of situations. The first one consists of sulfide ore bodies and the second one is consisting of quartz veins containing free gold, basically embedded in the levels of CAX (carbonate - actinolite - shale) of the intermediate package and corner sequence, northeast of Weber range. In the surface ten bodies of sulfide ore emerges of which eight are located in the first layer (thicker) and the two others in the second layer. The sulfide ore bodies are formed by a set of venules and veins , ranging from a few centimeters up to two meters thick. In the veins there are the occurrence of quartz, pyrite and arsenopyrite in different proportions. When the veins are in agreement with the foliation of the rock, the boundaries of the affected zone are regular and parallel to the edges of the veins.

Alteration zones bordering discordant veins are irregular and thicker, with a tendency to the appearance of jagged edges that penetrate laterally in the foliation planes of rock. In the affected zone there has been a decrease in the volume of chlorite, followed by an increase of albite and carbonates towards the vein. Magnetite is replaced by the sulfides and a small increase in biotite is observed. Carbonate and pyrite occur filling all the faults and fractures existing system in the mine, showing late barren hydrothermal event in gold, presented in many places cavities where well-formed crystals of carbonate and pyrite have been developed. The distribution of gold is very erratic, especially in quartz ore, where it is even possible to find visible particles, due to the gold on this type having a particle size larger than the one found in the sulfide ore.

A preliminary mineralogical characterization of the tailings was performed by X-ray diffraction indicating a significant presence of suphides and carbonates. The monitoring results along the years indicated that the tailings dam pond presents alkaline conditions and an increase of As and SO_4 concentrations with depth inside the dam. The arsenic concentrations in the lake are in the order of 10 mg/L while in the toe drain these concentrations are as high as 200 mg/L. All the effluent from the toe drains in recycled back to the reservoir resulting in no discharge to the environment. It is also possible to observe a variation in the Eh. The Eh conditions in the toe drain is -12 mV. This value is significantly lower than the ones monitored in the lake (265 mV). These conditions are expected since that in the toe drain, the water is not in contact with oxygen until it reaches the drain.

Differently from some other trace elements, As can be mobile under neutral to alkaline conditions, depending on the redox of the system (Craw et al., 2003). Since the operation is reaching its closure phase, it is important to evaluate the Acid Rock Drainage potential in the long term and understand the factors that are affecting the As mobility. This evaluation is important in order to establish mitigation actions for closure and post-closure and to immobilize and stabilize As concentrations.

A store and release cover system was designed based on field experiments that ran for 15 months. The objective of the designed cover is to avoid water to get in contact with the tailings. Since the

field experiments presented very good results, it is expected that once this cover is installed above the tailings in the closure stages, that the amount of water seeping at the toe drain decreases and eventually discontinue along the years, which would prevent elevated concentrations of arsenic from the anaerobic environment. This paper, documenting the site conditions and the ARD and As evaluations, is based on a Master of Science thesis presented in 2014 (Bissacot, 2014).

METHODOLOGY

Tailings Sampling

Tailings samples were selected for geochemical characterization beyond that of the standard protocols of the operation. The definition of the tailings sampling locations was carried out with the support of the mine's geology department. Twenty-one equidistant points on 150 meter centers were distributed along the tailings area and sampled at different depths (Figure 1). Two fresh CIL tailings samples and one composite sample of precipitated salts were also collected. For the deposited tailings, a cylindrical soil auger with 4.5 meters inches diameter and 39 cm length was used. The maximum depth achieved is 6 meters. A total of 55 samples of tailings were collected at different depths in the 21 points, totalizing 58 samples sent to the laboratory for further analyzes.

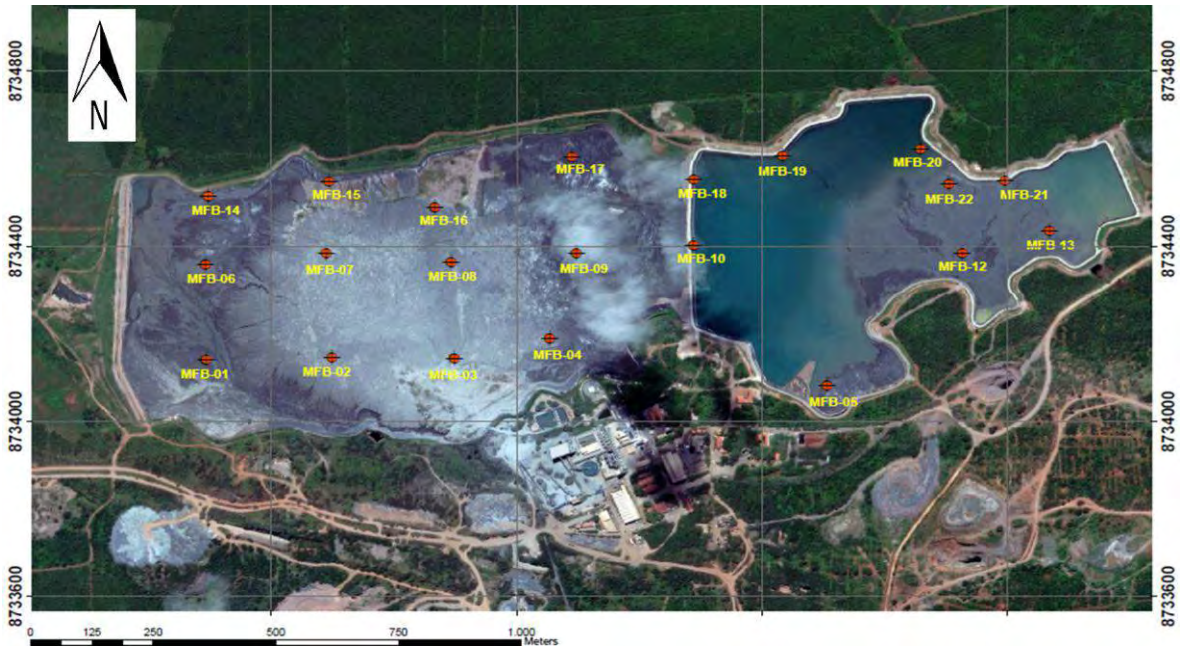

Figure 1 Sample Locations

Tailings Characterization

Several analyzes were performed for understanding the short and long term behave of these tailings and especially the arsenic mobility. The modified acid-base accounting (MABA) was performed in order to understand the potential of these samples for generating acidy. The Lawrence method (MEND, 1991) was selected for this analyzes. The Net Acid Generating test (NAG) was performed as an additional test according the procedure described by Stewart et al. in order to confirm the MABA results. The chemical composition of each sample was conducted by

digesting 0.500 g in aqua regia at 95°C for one hour. The extract was then diluted to 10.0 mL and analyzed for metals by combination of OES and MS using Optima 7300DV for ICP-OES and Elan 9000 for ICP-MS. These results were complemented by mineralogical analyzes by X-ray diffraction with Rietveld refinement and kinetic tests in leach columns according to the AMIRA (2002) procedure.

RESULTS AND DISCUSSION

Acid Rock Drainage Evaluation

The results of the MABA tests in the deposited tailings indicated an average sulfur concentration of 1.36% while the average sulfide sulfur was 1.09%, according to the figure 2 below.

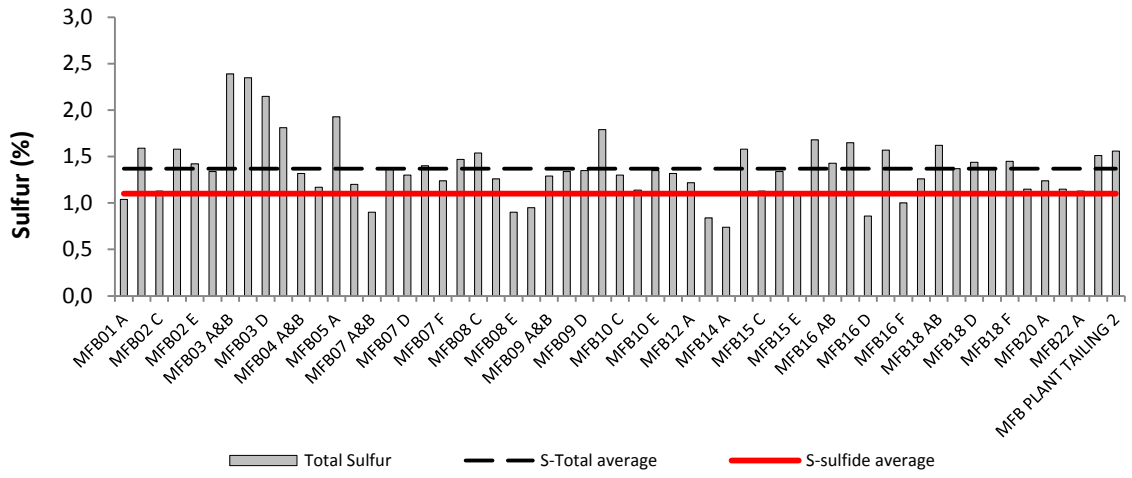

Figure 2 Comparison between S-total and S-sulfide

This can be related to the partial sulfur content that was oxidized into sulfates. In contrast, the fresh tailings collected after the CIL circuit presented an average concentration of 1.54% total sulfur and 1.48% sulfide sulfur. The composite sample collected of the precipitates presented 0.5% of total sulphur on its composition and 0.01% of sulfide sulfur. The average concentration of sulfur can be considered reasonably high, but the average neutralization potential (NP) was also elevated, with an average of 106 kgCaCO3eq/ton. In addition to these results, the NAG tests also indicated an elevated NAGpH for all the tailings tested. According to the NAG test procedure, a sample with a NAGpH greater than 4.5 can be considered as non-acid forming. The test results are summarized in Figure 2.

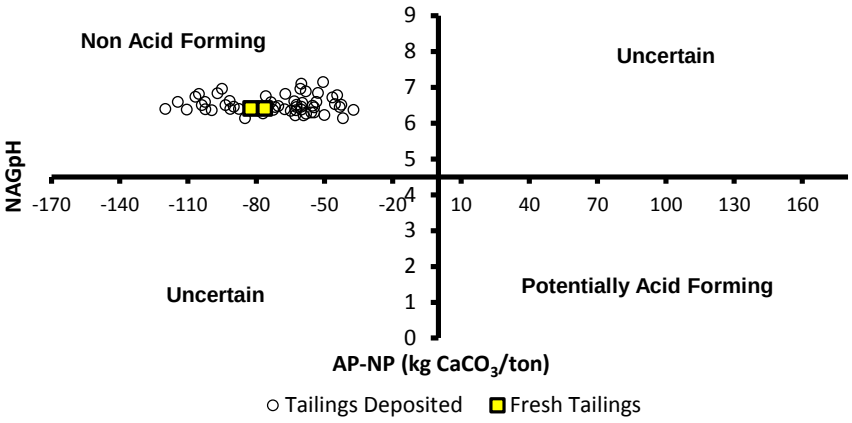

Figure 3 MABA x NAG diagram

Figure 2 combines the results of the MABA and NAG tests. The X-axis represents the MABA results as the difference of AP and NP. [Note that this is the Net Acid Producing Potential, the inverse of the Net Neutralization Potential typically used in North America. In the NAPP system values less than zero imply an excess of NP over AP.] The Y-axis represents the NAGpH. It is possible to observe that all samples were classified in the non-acid forming area of the diagram. In yellow it is possible to observe the fresh tailings and the circles represent the deposited tailings. Both deposited and fresh tailings presented similar characteristics in terms of ARD generation. The results indicated that acid rock drainage should not occur in the short and long term.

Chemical and Mineralogical Composition

The mineralogical characterization by X-ray diffraction with Rietveld refinement was carried out in all the samples. The advantages of this method are the quantitative nature of the method as well as the lower detection limits (Raudsepp & Pani, 2003). In terms of environmental relevance, the sulfides and carbonates are the most important. The silicates are relatively stable and do not significantly change the pH of the solution under most conditions in relevant time periods. The results presented a significant presence of pyrite (1%), arsenopyrite (0.5%) and pyrrhotite (0.7%). Regarding the carbonates, it was identified even higher concentrations of dolomite (3.7%), calcite (6.1%) and calcite/magnesian (2.9%). This may be explained by the limitations of the Rietveld method to identify arsenopyrite phase under at levels below 1%. The gypsum concentrations were detected in the deposited tailings with an average of 1.3%, while in the fresh tailings it was not detected. These concentrations of gypsum indicate that sulfate salts are being formed in the reservoir most like due to the sulfides oxidation. The presence of silicates represents around 80% of the minerals present in the samples, mostly present in the form of quartz and plagioclases. The mineralogy assessment summary is presented in Table 1:

Table 1 Average mineralogy composition - 58 samples

Mineral	Average %
Pyrite	1.0
Pyrrhotite	0.7
Arsenopyrite	0.5
Calcite	6.1
Ankerite – Dolomite	3.7
Calcite, magnesian	2.9
Gypsum	1.3
Silicates	80.3
Iron Oxides	3.6

In addition to these results, elevated grades of arsenic, with an average of 3860 mg/kg, were detected in all the 58 samples analyzed by ICP-MS. The average sulfur detected by ICP was 1.3%, confirming the results previously presented in the MABA.

Kinetic Tests

The kinetic tests are being performed in PVC columns according to the AMIRA 2002 procedure. The water addition is performed once a week in an entire cycle of four weeks. An amount of 200 mL of water is added in the first three weeks and in the fourth week, 800 mL is added. The leachate solution is collected and analyzed for pH, conductivity, sulfate and metals. The results of As and Fe are presented in Figure 3.

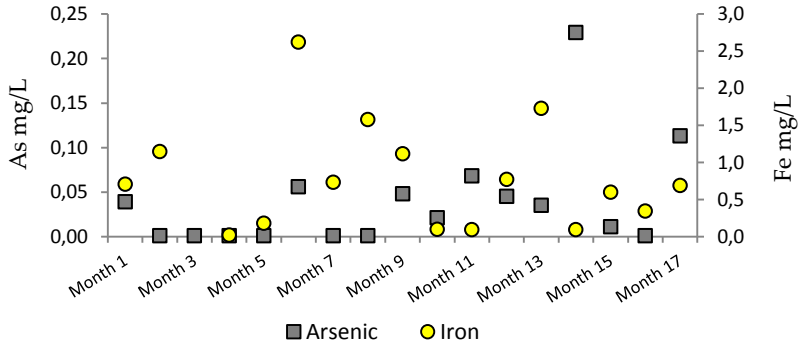

Figure 4 Arsenic and iron leaching after 17 months

It is possible to observe that after 17 months of water addition, the arsenic leached from below detection limit until concentrations of 0.229 mg L^{-1}. The iron concentrations varied from 0.09 to 2.6 mg/L. The concentrations of arsenic leached in the columns are significantly lower than the concentrations found deep in the lined tailings reservoir. According to the graph, it is possible to observe some correlation of the iron and arsenic concentrations in some of the cycles. Concentrations of iron on this order of magnitude are mainly in Fe^{2+} form since the Fe^{3+} would

precipitate quantitatively at pH 7 – 8.5. The low concentrations of As in the column can be related to the As co-precipitation with Fe^{3+} hydroxides that are stable under the pH-Eh conditions of the other months in the columns (Bissacot, 2014). These conditions are likely to be different from those conditions in the tailings pond water, where the redox varies from oxidizing to reducing conditions and concentrations of Fe of 5 mg L^{-1} are found at neutral pH. The results highlight the need to control the redox conditions to prevent arsenic mobilization and have important implications on environmental management in the industrial unit.

CONCLUSION

The mineralogical composition is consistent with both MABA results and current data available for the tailings dam, showing alkaline conditions. Arsenic mobility in the tailings water is mostly related to the presence and oxidation of arsenopyrite combined with the redox conditions variation along the tailings deposit (oxidizing to reducing). It is recommended that similar tailings with potential alkaline conditions and high concentrations of arsenic are disposed under oxidizing conditions and have the redox conditions controlled in order to avoid the long-term arsenic mobility. It is also important to avoid as much as possible seepage areas in the reservoir that creates reducing environments and potential discharges.

The oxidizing environment tested in the laboratory showed concentrations of leached As very low when compared to the ones observed in the anaerobic conditions of the toe drains. Also, as an alternative option, iron can also be added to the system in order to adsorb and decrease the dissolved arsenic concentrations but this action should be performed only when it is possible to maintain controlled redox conditions.

ACKNOWLEDGEMENTS

ABSTRACT

The objective of this study is to characterize former tailings impoundments from metallic sulfide ores exploited in the abandoned mining district of La Carolina (Spain). These fine grained tailings from flotation plants were built without any protection or isolation and, therefore, have a large interaction with the environment. Two selected sludge dams from La Aquisgrana and Apple mines were drilled to obtain continuous cores to subsequently perform sampling at different depths to analyze a series of variables (organic matter, pH, content of metal(oid)s and carbonates, among others). These boreholes were installed with fiber-optic oxygen sensors and TDR probes that determine humidity, temperature, electrical conductivity and oxygen partial pressure at different depths. Additionally, a piezometer was installed at each tailings disposal to allow the sampling of water from the saturated zone of the dams. Sediments analysis reveal elevated contents of Pb (8000 mg/kg), Zn (2200 mg/kg) and As (420 mg/kg), pyrite sulfur and organic carbon (up to 1,75% and 0,6%, respectively). Both sites present a large unsaturated zone of about 30 m with oxygen disappearing at 3-5 m depth due to high amount of electron donors. The monitored values decrease from 20% in surface to 0% below the first meters, indicating a shallow position of the oxidation front 30 years after closure. The water from the saturated zone presents an electrical conductivity of 3,3 mS/cm and a pH value of 6,5. The first results for TC, TOC and TIC show low values of these parameters (no more than 2% in any case) but that appear to be sufficient to have a buffering effect, since pH values are mostly alkaline.

ABSTRACT

The metallogenic district of La Carolina (Southern Spain, Jaen province) is characterized by the presence of vein deposits, which are primarily composed of galena (PbS). The mineral industrial activity generated numerous gravimetric and flotation washing sites, that were deposited in spoil heaps and impoundments, which occupied relatively extensive areas in the vicinity of the concentration plants; no remediation was performed.

This study employed indirect geophysical prospecting techniques, particularly electrical resistivity imaging (ERI) to locating recharge-discharge zones and identifying the contact between the residue and the substratum of this mine.

During the dry season, a significant change in resistivity is detected across the boundary between the tailings dam and the substratum with higher values in the basement. Consequently, the previously mentioned geophysical prospecting method is an excellent tool for characterizing the basin morphology under these conditions. Conversely, the detection of this boundary during the rainy season is not feasible with this methodology because the electrical resistivity values for the deposits and the basement are similar. This similarity can be attributed to the finding that the base of the tailings dam and the upper part of the Palaeozoic substratum (highly altered) are saturated in water. However, during the rainy season, this methodology facilitates the identification of preferential groundwater flow zones and areas where groundwater tends to accumulate. The ERI profiles show how percolation of rainwater and infiltration through the mine tailings contribute to the drainage at the toe of the dam, which affects the water and soil in the surrounding area.

ABSTRACT

Pit lakes form when surface mines close and open pits fill with water, either through groundwater recharge, surface water diversion or active pumping. Historically, the success in closing mines with pit lakes has varied tremendously: there are well known examples of legacy sites requiring perpetual treatment, whereas some other pit lakes have achieved various beneficial end uses. Although access to case studies is often limited, mining companies contemplating new open pit mines have a number of examples in both success and failure from which to draw "lessons learned" that can be used in future mine closure planning.

This paper discusses key issues that should be addressed in the mine planning process to increase the likelihood of successful mine closure. Examples of issues and potential management strategies to address them are given. The key issues examined in this paper include: determining potential risks and beneficial end use opportunities, developing closure objectives and criteria, which may include various water quality, riparian and littoral targets; anticipating and meeting stakeholder and regulator expectations; subaqueous disposal of liquid and solid mine waste; predicting and managing water balances; identifying contaminants of concern; historical reliability of model predictions; mitigating acid mine drainage; the importance of understanding long-term vertical mixing regimes; and health and safety issues.

Keywords: mine pit lakes; sustainability, AMD, closure, planning

INTRODUCTION

Pit lakes form when surface mines close and open pits fill with water, either through passive groundwater recharge, surface water diversion or active pumping. They often display poor water quality through Acid Mine Drainage/Acid and Metalliferous Drainage (AMD). Historically, the success in closing mines with pit lakes has varied tremendously: there are well known examples of legacy sites requiring perpetual treatment, whereas some other pit lakes have achieved various beneficial end uses. Although access to case studies is often limited, mining companies contemplating new open pit mines have a number of examples in both success and failure from which to draw "lessons learned" that can be used in future mine closure planning (Castendyk 2011).

This paper discusses key issues that should be addressed in the mine planning process to increase the likelihood of successful mine closure. Examples of issues and potential management strategies to address them are given with reference to previous experiences in North America, Australia and Asia.

KEY ISSUES

Determining Closure Objectives and Developing Closure Criteria

Discharge criteria applied to pit lakes are site-specific and dependent on the responsible regulatory agency. In most jurisdictions, there are no set guidelines for pit lake discharge. If pit lake water concentrations are below applicable generic water quality guidelines, then water quality would be deemed acceptable, but this will rarely be the case. More likely, site-specific objectives will need to be developed by the proponent of each pit lake. Site-specific objectives can be derived based on effects thresholds, technological limits, background concentrations, or combinations thereof.

Pit lakes are generally expected to be managed as closed-circuit waterbodies until they achieve water quality that will not cause adverse effects to aquatic life, at which time they can be reconnected to the receiving environment. If water quality in the pit lakes is not adequate by the time the lakes fill, active treatment may be required, as well as water diversions around the pit lake.

There are three nested "layers" that can be used to define and gauge success in pit lake closure:

1. **End use** – will the pit lake and associated watershed meet land use requirements for post-closure mine sites that are set regionally and nationally?

2. **Objectives** – will the pit lake meet functional targets that are achievable, desirable to stakeholders and acceptable to regulators?

3. **Criteria** – will the pit lake meet prescriptive criteria, such as site-specific water quality and toxicological thresholds?

There are several sources of information that can be used to define success, such as:

- Corporate sustainability goals and targets (MMSD 2002);
- Commitments made by the mining company in environmental impact assessments (EIAs) and other applications, which include commitments made by previous property owners;
- Numerical predictions that have been generated in EIAs and that have been used in ecological risk assessments;

- Stakeholder expectations;
- Regulatory requirements (Jones and McCullough 2011);
- Analogue lake studies (Van Etten et al. 2014);
- Observed water quality from existing pit lakes in similar geologic deposits (Johnson and Castendyk 2012)
- Leading, international mining-industry practice; and
- Prescriptive, site-specific objectives that are based on biological thresholds and ecological risk assessments.

The importance of developing closure criteria for pit lakes early in the planning process cannot be overstated, because all mine closure design and mitigation should be directed toward meeting these criteria.

Anticipating and Meeting Stakeholder and Regulator Expectations

As with the other components of mine operation and closure, all stakeholders should be identified early and consulted for their input on end of mine life quality and objectives, including objectives for pit lakes (Swanson 2011). Early engagement of stakeholders can lead to constructive input into the planning of pit lakes, reduced costs, fewer delays, and overall public/stakeholder/regulator acceptance.

Design for pit lakes is typically done by involving engineers and scientists, but not stakeholders (Swanson 2011). It is recommended to consult stakeholders on visions for pit lakes and potential beneficial end uses of pit lakes (McCullough and Lund 2006). Participation by communities in developing mine remediation targets leads to better decisions, and in some cases to lower overall costs for mine remediation (NOAMI 2003). This is because the major stakeholders were involved from the beginning in decisions that could affect their enjoyment/use of the landscape. Information presented to communities on pit lake predictions can be complex, and thus information should be presented in an easy-to-understand format in order to engage the stakeholders in constructive discussions (NOAMI 2003).

Predicting and Managing Water Balances

The time to refill pit lakes is site-specific and must be determined on a case-by-case basis. In cases with high rates of evaporation or highly permeable aquifers, the pit lakes can refill in a few years. In arid regions, some pit lakes will never refill passively, and are termed "terminal" pit lakes (McCullough et al. 2013) because they act as a groundwater sink. While not ideal, such lakes may be used as mitigation to prevent contaminated groundwater from migrating away from a mine site. In terminal lakes, evaporation is the only route through which water leaves a pit lake, so it can be expected (and readily predicted with mass balance models) that concentrations of solutes will increase over time (Castendyk and Eary 2009; Geller et al. 2013a). The ultimate concentrations may be controlled by solubility, which can be predicted using geochemical software.

In the sub-Arctic region of Canada, where net evaporation is low, it is expected that pit lakes will refill passively, but it is preferable to accelerate the filling process to reduce the closure management period. This option should be evaluated as part of the closure planning process, in consideration of regional surface hydrology and availability of water to be used for filling.

Connection of the pit lake to surrounding groundwater sources can play a large role in the water quality and hydrological cycle/budget of the pit lake; if a pit lake water surface is above the water

table, water will flow out of the pit to the groundwater and thus provide a pathway to transport potential contaminants to a larger area (Castendyk and Eary 2009).

Understanding Long-term Vertical Mixing Regimes

Compared to natural lakes, pit lakes are more prone to become meromictic (lower layers non-mixing) because they generally have smaller surface areas, larger depths and higher salinities. Vertical mixing in lakes is primarily driven by wind currents across the lake surface, and the smaller fetch of pit lakes provides less opportunity to translate wind energy into water currents that are necessary for lake turn-over.

In pit lakes, as in natural lakes, the frequency and depth of vertical mixing will affect many other variables. These parameters must be defined in advance of developing geochemical predictions of water quality so that accurate volumes for epilimnion, hypolimnion, and monimolimnion layers can be accurately represented and mixed at appropriate intervals. Vertical mixing transports oxygen to the lower portion of the lake, which in turn affects biological and chemical reactions. For example, oxidation state influences the mobilization of metals and cycling of nutrients. Of particular importance is the potential effect of oxidation state on sulfide minerals; under oxidizing conditions, sulfide minerals will react to form sulfuric acid and dissolved metals, whereas under reducing conditions, sulfide minerals will precipitate – a process that has been used to mitigate AMD in meromictic pit lakes (Pelletier et al. 2009). Given the influence of vertical mixing on these processes, the anticipated mixing behavior of a pit lake should be evaluated and understood as early as possible in the mine planning process.

There are a variety of guidelines that describe lake geometries that will affect lake mixing. The most common is the relative depth, defined as the maximum depth as a percentage of mean diameter. Natural lakes usually have relative depths of less than 2%, whereas pit lakes typically have relative depths of 10 to 40% (Doyle and Runnels 1997). While measures such as relative depth provide useful descriptors of pit geometries, they are not predictive measures because they do not account for other important variables, such as water density and wind speed. The most reliable method for predicting lake mixing is through the use of numerical models (such as CE-QUAL-W2 or DYRESM) that mechanistically account for these variables.

Identifying Contaminants of Concern

There are a wide range of contaminants of concern (COCs) in pit lakes. The most common COCs in hardrock pit lakes are low pH and elevated element concentrations caused by acidic mine drainage (AMD). AMD is a phenomenon that occurs when sulfur-bearing waste rock, tailings or other materials are weathered during mining and mine closure practices. Weathering of sulfide minerals can lead to release of acid and elevated concentrations of contaminants in runoff, groundwater or pit lake water. These acidic waters often carry a high load of elements that are more soluble at low pH. AMD is commonly associated with coal and hard rock mines

The COCs at a given mine are often, but not always, related to an obvious source such as the ore body or extraction chemicals. For example, the Berkeley Pit Lake in Montana, which is perhaps the most famous “worst-case” example of a pit lake, is a former copper mine pit that now contains levels of copper, zinc, and iron that exceed water quality guidelines by orders of magnitude (Gammons and Duaime 2006). Similar contamination has been observed at copper mines in California (Levy et al. 1997) and Sweden (Ramstedt et al. 2003).

Long-term water quality in a pit lake can be influenced by hydrochemical processes such as geoenvironmental characteristics, water balance, mineral solubility, and sediment biogeochemical processes (Geller et al. 2013a). Constituents that most often exceed guidelines are copper, cadmium, lead, mercury, nickel and zinc, followed by arsenic, sulfate, and cyanide (Kuipers et al. 2006). Blasting residues such as ammonia and nitrate are also often elevated in mine waters, and may persist into closure (Banks et al. 1997). In sub-Arctic Canadian mines, salinity and major ions are typical COCs (Environment Canada 2012) because of saline groundwater that must be dewatered for mining. The saline groundwater may be disposed of in pit lakes, or saline groundwater may flow passively into pit lakes at closure when dewatering ceases. In oil sands pit lakes, the COCs are primarily organic constituents such as naphthenic acids, phenolics and polycyclic aromatic hydrocarbons originating from process waters and tailings (CEMA 2012).

Less obvious COCs may be present as well. For example, at the proposed Gahcho Kué Diamond Mine (De Beers 2012), geochemical testing of pilot plant tailings identified phosphorus as a COC, which led to changes in the closure plan to mitigate runoff from mine wastes and to avoid eutrophication of closure waterbodies. Total suspended solids can be expected to be elevated during the early years of lake development, before vegetation becomes established in the littoral zone, but this should be a temporary phenomenon in a properly designed pit lake.

In summary, while there may be obvious COCs at a given mine, a full suite of metals, major ions, nutrients and organics should be evaluated to determine site-specific COCs prior to mine development.

Mitigating Acid and Metalliferous Drainage (AMD)

Poor water quality degraded by AMD is the single biggest environmental risk and cause of beneficial end use loss for pit lakes (McCullough 2008). Mine drainage may be acidic, neutral or even alkaline as constituents such as metals and metalloids may be in elevated concentrations in all. Once begun, the process of AMD is very difficult to stop. Hence, the emphasis on AMD management should always be first on preventing weathering of potentially acid generating (PAG) materials by exposure to water and oxygen (Castendyk and Webster-Brown 2007). This process begins by long-term geochemical characterization of all materials that may contact pit lake water or water sources including above ground sources, such as waste rock dumps and tailings impoundments, and below ground sources, such as backfill and fractured geologies.

Disposal of PAG materials above the water table is usually best suited to arid climates where AMD production will be limited by water availability. However, a strategy often considered to reduce pit lake AMD issues is subaqueous disposal of PAG occurring in tailings, waste risk and pit shell exposures (Dowling et al. 2004). However, subaqueous disposal of waste should not be thought of as a singular solution to PAG management. Rather it is merely one consideration of a broader closure strategy that, when used appropriately and in certain circumstances, may reduce AMD production and long-term environmental and social liability.

Where AMD has not been prevented, a number of active and passive treatments are available, although all of these treatments should be considered requiring ongoing attention and maintenance (Gammons et al. 2009; Geller et al. 2013b; Younger and Wolkersdorfer 2004). Active treatments may be simple limestone or lime putty additions to treat acidity, although the ongoing cost, particularly in remote areas once mine infrastructure is closed should not be under-estimated. The economic liability to the remaining responsible jurisdiction is likely to exceed the economic benefit from

mining with a few generations of treatment, which is why active treatment is only typically sought when there is a risk of off-site contamination exposure to social or environmental receptors.

Passive treatments may range from strategic catchment-scale diversions of inflows to attenuate and dilute pit lake waters (McCullough and Schultze 2015) to initial or ongoing treatment with biologically active materials such as nutrients and organic matter (Kumar et al. 2011).

Subaqueous Disposal of Liquid and Solid Mine Waste

The option to dispose of mine waste in pit lakes is often attractive to mining companies because it is more cost effective than other treatment or disposal technologies. Disposal of mine waste in pit lakes is an accepted practice in some industries and regions (Davé 2009; Dowling et al. 2004; Schultze et al. 2011). However, it is controversial and considered unproven until demonstrated at the field scale in the oil sands industry (OSTC 2012). If successful, several other companies in the region will likely apply water-capped tailings technology with a potential savings of billions of dollars for the industry as a whole compared to other disposal technologies. Deep pit disposal of fine tailings has also been approved for the diamond mining industry in Northern Canada (De Beers 2012).

If subaqueous disposal of tailings are contemplated, the following issues should be evaluated to reduce risks to closure water quality:

- **Tailings resuspension** – a hydrodynamic analysis should be completed to understand the potential for resuspension of fine particles, and the formation of buoyant plumes;
- **Metal leaching and AMD** – geochemical testing should be completed to predict the potential for acid generation and metal leaching, and to understand which oxidation state would minimize these effects on water quality; and
- **Sediment toxicity** – standard bioassays should be conducted to predict the toxicity to benthic organisms.

Health and Safety Issues

The most significant acute health and safety risks for persons in and around pit lakes relate to falls and drowning. Pit lake highwalls may often be unstable, particularly following rebounding groundwater pore pressures and decades of wave action. Unstable walls frequently result in slips that may endanger nearby structures and persons near the highwall (McCullough and Lund 2006). Where communities reside nearby, pit lakes may present risks for recreational swimmers where there is a risk of drowning with the steep lake margin typically of pit lake edges or by falls from high walls into water or submerged obstacles that have not been regraded (Ross and McCullough 2011).

Chronic health risks are not well understood, but there is potential for health issues for recreational users in AMD contaminated pit lake water; even in remote areas where pit lakes may be used as recreational opportunities. Low pH and elevated contaminant concentrations may lead to skin and eye damage and irritation, particularly for regular exposures in vulnerable groups such as children and the elderly (Hinwood et al. 2012).

There are also human health risks where end uses include fisheries; either planned or unplanned. Aquatic ecosystem foodchains have been found to accumulate contaminants such as selenium, mercury and cadmium. These metals bioconcentrate in keystone predator sportsfish and crustacea (McCullough et al. 2009b; Miller et al. 2013).

Historical Reliability of Model Predictions

The reliability and accuracy of mine water predictions was examined by Kuipers et al. (2006) in a comparison of water quality predictions made in environmental impact statements to operational water quality observed at hardrock mines. The mines that were examined included major mines across the Western USA, but the issues they identified are applicable to mines worldwide. They found that in the majority of cases, water quality predictions did not perform well, and impacts were often underestimated. They identified three main causes for the discrepancies:

- **Inadequate hydrologic characterization** – inaccuracies arose from overestimating dilution potential, poor characterization of the hydrologic regime and poor flood forecasting.
- **Inadequate geochemical characterization** – inaccuracies arose from inadequate sampling of geologic materials, lack of proper geochemical testing of materials such as metal leaching and AMD potential and improper application of test results to models.
- **Mitigation failure** – in many cases, mitigation was assumed to reduce concentrations, but the mitigation was either not effective or not implemented.

Although poor water quality prediction performance has been found at hardrock mines, present and future pit lake modelling efforts should be able to improve upon this record. Success in predicting water quality will be reliant on following leading modelling practices that were not adhered to in many of the case studies in Kuipers et al. (2006). Guidance for predicting pit lake water quality is provided in a companion document by Maest et al. (2005) as well as by Vandenberg et al. (2011).

In particular, a post-audit of water quality predictions is essential (Dunbar 2013) for identifying excursions from predictions early in the mine life and applying adaptive management strategies as soon as possible. Post-audits of modelling predictions should be available to stakeholders, reviewed by regulators, and ideally, disseminated to the wider modelling community so that they can learn from the strengths and weaknesses of past experiences and continually improve their methods.

CONCLUSIONS

Pit lakes are highly variable systems with a wide range of outcomes observed worldwide in terms of chemical characteristics and suitability for aquatic habitat. While there are examples of very unsuccessful pit lakes, these serve as "lessons learned" that can be followed to increase the likelihood of success in constructing future pit lakes (Castendyk 2011). The most important lessons learned are to develop a conceptual model of the pit lake and understand its processes as early as possible; engage stakeholders early in the process; begin environmental monitoring at the exploration stage and conduct a post-audit of predictions to guide adaptive management (Castendyk 2011; Gammons et al. 2009).

The key issues described above should be considered in each of the planning, designing, commissioning, and abandonment stages of a pit lake. The outcome of a decision made or an assessment completed during a previous stage of development may be found to be incorrect or no longer valid as environmental data or stakeholder or regulator requirements evolve. Or, the pit lake and its inflows may be altered by changing mine plans or mine closure plans in response to fluctuating commodity prices. Consequently, mining companies should anticipate an iterative process whereby assumptions and decisions are refined to reduce uncertainty related to the issues

above. This may involve reconsidering options and revisiting strategies discounted earlier under different circumstances such as understanding of the physico-chemical context and of regulatory and other social constraints and expectations. This iterative process of pit lake closure planning refinement should form an explicit part of mine closure planning for the broader site (McCullough et al. 2009a).

Guidance manuals (e.g., CEMA 2012; McCullough 2011) and compilations of pit lake experiences and research (Castendyk and Eary 2009; Gammons et al. 2009; Geller et al. 2013a) have been developed in the past five years, and these should be consulted throughout the planning, design, and construction process for additional details.

Designing Meromictic Pit Lakes as a Mine Closure Mitigation Strategy in Northern Canada

Michael Herrell, Jerry Vandenberg and John Faithful
Golder Associates, Canada

ABSTRACT

Deep groundwater stored in the Canadian Arctic Shield is characterized by high salinity that increases by orders of magnitude with depth. Mining in these areas has the potential to upwell saline groundwater into the mine workings. Due to the pristine nature of the downstream receptors in Arctic Canada, treatment of saline water is often required prior to being discharged. Mitigation using conventional salinity treatment plants may not be economically feasible due to the remote nature of the northern Canadian mine sites and the harsh climates in this region. Furthermore, treatment of saline waters requires disposal of concentrated brine, rendering this strategy impractical for several mine sites.

An alternative mitigation strategy is to store saline waters on site and use them to create meromictic conditions in mined out open pits at closure. In this manner, the denser saline water is isolated from mixing with freshwater stored in the mixolimnion. This is the proposed strategy for the De Beers Gahcho Kué diamond mine, located in the Northwest Territories, Canada.

This paper focuses on the mine plan for the Gahcho Kué Project and the approach used to evaluate the likelihood of meromictic conditions developing and remaining stable in a flooded, mined-out, open pit. A discussion of the model results is presented to demonstrate the merits of the closure strategy.

Keywords: mine closure, mine water quality, pit lakes, meromixis

INTRODUCTION

Currently, there are three existing diamond mining operations (Diavik, Ekati, and Snap Lake) in the Northwest Territories (NWT), in Northern Canada. The Gahcho Kué mine is under construction, and others are being contemplated. Mining diamonds in the NWT can pose several challenges. The region is dominated by lakes, which can make access to the kimberlite pipes difficult and in the case of mines using open pit methods, often whole lakes, or a portion of a lake needs to be dewatered to facilitate access to the mine workings.

Open pit mining can also induce large volumes of groundwater that need to be managed during operations. Untreated discharge of these flows is not always feasible for the following reasons:

- Groundwater salinity in the Canadian Shield is known to increase by orders of magnitude with depth (Fritz and Frape, 1982);
- The remoteness, harsh weather conditions, and lack of roads during the open water season render all construction activities much more expensive than elsewhere;
- The mines are often located in regions of continuous permafrost limiting the amount of fresh lake water available to recharge the groundwater table during periods of draw down, promoting upwelling of deep seated saline groundwater and rapid increases in mine water salinity;
- Lakes in northern Canada are pristine with very low concentrations of total dissolved solids (TDS) (i.e. <20 milligrams per litre [mg/L]) with aquatic biota that are sensitive to changes in salinity; and,
- Conventional treatment of salinity is through reverse osmosis and disposal options of the treated brine are limited due to the remote nature of the mine sites.

Diamonds will be mined from three open pits at the Gahcho Kué Project (the Project), which will require the partial dewatering of Kennady Lake to access the mine workings. Water quality modelling (De Beers, 2012, Vandenberg et al. (in review)), indicates that mine-related activities at the Project is expected to increase salinity in mine site water during operations. To mitigate the discharge of saline water, De Beers Canada Inc. (De Beers) has developed a zero site water discharge water management plan after year three of operations (EBA 2013). At closure, saline water stored on site will be pumped to the bottom of a mined-out open pit and capped with natural local catchment runoff and supplemental freshwater from a nearby lake (Lake N11), promoting the development of meromictic conditions that will minimize the mixing of saline water with the overlying lake.

To demonstrate the feasibility of the proposed water management strategy to regulators and stakeholders, a numerical model was developed to evaluate the likelihood of meromixis occurring in the pit lake during post-closure. This paper presents the model development and results to illustrate the merits of this approach.

PROJECT DESCRIPTION

The Project is located approximately 280 kilometres (km) northeast of Yellowknife, NWT, Canada (Figure 1). Diamondiferous kimberlite will be mined from three open pits (5034, Hearne and Tuzo), located below Kennady Lake (Figure 2). Mining of the three open pits will take place over an

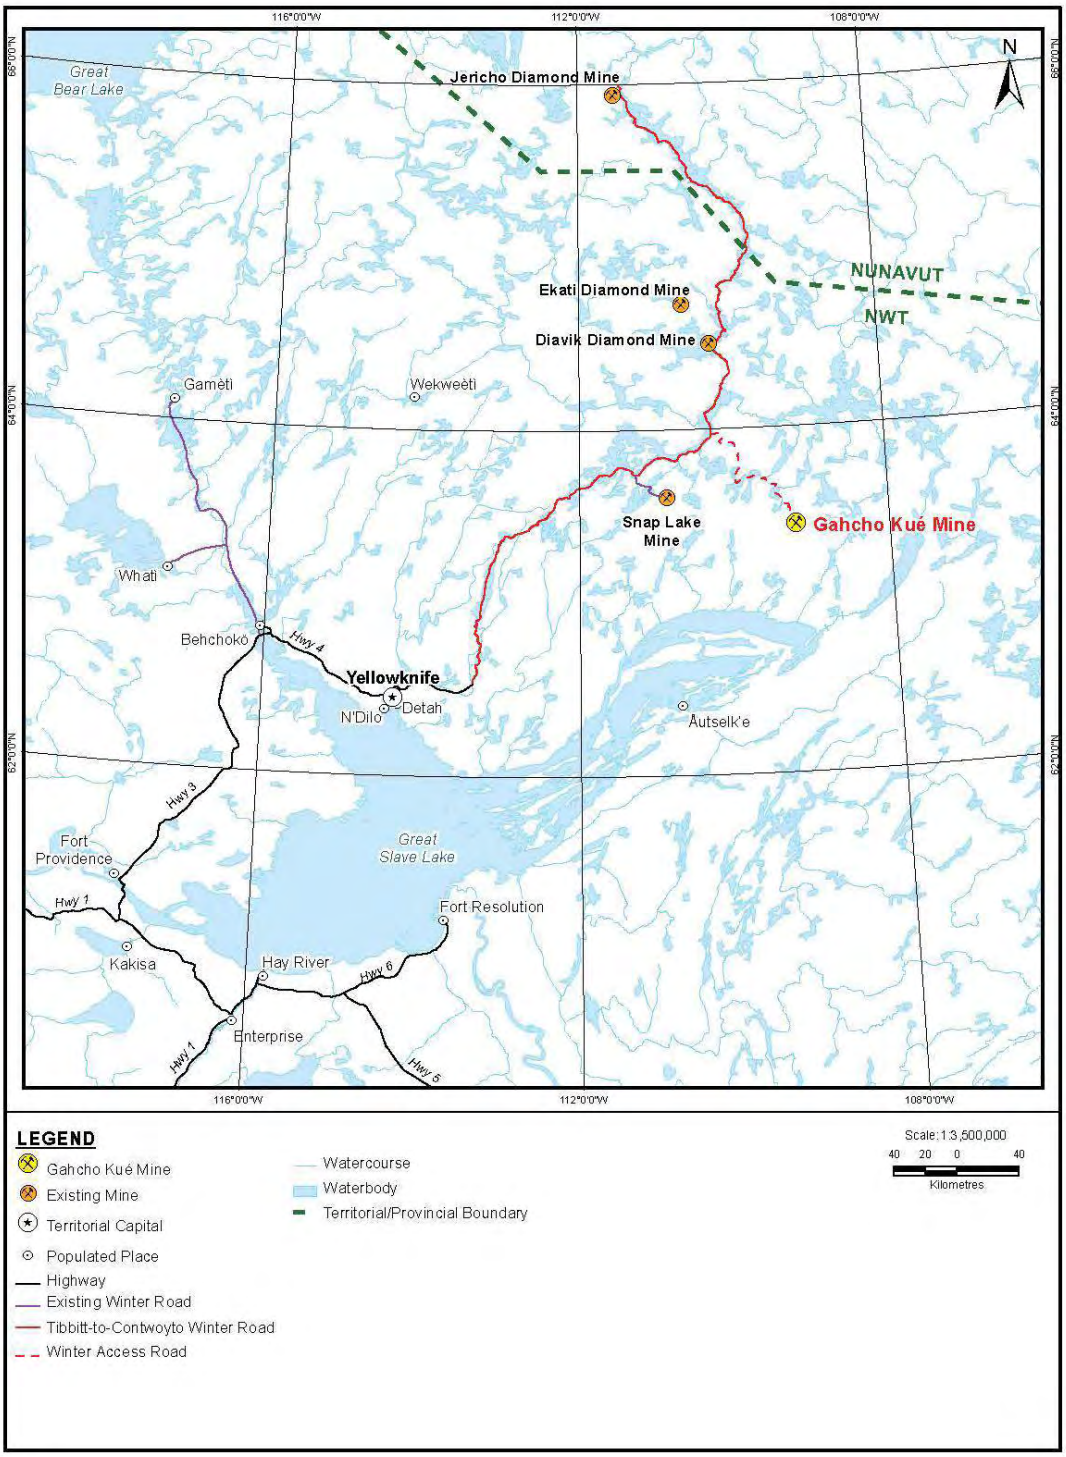

Figure 1 Location of the Gahcho Kué Project

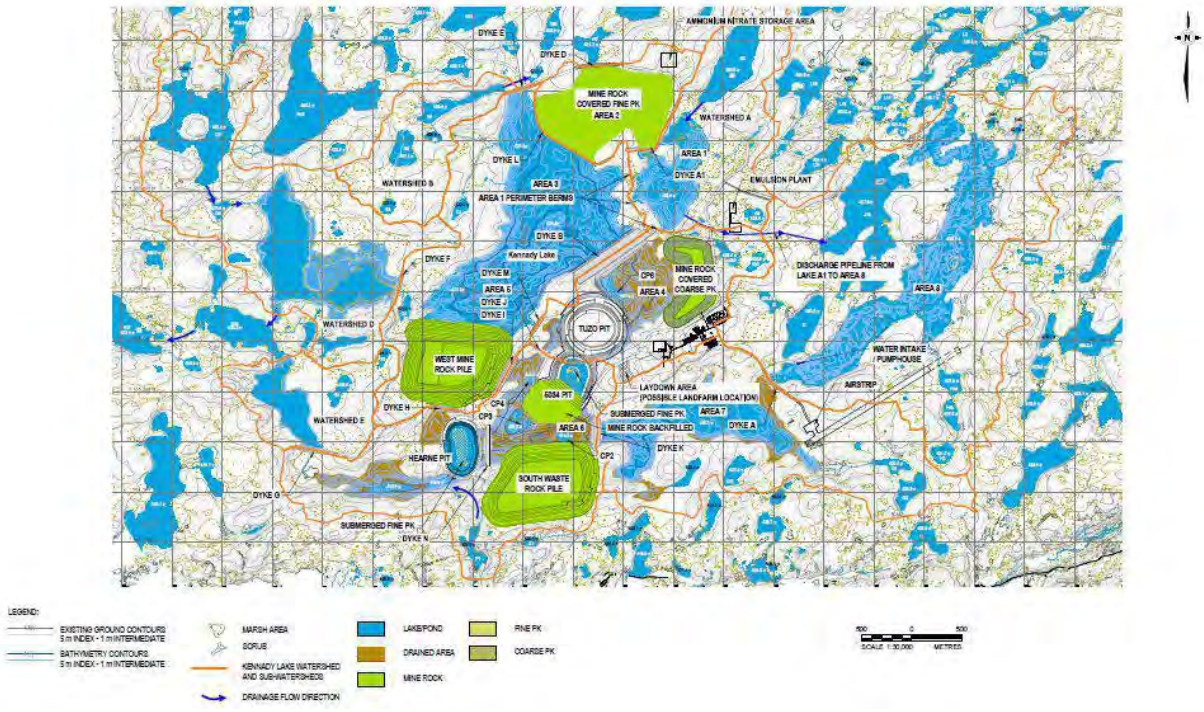

Figure 2 Gahcho Kué Mine Site Facilities

operational period of 11 years and produce 33.4 million tonnes [Mt] of ore, 300 Mt of mine rock, 10 Mt of fine processed kimberlite [PK] and 23.4 Mt of coarse PK (EBA 2013). The mine plan for the Project has been designed to minimize the surface disturbance and to facilitate progressive reclamation of mine site facilities during operations. The 5034 and Hearne pits will be mined first. During this period, fine PK will be stored in the Fine PK Containment (PKC) Facility in Area 2 and mine rock will be stored in the West and South Mine Rock Piles (Figure 2). Following the cessation of mining in the 5034 and Hearne pits, they will be used to store mine rock and fine PK, respectively, as well as process water and other mine site flows (e.g. pit groundwater inflows and natural runoff). Reclamation of the Fine PKC and mine rock piles will begin at this stage of the mine life. Mining of the Tuzo Pit will commence in Year 4 of operations. At completion it will remain an open void space.

The kimberlite pipes extend from near the bottom of the lake to approximately 300 metres (m) below the lake. To access the open pits, Kennady Lake will be segregated into six water management areas (2 to 7) separated by permeable and impermeable dykes. Area 2 is designated for deposition of fine PK. Areas 3 and 5 (referred to as Area 3/5) will be partially dewatered and converted into a water management pond (WMP) to settle solids in site discharges and to store process water during operations, open pit groundwater inflows, and natural catchment runoff from within the site area. All other areas (4, 6 and 7) will be fully dewatered to allow access to the mine workings.

The natural elevation of Kennady Lake is 420.7 metres above sea level [masl] with a total capacity of approximately 35 million cubic metres [Mm^3], in Areas 2 to 7 (EBA 2013). During the first year of dewatering, approximately 1 Mm^3 of water will be pumped from Area 7 to Area 8, a lake located

downstream of the mining disturbance (Figure 2). Subsequently, water stored in Area 7 will be pumped to Area 3/5 since it is expected that, at this point, total suspended sediment (TSS) concentrations will be elevated and preclude discharge from this area.

To maximize the operational storage capacity of the WMP, approximately 22 Mm^3 of water will be pumped from Area 3/5 to Lake N11 (located to the north of the Project) during the dewatering period, lowering the elevation of Kennady Lake to 418 masl. During the first three years of operations, 3.5 Mm^3 of water will be pumped annually from Area 3/5 to Lake N11. A total volume of 33.5 $Mm^3$of water will be discharged from the Project during dewatering and operations. Open pit groundwater inflows, process water, and natural catchment flows will be stored in the WMP and mined out open pits after the third year of operations.

At closure, the elevations in Area 3/5, Area 6 and Area 7 will be 422, 421.3, and 420.5 masl, respectively. The water level in these areas will be lowered to 417 masl and all the water stored above this elevation will be siphoned to the mined out Tuzo pit. Following the water transfer to the Tuzo pit, the available water storage capacity in the Tuzo pit and the overlying Kennady Lake will be filled primarily with natural catchment runoff and water pumped from Lake N11, a nearby lake in the adjacent watershed. Some residual groundwater flows will continue to report to the mined out Tuzo pit. Conceptually, this approach will promote the development of meromictic conditions in Kennady Lake, permanently isolating the high density saline water in the Tuzo pit (the monimolimnion) from interacting with the overlying low density water stored in Kennady Lake (mixolimnion). The phenomenon of meromictic conditions being established in pit lakes has been observed at several mines (Boehrer and Schultze, 2006).

Once Kennady Lake has re-established the natural lake elevation of 420.7 masl, and the water quality in the lake is of a suitable water quality and meets closure objectives, the lake will be reconnected to the downstream watershed. Water balance modelling (EBA 2013), indicates approximately eight years will be required to refill Kennady lake during the closure period of the Project.

METHODOLOGY

A site mass-balance water quality model was developed in GoldSim (GoldSim 2010) to assess the expected discharge concentrations during operations (from Area 3/5) and the average water quality in Kennady Lake following refilling. This model calculated the site water quality on a monthly basis using inputs from hydrology (EBA 2013, De Beers 2012), hydrogeology (De Beers 2012) and geochemistry (De Beers 2012). Details of the site water quality model are provided in De Beers (2012) and Vandenberg et al. (in press). As GoldSim does not have the inherent ability to simulate the hydrodynamic properties of water bodies, the stability of stratification in the Tuzo Pit was analyzed using two methods:

- hydrodynamic modelling of the first 100 years after refilling, using CE-QUAL-W2 (Cole and Wells 2008); and
- mass balance calculations over 15,000 years using a vertical slice spreadsheet model.

The spatial extent of the hydrodynamic model was Kennady Lake and Tuzo Pit. A model grid was developed based on GIS shapefiles of these connected water bodies. The grid was optimized to account for the full fetch of the lake with higher resolution near the pit.

CE-QUAL-W2 Model

The CE-QUAL-W2 (W2) model was used to compute TDS, temperature and density in Tuzo Pit. Near-surface layers were spaced at 1 m intervals, and deeper layers were spaced at 3 m intervals. The model also requires meteorological forcing data to drive currents and thermal behaviour in the lake. Meteorological data were obtained from weather stations at the nearby De Beers Snap Lake Mine and the Yellowknife, NWT Airport. Data were selected preferentially from the Snap Lake station because this station is closer to the Project, and data gaps were filled in using data from Yellowknife Airport. The required meteorological data were air temperature, dew point, wind speed and direction, and solar radiation.

In the W2 model, initial concentrations in the pit lake were determined by concentrations in Kennady Lake at closure, as simulated in the site mass balance water quality model. The 23 Mm^3 of water in the bottom of the pit was set equal to the concentration in the water storage areas Kennady Lake (e.g., the WMP) prior to refilling, because this volume will be drawn from the surface to fill the pit until Kennady Lake is lowered to 417 masl. 1.2 Mm^3 of groundwater is predicted to flow into the pit during the refilling period, so this was added as well, at time-varying constituent concentrations predicted by the hydrogeological model (De Beers 2012; Vandenberg et. al. in review). The upper portion of the lake was assumed to have a TDS concentration that was equal to the refilled Kennady Lake.

It is recognized that these layers will not form a sharp boundary due to turbulence caused by refilling and other factors. Therefore, the gradient was assumed to span a vertical transition depth of 40 m, and concentrations were calculated for the upper and lower portions respecting the mass of TDS in both layers and within the gradient.

It is not known exactly when the pit will be filled in terms of months of the year. Therefore, an average temperature of Kennady Lake was calculated based on samples that were skewed toward available site-specific, open-water sampling data. The resulting average temperature (5 degrees Celsius [ºC]) is anticipated to be reasonable, because refilling activities are also expected to be most intense during open water periods. The uniform temperature of 5ºC was used to initialize the pit lake water column. The temperature profile could be manipulated to increase the stability in the pit, but that manipulation was not examined as part of this modelling to conservatively assess pit lake stability.

Once the model was initialized, it was run for 100 years to predict the change in elevation of the pycnocline (i.e., the layer within the refilled pit where the density, or TDS gradient is greatest), and therefore the volume of water that will essentially be isolated from Kennady Lake. Groundwater discharge from the hydrogeological model was input to the hydrodynamic model at several vertical points according to time-varying volumes and constituent concentrations throughout the modelled time frame, and natural inflows to Kennady Lake were also included.

Vertical Slice Spreadsheet Model

To estimate the long-term stability of Tuzo Pit, long-term TDS profiles were calculated using a vertical slice spreadsheet model. A spreadsheet model was used because it was not feasible to run a hydrodynamic model for this length of time due to the computational limitations. The vertical slice spreadsheet model incorporated long-term inflows that were predicted by the hydrogeological model (De Beers 2012; Vandenberg et al. in review) to simulate TDS profiles over 15,000 years at 25 m vertical intervals in Tuzo Pit. This simplified approach is intended to evaluate directional

changes to TDS concentrations at depth over the very long-term and does not consider all processes influencing pit lake stability (e.g. climate change, diffusivity).

The main inputs used in the mass balance calculation were initial conditions in Tuzo Pit, which were the same as those used for the W2 model, and long-term groundwater inflows and outflows. Groundwater inflow volumes and constituent concentrations and outflow volumes were predicted for the first 1,000 years after Tuzo Pit is filled. After 1,000 years, the inflows were assumed to continue at constant volumes and concentrations.

To complete the calculations, inflow volumes and concentrations were directed to the appropriate 25 m interval within the pit. Within each interval, a mass-balance calculation was performed, and excess water (difference between inflow and outflow) was directed upwards to the next segment. The vertical slice spreadsheet model generated annual time series at 25 m intervals over a 15,000 year timeframe.

RESULTS AND DISCUSSION

The results of the W2 model are presented in Figure 3. The W2 model results indicate meromixis will occur in the Tuzo pit following refilling of Kennady Lake and remain permanently stratified; however, the model also indicates there will be some interaction between the monimolimnion and the mixolimnion during the 100-year model period (Figure 3). During the 100-year modelling period, the transition zone increases, reflecting an upward transfer of mass from the monimolimnion into the mixolimnion. This vertical movement is predicted to occur relatively rapidly after refilling, and gradually thereafter.

Concentrations of TDS decrease in the mixolimnion from approximately 170 mg/L to 60 mg/L (Figure 3). The gradual replacement of Kennady Lake waters with natural runoff will continue to reduce the TDS of the overlying water, thereby strengthening the stratification by increasing the density difference between the surface and deep water zones. A small influx of groundwater to the pits predicted by the groundwater modelling is not projected to increase TDS at depth over the modelled 100-year time frame and concentrations remained stable at approximately 915 mg/L.

The vertical slice mass-balance model projected a rising and strengthening stratification in Tuzo Pit in the long term (Figure 4). Although the hydrodynamic simulation indicated very little change in TDS in the monimolimnion in the first hundred years, the mass-balance slice model indicated that groundwater inflows would begin to change TDS at depth in the first thousand years. After 15,000 years, the model predicted that the monimolimnion would increase in TDS and expand upwards due to the slight net inflow (Figure 4). The deeper pit water will eventually, over the very long-term, take on the characteristics of the surrounding deep, high TDS groundwater.

While the general trend of increased TDS and upward expansion of the pycnocline is likely reliable, this model may over-predict the extent to which these phenomena may occur. The model did not account for upward diffusion due to a concentration gradient, and it extrapolated groundwater inflows beyond the timeframe modelled by hydrogeological modelling. Nevertheless, it may be concluded with some confidence from this modelling, that stratification in Tuzo pit, and hence its meromictic state, will strengthen with time.

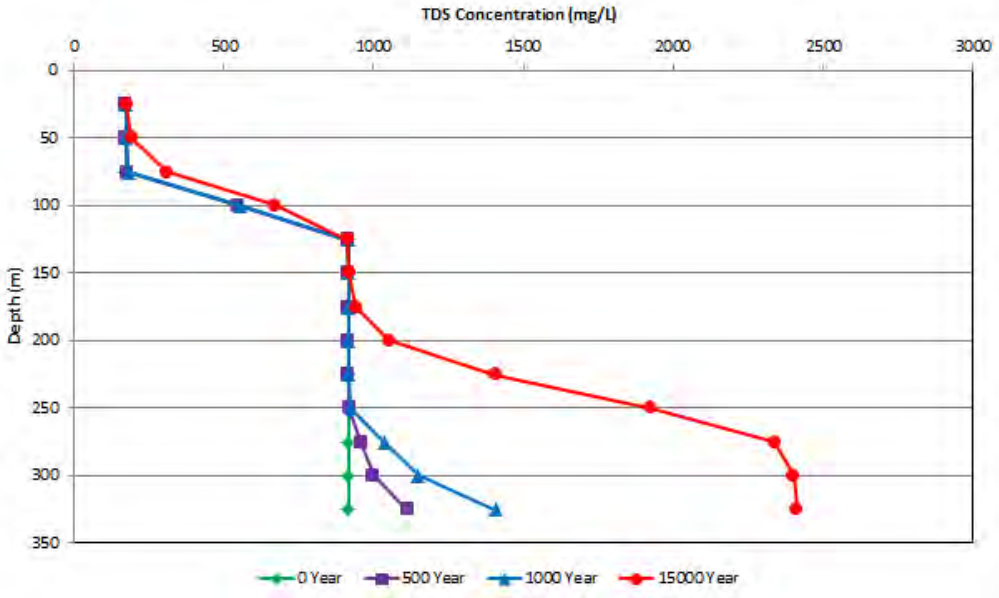

Figure 4 Vertical Slice Mass Balance Model Results

CONCLUSION

De Beers proposes to mine diamonds from three open pits (5034, Hearne, and Tuzo) at the Gahcho Kué Project. The mine waste and water management plan developed for the Project (EBA 2013), maximizes the use of mined out facilities for storage of mine waste and mine water to minimize the amount of discharge required from the Project during operations. In this manner, De Beers will only be required to discharge for the first three years of operations and water originating from natural runoff, groundwater inflows, or process water during the remaining years of operation can be stored on site.

Simulated water quality conditions in water storage facilities at the site, including the WMP and mined out Hearne pit during operations, indicate that TDS concentrations will increase (De Beers 2012; Vandenberg et al., in review). A pit lake hydrodynamic water quality model demonstrated that the transfer of the high TDS water stored in these areas during operations to the bottom of the Tuzo pit at closure will produce a density difference and meromictic conditions will be established following refilling, permanently isolating the high TDS water from interacting with the overlying freshwater stored in Kennady Lake after approximately 100 years (Figure 3). The vertical slice spreadsheet model indicates that as groundwater inflows increase TDS concentrations at depth in the long-term (i.e. >1000 years) in Tuzo pit, the continual replacement of Kennady Lake water with natural runoff and direct precipitation, lowers the concentrations near the surface, increasing the density difference and stratification stability of the pit lake (Figure 4).

In general, for mine sites where it can be demonstrated that density differences can be established and maintained over the long term, storage of mine waters in pit lakes is a viable option for permanent disposal of these solutions. This paper focused on the salinity (e.g. TDS) of the mine water to be produced at the Project; however, the Project water management strategy has the indirect benefit of managing elevated concentrations of other constituents of concern. For example, use of ammonium nitrate fuel oil (ANFO) can lead to elevated nitrogen concentrations in mine waters during operations. If it can be reasonably demonstrated that density differences can be used to segregate operational mine waters at closure, other constituents with elevated concentrations during operations can also be mitigated through being permanently stored in the pit lake monimolimnion.

It is recognized that the purpose of modelling is not to produce predictions of forecasts of future conditions, but rather to provide an estimate of the direction and magnitude of impacts from proposed mining operations, and to provide projections that are suitable for the assessment of effects. Therefore, mining projects that are relying on the use of pit lakes to mitigate the potential for effects of mine waters originating during operations to the surrounding environment (i.e., downstream waters), it is of utmost importance that the water quality model is periodically evaluated and updated in the context of field-based water quality monitoring during operations and closure to allow for calibration to existing conditions and to more accurately project future conditions. Furthermore, it is necessary to have alternate mitigation strategies available in the instance that the future performance of the modelled system does not behave as projected.

ACKNOWLEDGEMENTS

The authors of this paper would like to thank Ms. Veronica Chisholm of De Beers Canada Inc. for allowing Golder Associates Ltd. to publish results from the Gahcho Kué Project. The authors would

also like to thank George Wang of Golder Associates Ltd. for his assistance in developing the water quality model that was used for the current assessment.

Variable-Density Transport Modeling in Hypersaline Pit Lakes

Guy Roemer, Colleen Burgers and Sonya Cadle
Tetra Tech, USA

ABSTRACT

In Western Australia there is the potential for many pit lakes to become point sources of hypersaline water. The low annual rainfall and high evaporation produces a rainfall deficit, contributing to the development of hypersaline pit lakes. The salinization of pit lakes can affect local and regional groundwater resources, as well as the broader natural environment. The extent of impact on the surrounding groundwater system is largely dependent on the local hydrogeology, which dictates whether the pit lake will act as either a terminal sink or a flow through system. A long-term concern is the downgradient movement of saline plumes from pit lakes, especially in flow-through systems.

In this study we perform variable-density transport modeling using SEAWAT to examine the potential for salinity migration from terminal sink pit lakes in Western Australia. As the pit lake water becomes denser over time due to evapoconcentration, the potential for migration into the groundwater system beneath the pit floor is more probable. SEAWAT model results are compared to constant-density transport results. The comparison indicates that failing to consider density changes in the pit lake water causes underestimation of the plume migration distance. Sensitivity analyses were also conducted to examine the sensitivity of model parameters, such as dispersivity, effective porosity, simulation time, and hydraulic conductivity. Results from this study show that given the low permeability of the bedrock beneath the pit floor, salinity migration from this pit will be limited and will not impact downgradient groundwater dependent ecosystems.

Keywords: salinity, pit lake, transport, density, groundwater

INTRODUCTION

The Cameco Corporation Australia in conjunction with Mitsubishi Development Pty. Ltd. is planning the Kintyre Uranium open-pit development in the East Pilbara region of Western Australia, approximately 80 km south of Telfer on the edge of the Great Sandy Desert. If the project was to eventually move forward utilizing the current mine plan, it could potentially run for approximately 14 years based on a total indicated resource of 55.2 million pounds of U_3O_8. The project is located immediately north of the Karlamilyi (Rudall River) National Park (Figure 1).

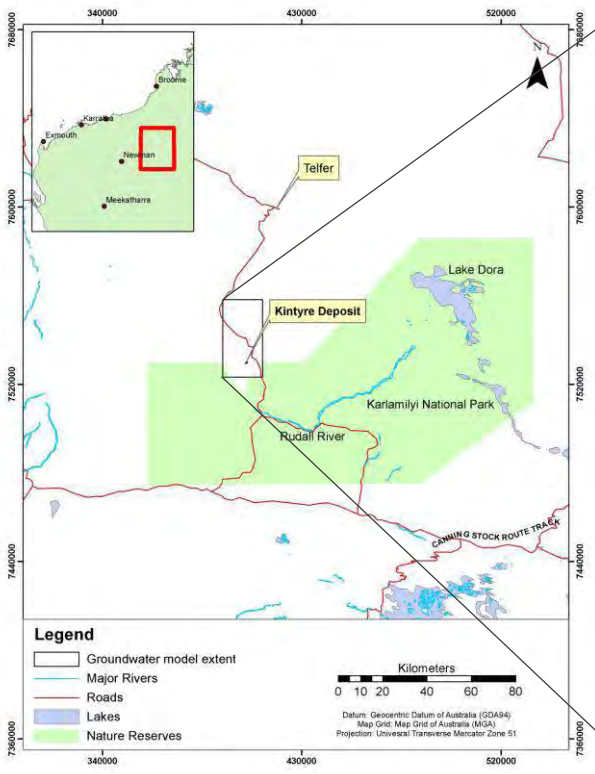

Figure 1 Kintyre Location Map

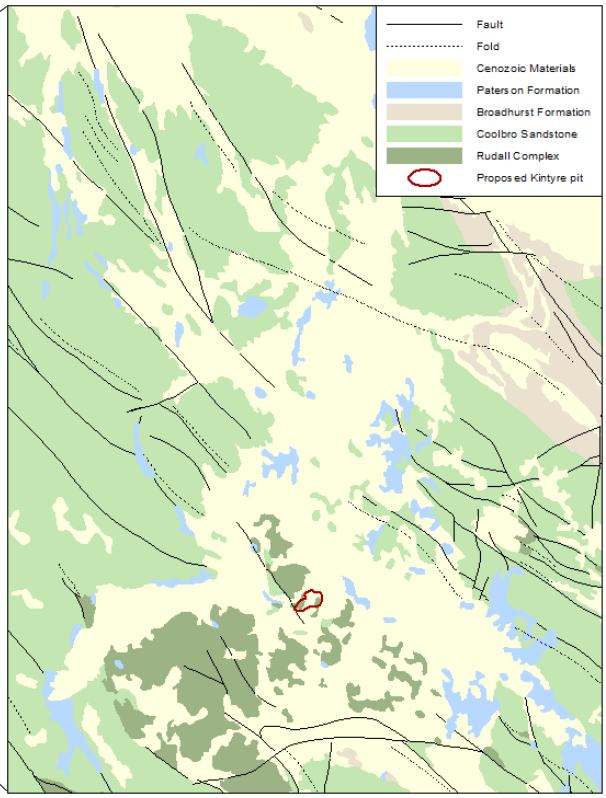

Figure 2 Regional Surficial Geology

The pit is required to be dewatered and, following closure, a pit lake is likely to form. As part of the Environmental Review and Management Program, groundwater, geochemical pit lake and salinity plume models were required to determine the potential for risk to downgradient receptors.

Geological environment

The site is located on a slight topographic high between two branches of the Yandagooge Creek. The creek flows toward the north-northeast between two nearby mountain ranges comprised of sedimentary Neoproterozoic rocks (Broadhurst Formation and Coolbro Sandstone) and metamorphic Paleoproterozoic rocks (Rudall Complex). Yandagooge Creek roughly follows the footprint of a Permian glacial valley that is incised into the Proterozoic rock. The glacial valley is mostly filled with Permian age glaciofluvial and glaciolacustrine sediments (Paterson Formation). The basal Permian is generally tillite and is overlain by

sandstone, siltstone, and claystone. Coarser-grained Cenozoic sediments overlie the Permian materials in most locations but tend to be unsaturated. Figure 2 illustrates the site layout and surficial geology.

Pit lakes

The pit shell used in the pit lake model was determined from the mining plan to be predominantly schist with areas of ore host rock, tillite and carbonate material (Figure 3).

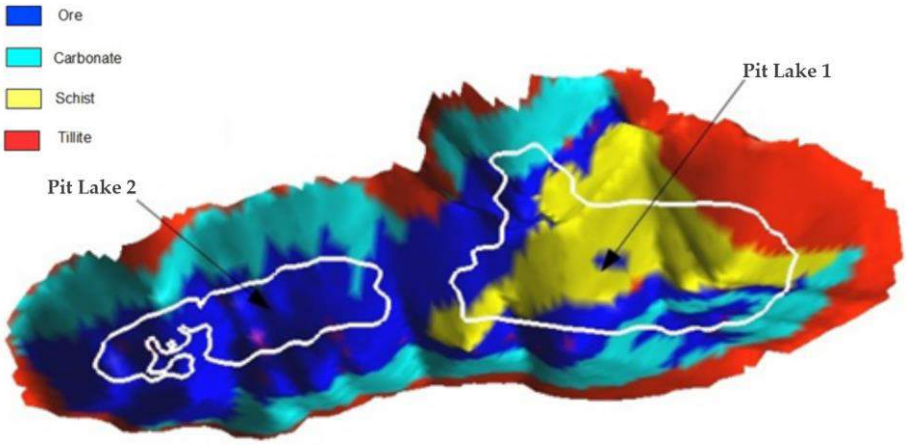

Figure 3 Cross section of pit showing locations of lakes and simplified geology

In semi-arid climates the dissolved constituents in water bodies become highly concentrated and there is an increasing concern that pit lakes will become point-sources of hypersaline groundwater. The Kintyre site occurs in the region with the highest average pan evaporation in Australia, at greater than 4 m per annum. This high evaporation coupled with a low mean rainfall of 372 mm per annum measured at Telfer (BOM, 2014) results in the pit lake becoming an evaporative, 'terminal' sink system (Figure 4) whereby the volume of water egress greatly exceeds ingress and the hydrogeological gradient is towards the pit. McCullough, *et al.* (2013) discusses the feasibility of allowing terminal sinks to form in order to reduce the impact to groundwater systems. The terminal sink draws all groundwater or leachate from tailings or waste rock material towards it, ensuring that it will not leave the footprint of the mine area and downgradient receptors will not be impacted by elevated uranium or other metals.

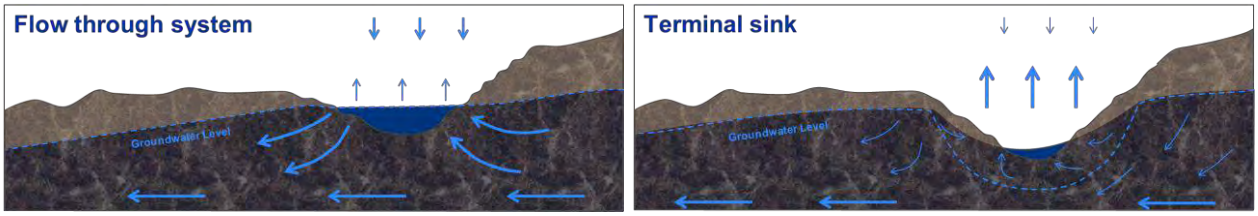

Figure 4 Illustration of pit lake systems

Despite the capture of any elevated element concentrations present in the groundwater by the pit lake evaporative sink, there was concern that a salinity plume could spread, against the flow gradient by diffusion and salinize the surrounding groundwater resources. In order to determine this risk the distance of likely diffusion was modelled.

The geochemical model integrated the pit lake volumes and dimensions to determine the limnological characteristics of the pit lakes. The dimensions of the pit lakes are shown in Figure 3 with the simplified geology used for the pit walls. If the depth of a lake relative to the area is greater than 20 percent, the lake is likely to be permanently stratified (Castendyk and Jewell, 2002). Table 1 shows the maximum depth, surface area, volume and the calculated relative depth. As the relative depth of Lake 1 is 38.6%, which is very much higher than the 20% point above which stratification is likely. It is estimated that Lake 1 will permanently stratify and not be subject to mixing while Lake 2 may not permanently stratify and will be subject to some mixing. Mixing will reintroduce oxygen into the deeper portions of the lake allowing chemical reactions to continue under oxygenated conditions.

Table 1 Pit lakes physical dimensions

Lake	Maximum lake depth (m)	Area (m^2)	Maximum volume (m^3)	Relative Depth %
Lake 1	139	1.02E+05	5.70E+06	38.6
Lake 2	58	8.69E+04	1.90E+06	17.4

The geochemical model was advanced to 1,000 years although chemical equilibrium was predicted to be reached within 10 years after closure. The final major ion, pH and total dissolved solids concentrations are given in Table 2.

Table 2 Pit lakes major ion concentrations predicted at 1,000 years

mg/L where applicable	Lake 1	Lake 2	mg/L where applicable	Lake 1	Lake 2
pH	7.58	7.52	Magnesium	4.66E+03	5.38E+03
Alkalinity as $CaCO_3$	219	243	Potassium	4.58E+03	5.26E+03
Calcium	432	439	Sodium	3.89E+04	4.49E+04
Chlorine	5.33E+04	6.15E+04	Sulfate	2.46E+04	2.82E+04
Fluorine	29.3	37.2	Total dissolved solids	1.27E+05	1.46E+05

METHODOLOGY

Groundwater flow models were developed and calibrated using MODFLOW-SURFACT to support permitting of the Kintyre project. Both regional and local-scale modelling were performed to assess the potential effects of mining on groundwater dependent flora and fauna (including subterranean) and to evaluate water supply availability. The local-scale model had identical properties to the regional model, but with finer discretization and smaller extents. The flow modelling predicted formation of terminal sink pit lakes. Geochemical models of the pit lakes' water quality using PHREEQC were developed next. The groundwater and geochemical models were used to develop a variable-density transport model using SEAWAT to examine the potential for salinity migration from the predicted terminal sink pit lakes.

Groundwater Flow Model

For modelling purposes, the geologic units were grouped into layers. The layer thicknesses were engineered such that the base of key layers corresponded to the base of the Cenozoic and Permian units

where these were present. Outside the vicinity of the paleochannel, the layers were flattened into a subdued representation of topography to maintain layer thickness. Hydraulic conductivity zones were used to represent the different geologic units. The ground surface was used to represent the top of the model.

The uppermost layer (Layer 1) of the model extends from ground surface to approximately 25 meters below ground. Layer 1 includes all Cenozoic materials; where the Cenozoic materials pinch out at the edges of the drainages, Layer 1 includes a portion of the uppermost bedrock unit (Permian or Proterozoic) to maintain layer thickness. Layer 2 includes the first 50 meters of the Permian units, which corresponds to the sandstone, siltstone, and claystone lithologies. Because the Permian units pinch out at the edge of the paleochannel, Layer 2 also includes a portion of the Proterozoic basement rock outside the channel to maintain layer thickness. Layers 3, 4, and 5 each include a 50-meter-thick section of the Permian tillite, with the lateral extent varying based on the paleochannel thickness at that depth. The remainder of each these layers is composed of Proterozoic basement rock to maintain layer thickness. The remaining layers represent the Proterozoic basement rock.

Model recharge was distributed by surficial geology, based on chloride balance data indicating approximate recharge rates. Model hydraulic conductivities and storage coefficients were distributed based on geologic unit.

Geochemical Model

A geochemical model of the final pit lake chemistry was developed using PHREEQC (Cameco Australia, 2013). The major conclusions were:

- The quality of the pit lake water is predicted to be hypersaline;
- Alkalinity is predicted to be moderate over the pit lake life;
- The pH ranges between approximately 7.5 and 8 and is not predicted to become acidic;
- Evaporative losses increase the concentrations of elements such as boron, fluorine, manganese, molybdenum, nickel and uranium over time;
- Salt inputs from the pit walls dissolved by direct rainfall increase the concentrations of arsenic, chromium, copper, lead, nickel, and selenium over time; and
- As a result of the alkaline pH, no iron is predicted to be in solution and aluminium concentrations are predicted to be low.

Variable-Density Flow Model

To simulate transport of salinity or any other solute, the initial concentration must be determined. For this study, the final equilibrium total dissolved solids (TDS) concentration calculated from the geochemical model PHREEQC was used as the initial salinity concentration for each pit lake (Lake 1 and Lake 2). Geochemical model results from PHREEQC do not explicitly calculate TDS concentrations, so the following equation (Csuros, 1997) was used to determine pit lake TDS values:

$$TDS = (0.6 \times Alk) + Na + K + Ca + Mg + Cl + SO_4 + SiO_2 + NO_3 + F \quad (1)$$

The components of this equation are the cations and anions that compose the TDS value. The calculated TDS of Lake 1 used in this model is 127,100 mg/L or 127.1 kg/m³ while the Lake 2 TDS is 146,400 mg/L or 146.4 kg/m³. Both lakes are considered to be hypersaline.

No manual activity corrections were made, beyond those adjustments that occur through the geochemical modelling associated processes. However, oversaturation of species was prevented by allowing chemical precipitation to remove chemical mass from the pit lake, and establish a limit on the maximum dissolved concentration for the associated components of that mineral. As a consequence, over the modelled evolution of both lakes, specific mineral species were predicted to precipitate, including phases containing chloride, sulfate, and fluorine as well as carbonate bearing species and silica.

Two other model parameters required to simulate solute transport are effective porosity and dispersivity. Effective porosity is defined as the ratio of volume of interconnected pore space to total volume of a rock sample. The bedrock units at Kintyre were assumed to have an effective porosity of 0.05 based on literature values for fractured crystalline rock that range between 0 to 0.10 (Freeze and Cherry, 1979).

Estimating dispersivity is challenging when there is no pre-existing solute plume. However, guidance exists regarding dispersivity in relationship to the model grid cell dimensions. The grid Peclet number is the grid spacing (25 m) divided by longitudinal dispersivity, and Peclet numbers should be five or less to minimize numerical errors or numerical dispersion during modelling (Delleur, 2006). For this study, therefore, longitudinal dispersivity is assumed to be 6.25 m, resulting in a Peclet number of 4.

SEAWAT includes a variable-density flow package that requires input values for minimum density, maximum density, as well as the slope of the linear equation of state, which relates fluid density to solute concentration. Density values were determined from standard values of sodium chloride solutions at different concentrations at 25°C (UCSD, 2014). The minimum density is estimated to be 1,075 kg/m³, which is slightly lower than the TDS concentration of Lake 1. The maximum density is estimated to be 1,100 kg/m³ which is slightly higher than the TDS concentration of Lake 2 to compensate for the simulated pit lake water temperature of 32°C. For reference, seawater has a density of 1,025 kg/m³. The slope of the linear equation of state is calculated to be 0.171.

Boundary conditions for the variable-density flow and transport model are identical to previous groundwater models (i.e., General-Head Boundaries around the model grid) except the pit lake cells are specified as either "no flow" for cells located above the water table or as constant head and constant concentration cells. The constant head pit lake cells are set to a hydraulic head equivalent to the final pit lake elevations from the previous groundwater flow model after 1,000 years. Lake 1 is set at 266.8 meters Australian Height Datum (mAHD) and Lake 2 is set at 268.82 mAHD. The constant concentrations at the pit cells are the final equilibrium TDS concentrations from the geochemical model.

Assumptions

Steady-state variable-density modelling was chosen for this study as previous groundwater and geochemical models predicted conditions to 1,000 years and showed that new steady-state conditions were achieved in approximately 100 years. Steady-state modelling was also chosen to reduce computational duration given the small time steps required to perform transport simulations. Assumptions for the variable-density modelling simulations are as follows:

- Precipitation of solids from pit lakes onto the pit lake floor (a process which would reduce permeability of the pit lake floor) is not simulated;

- TDS concentration and water-level elevation is constant in the pit lakes; and
- Salinity concentration of groundwater is zero.

Background salinity concentration of the groundwater was assumed to be zero instead of the mean concentration of 3,300 mg/L to assess only the effects of the pit lake on the groundwater system. This is a conservative assumption, as using zero for the surrounding salinity increases the concentration gradient from the pit lake water to the surrounding groundwater. Using the actual groundwater salinity concentration of 3,300 mg/L would potentially decrease the diffusion of pit-related salinity. Further, since the pit lake water-level elevations and salinity concentrations are held at their maximum simulated values and precipitation of solids from the pit lake are not included; this model is considered to be conservative.

RESULTS AND DISCUSSION

The groundwater flow model was calibrated to within 10% of observed data for both steady state and transient data sets. The calibration data set represented water levels measured in 2011 and 2012 when no onsite pump testing was occurring and as a consequence, the system was assumed to be at steady state. Multiple groundwater pumping tests were performed in a phased and overlapping sequence in six wells during 2011 and in three more wells during 2012. Monitoring data from nearly 50 wells monitored during the tests was used to calibrate the transient model.

Figure 5 summarizes the results of the hydrogeological and geochemical models as the recovery of the groundwater system to equilibrium after approximately 15 years and the achievement of a steady state in water quality after approximately 10 years. In the two pit lakes that are predicted to evolve at Kintyre, the total dissolved solids (TDS) of pit lake water will reach hypersaline concentrations of between 120,000 mg/L and 150,000 mg/L (Figure 5) and the pH will remain circumneutral to slightly alkaline.

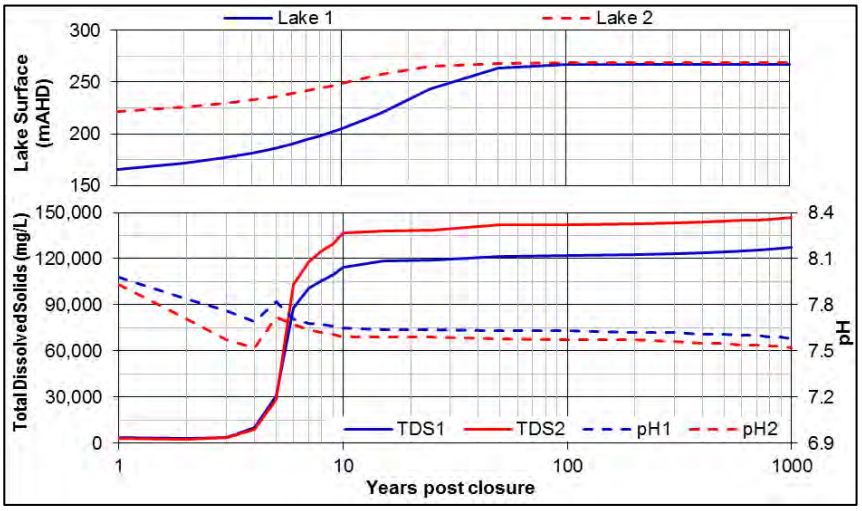

Figure 5 Pit lake level recovery with TDS and pH

Figure 6 shows the maximum extent of the salinity plume in the horizontal direction (from model layer 8 in the bedrock) for the constant-density case after 100 years. Contour intervals in Figures 6 through 9 are

1, 10, and 100 kg/m³, which are equivalent to 1,000, 10,000, and 100,000 mg/L, respectively. The mean TDS concentration of groundwater at the site is approximately 3,300 mg/L (i.e., brackish) so a minimum TDS contour of 1,000 mg/L was used. In Figure 6, salinity migrates less than 100 m horizontally from the pit lake as a result of dispersion because the pit lakes are terminal sinks.

Figure 8 shows the vertical extent of the salinity plume for the constant-density case through a west-east line indicated on Figure 6, over a distance of approximately 1 km after 100 years. Each model layer is approximately 25 m thick below the pit until a depth of approximately 320 m below ground surface (bgs). The lower model layers after a depth of approximately 320 m bgs are omitted from the vertical extent figures. Gray and blue cells represent no flow and pit lake cells, respectively. The blue and black contours represent the water table and the TDS concentration, respectively. Figure 7 indicates that a salt plume migrates approximately 50 m vertically before being indistinguishable from mean groundwater salinity.

Figures 7 and 9 show the horizontal and vertical extent of the salinity plume for the variable-density case after 100 years. In Figure 7, the horizontal extent is nearly identical to the constant-density case and the salinity plume does not move beyond the surface extent of the pit. In Figure 9, salinity migrates further vertically (approximately an additional 75 m) than the constant density case as a result of pit lake density effects, to a maximum depth of 150 m before it is indistinguishable from the salinity of the groundwater. There is no horizontal migration in the deeper model layers as a result of the low horizontal hydraulic conductivity (0.008 m/d) arising from decreased fracture density and aperture of the metamorphic rock at those depths, and consequently the salinity plume is not predicted to migrate offsite.

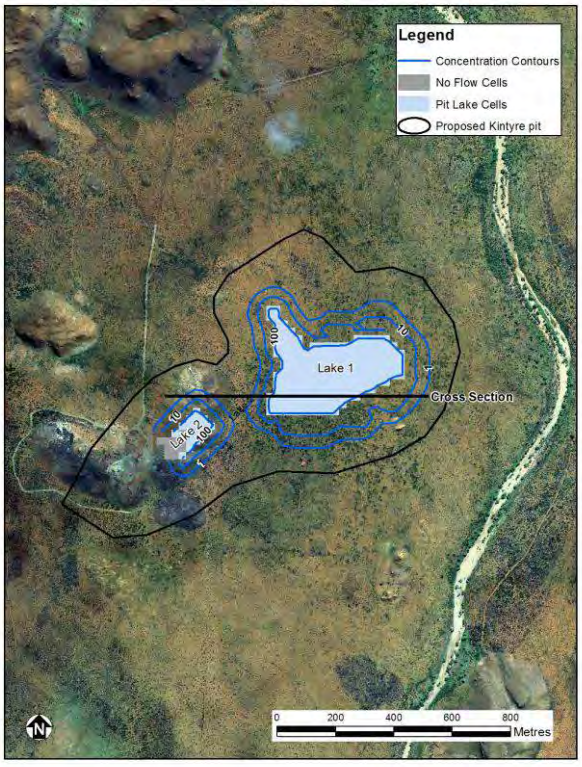

Figure 6 Constant-density salinity contours

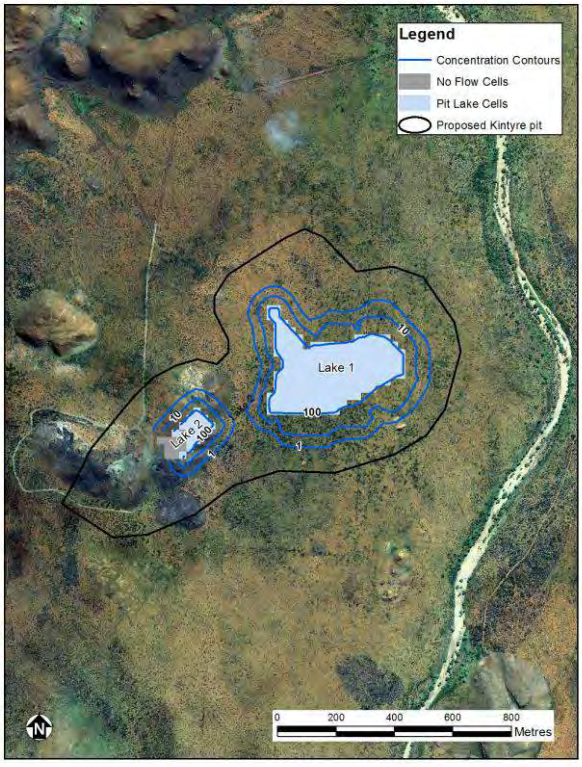

Figure 7 Variable-density salinity contours

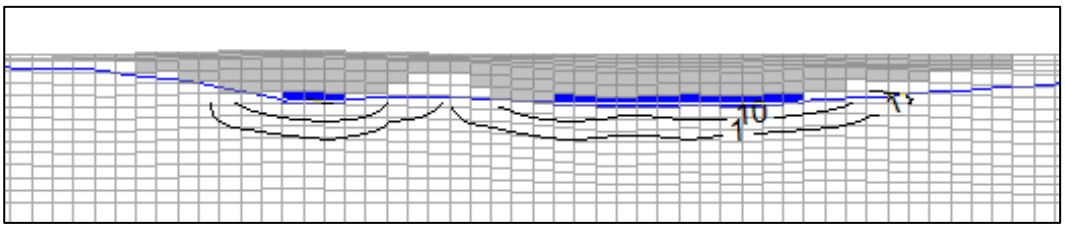

Figure 8 Vertical constant-density salinity contours along cross section from Figure 3. Contour interval is 1, 10, and 100 kg/m^3. Vertical grid spacing is 25m below the pit floor.

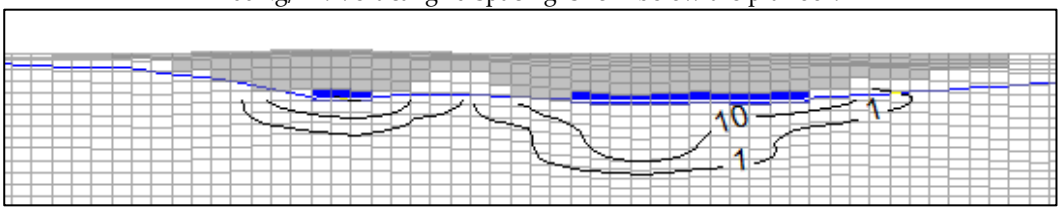

Figure 9 Vertical variable-density salinity contours along cross section from Figure 3. Contour interval is 1, 10, and 100 kg/m^3.Vertical grid spacing is 25m below the pit floor.

Given the uncertainty in dispersivity and effective porosity values, three sensitivity simulations were performed to bracket the salinity plumes horizontal and vertical extent:

- Dispersivity factor of four increase [Peclet Number (Pe) = 1];
- Dispersivity factor of 2.5 decrease (Pe = 10); and
- Effective porosity factor of 5 decrease (n = 0.01).

Table 3 provides the change in downgradient distance of the 1,000 mg/L concentration contour for each sensitivity simulation in the horizontal and vertical directions when compared to the variable-density case. Results show that increasing dispersivity could causes the 1,000 mg/L contour to reach the surficial pit shell boundary, but does not leave the site.

Table 3 Variable-density model sensitivity analysis results

Simulation	Horizontal Distance Change (m)	Vertical Distance Change (m)
Dispersivity factor increased (Pe = 1)	+100	+50
Dispersivity factor decreased (Pe = 10)	-25	-30
Effective porosity decreased (n = 0.01)	~0	~0

CONCLUSION

Detailed numerical analyses were conducted to assess if a salt plume originating from the Kintyre pit lakes could migrate offsite toward groundwater receptors. Results show that salinity does migrate horizontally and vertically from the pit lake, but the 1 kg/m^3 or 1,000 mg/L TDS contour progresses less than 100 m from the pit lake using base case parameters. Results from this study show that given the low permeability of the bedrock beneath the pit floor, salinity migration from this pit will be limited and will not impact downgradient groundwater dependent ecosystems.

ABSTRACT

Information on costs and environmental management strategies related to the closure of open pit mines requires results from comprehensive numerical hydrogeological and hydrochemistry models. Ideally, each model input parameter is defined by comprehensive field or laboratory tests.

Since closure assessments are now carried out earlier in the lifetime of a mine, it is rare that each input parameter can be accurately quantified prior to modelling. To compensate for data limitations, pit lake models increasingly incorporate additional, theoretical assumptions which are subsequently evaluated using sensitivity analyses.

Based on a study in equatorial Africa of three existing pit lakes (gold mines), we compare the water quality results of the initial water mixing models with the results of the more complex pit wall interaction models. The initial models only used water quality samples collected in the field while the more advanced models incorporated the results of the static and the kinetic leach tests for solids.

The differences between the model results are partially reduced by incorporating more laboratory data and by increasing the level of model complexity. But, additionally, for large operations where pits are in various stages of development, basic field sampling data facilitates a "calibration" to known conditions.

We recommend designing models based primarily on water balance components and available water quality data supported by the mineralogical and leaching characteristics of the wall rock. In circumstances where specific inflows dominate the water balance, simplified mixing models can provide defensible initial estimates with regard to the long term trends of the pit lake water quality.

Keywords: pit lake model, hydrogeology, hydrochemistry

INTRODUCTION

Financial, social and environmental obligations need to be met after the closure of a mining operation. As a result, the project developer, even at the earliest stages of an ore body's assessment, aims to incorporate the final closure conditions and determine their eventual impact on the planned development.

Due to the limited amount of data available at such early stages of a project, we increasingly rely on theoretical models to predict the future closure conditions. Specifically for pit lake studies, we use numerical hydrogeological and hydrochemistry models to simulate the pit lake rebound behavior and the pit lake quality, well before any excavation has taken place. In order to do so, ever more complex theoretical assumptions are made, which are then subjected to numerous sensitivity analyses.

In this paper, we compare the results of simple water mixing models with subsequent, more complex, mineral / water interaction models. We evaluate whether the increase in laboratory data and model complexity leads to a better understanding of the final closure conditions.

METHODOLOGY

The chemistry of pit lakes varies widely, ranging from circum-neutral or alkaline type waters with a low metal concentration to highly acidic waters with elevated metal concentrations. The type of lake chemistry is the result of physical and chemical interactions, namely (Bowell, 2002):

1. Geological controls: The composition of the host rock and the ore body determine the extent to which any geochemical reaction may occur (i.e. the source);
2. Geochemical controls: The types of minerals, the chemistry of the reactive water and the physical and chemical conditions determine the release and attenuation mechanisms;
3. Hydrological and hydrogeological conditions: The flow of water which, upon contact with the minerals, mobilizes the metals and mixes the different effluents; and
4. Limnological processes: Temperature and density variations related to the lake geometry influence the circulation and the stratification of the water inside the pit.

This paper focusses on the water balance calculations, the mixing of the different water qualities and the chemical reactions along the exposed pit wall. Many of the factors discussed by Castendyk et al. (in press) are included in the construction of the models. We compare these theoretical predictions with the actual lake rebound and water quality trends observed in three existing pit lakes.

Field sampling and laboratory tests

Since starting operations in 2000, the mine has collected and analysed approximately 1750 water samples, including surface water, groundwater, waste rock seepage and pit lake samples. The samples are collected quarterly in accordance with the environmental monitoring practices described by the US Geological Survey National Field Manual (USGS 2003) and the Standards Association of Australia (1998). The laboratory analyses are carried out in an accredited laboratory using standard techniques and protocols.

Mine safety regulations prohibited the collection of pit wall rock samples from the three closed open pits, "K", "M" and "L". Instead, 40 rock samples were collected from stockpiled materials on

site. The rock samples were subjected to a shake flask extraction (SFE) leachate test and a single addition net acid generation (NAG) test. These tests measure the composition of the contact water after the reagent (either distilled water for the SFE, or hydrogen peroxide for the NAG) has been in contact with the rock samples. The laboratory procedures recommended in the Acid Rock Drainage Prediction Manual (Coastech Research, 2008) and the ARD Test Handbook (AMIRA International, 2002) for these types of tests were followed.

Pit lake water balance

Open pit operations form depressions in the ground that collect rainfall, surface water run-off and groundwater (if the pit extends below the original groundwater table). The water body collecting inside the pit is also affected by losses, such as evaporation, pit rim overflow and seepage.

Therefore, a pit lake rebound calculation is essentially a water balance calculation to a terminal recipient (i.e. sink) or a through flow recipient (if overflow or seepage of lake water occurs). At specific time intervals (e.g. monthly or annually), the sum of the outflows is subtracted from the sum of the inflows to calculate the net gain or loss from the pit. The cumulative volume is then converted to the equivalent stage height and lake surface area using the pit geometry curves.

The following mathematical equations summarize the water balance calculation:

$$V_{tot}(t) = V_{tot}(t_0) + \int_{t_0}^{t} F_{in}(\tau).d\tau - \int_{t_0}^{t} F_{out}(\tau).d\tau \quad (1)$$

$$F_{in}(\tau) = F_{rain}(\tau) + F_{runoff}(\tau) + F_{runoff\_wall}(\tau) + F_{GWin}(\tau) \quad (2)$$

$$F_{out}(\tau) = F_{GWout}(\tau) + F_{evap}(\tau) + F_{discharge}(\tau) \quad (3)$$

The flow concepts are graphically shown in Figure 1.

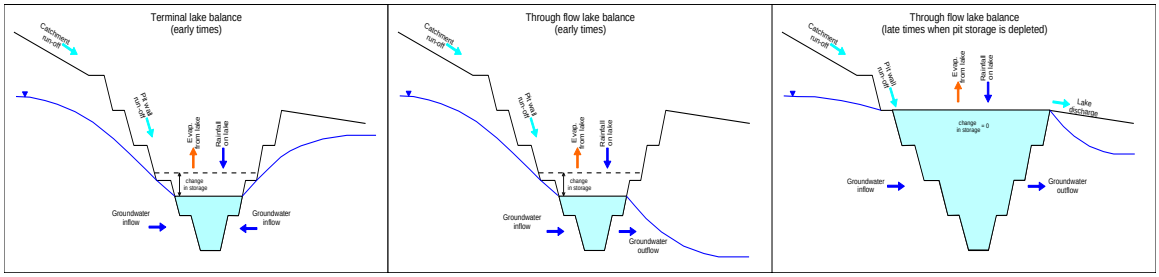

Figure 1. The dominant flow mechanisms during different stages of pit lake filling.

Pit lake chemistry

The pit lake geochemical model is a PHREEQCI Version 3 (Parkhurst and Appelo, 2013) model that represents a leaking beaker exposed to the atmosphere. The water inside the beaker is well mixed and is not stratified. Figure 2 shows the basic aspects of the two different models, including:

- Inflow of different water quality sources (such as rainfall, run-off and groundwater);
- Mineral / water interaction reproduced by an empirical formula. The incorporation or absence of this formula constitutes the main difference between the simple mixing model (A) and the more complex pit wall interaction model (B);

- The evaporation rate increases proportional to the expansion of the lake surface area, producing an evapo-concentration effect in the solution. At this site, the annual lake evaporation rate was approximately 1.3 times higher than the mean annual precipitation rate.
- Discharge is allowed via the seepage to the groundwater and/or discharge across the pit rim (the latter only occurring when the pit storage has been depleted);
- The model steps include the equilibration between carbon dioxide gas (CO_2) and oxygen gas (O_2). For the CO_2 gas, the partial pressure has been increased to $10^{-3.0}$ atmospheres to reflect the roll of biological activity in the lake (Cole et al., 1994);
- Finally, mineral precipitation and dissolution reactions may also take place inside the pit lake in accordance with a continuously stirred batch reactor.

This general approach has been used in other locations in Africa (Duthe et al., 2011) where it was originally set up for the removal of reactant phases. As minerals precipitate, the components are removed from the solution and the subsequent calculations, preventing the re-dissolution of the solids.

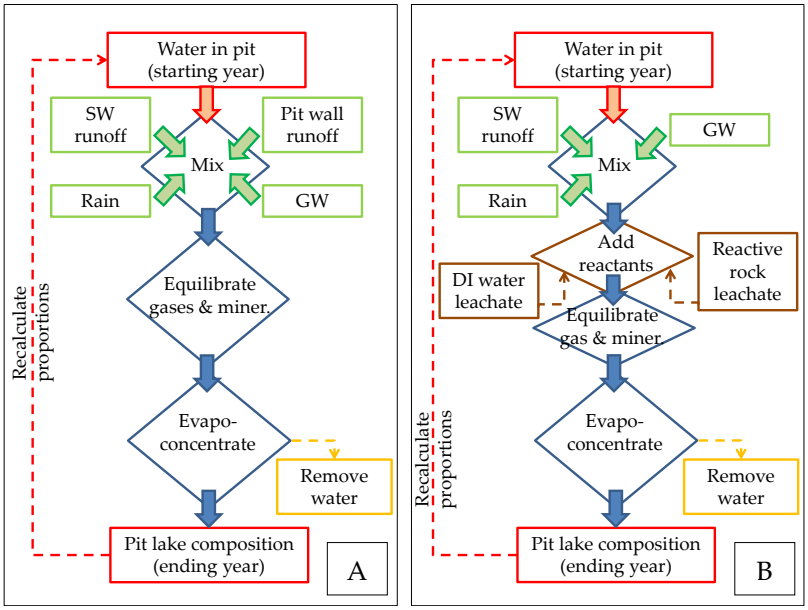

Figure 2. The PHREEQC water mixing model (A) and the pit wall interaction model (B).

RESULTS AND DISCUSSION

Water quality monitoring versus laboratory results

Figure 3 compares the results of 10 years of water quality monitoring at an acidic waste rock seep with the laboratory leach test results for 7 rock samples taken at the same acid forming waste rock dump. In contrast, Figure 4 compares the water quality monitoring data from a benign waste rock seep with the leach tests carried out on 3 rock samples taken from the same non-acid forming waste rock dump.

Based on a select number of signature parameters (such as pH, TDS, SO_4, Al, Mn and Fe), it is shown that the leach tests do not consistently identify the acid generation potential of the waste materials. For the acid forming materials, the laboratory tests overestimate the pH value and underestimate the sulphate and metal leaching effect. This is commonly observed when the rate of release of acidity and/or alkalinity is slower than the actual duration of the test.

Meanwhile, leach tests performed on the non-acid forming materials are generally similar to the water quality observed in the field.

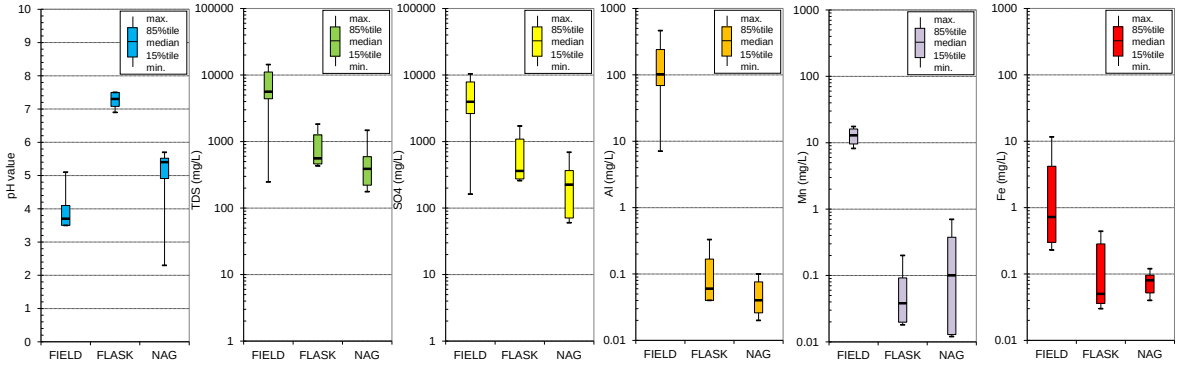

Figure 3. ARDML water quality field samples compared with leach test results for PAF materials.

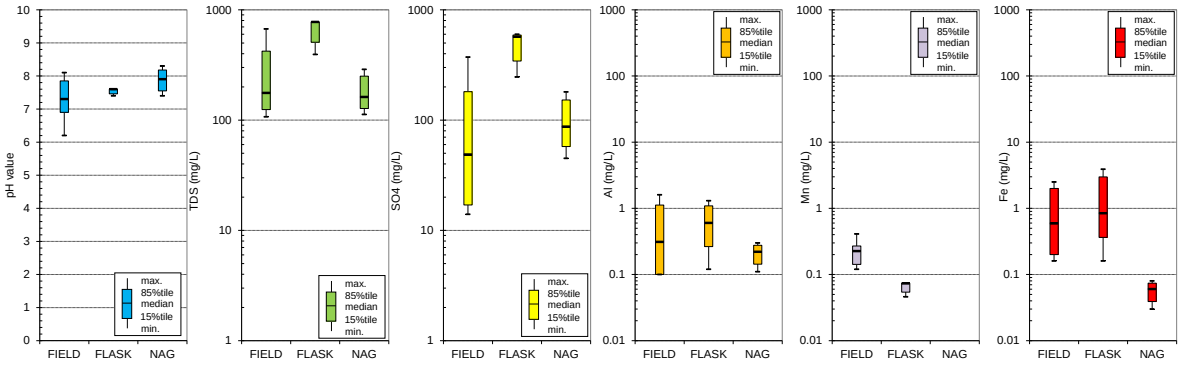

Figure 4. Benign water quality field samples compared with leach test results for NAF materials.

Pit lake water balance predictions

The mean annual precipitation (MAP) at the mine is in the order of 1000 mm/year and occurs mostly between November and April. The evaporation across open water bodies amounts to approximately 1300 mm/year. The surface water run-off and the groundwater infiltration rate are equal to 5% and 3% of MAP, respectively. The run-off from the exposed pit walls was set at 55% MAP after a calibration.

Figure 5 compares the predicted with the measured lake level rebound for the existing pit lakes "K", "M" and "L" during the 6 year monitoring period. The water balance conditions were

subsequently extrapolated using a statistical sequence based on 14 years of measured rainfall and evaporation records. The results are shown in Figure 6, indicating:

- A gradual filling of pit lake "K", eventually leading to overflow and groundwater seepage;
- A stabilizing condition at pit lake "M", maintaining a long term evaporative "sink"; and
- A relatively rapid rebound and overflow of pit lake "L", mainly due to a groundwater inflow contribution absent at "K" and "M".

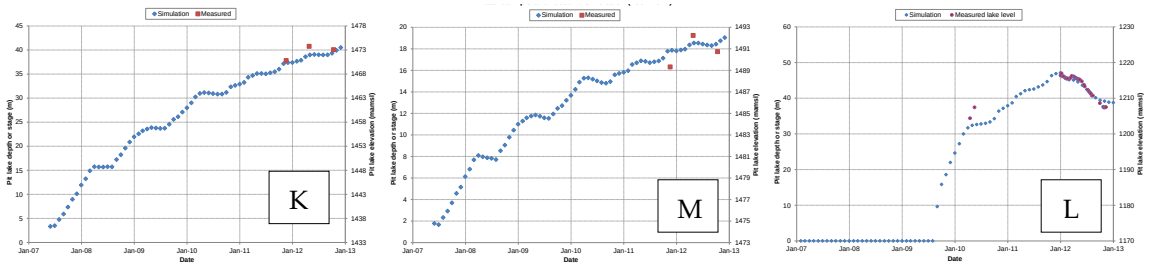

Figure 5. Predicted versus measured pit lake rebound behaviour at "K", "M" and "L".

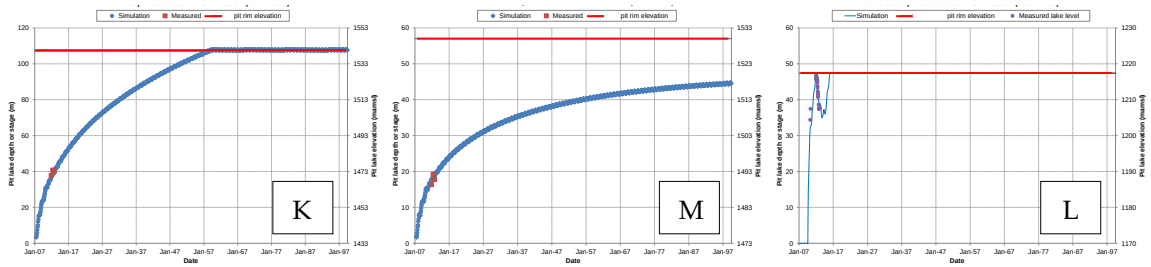

Figure 6. Long term predicted lake level rebound at "K", "M" and "L".

Pit lake chemistry predictions: water mixing models

The field samples of the "M" pit lake display a slight but apparently continuous improvement in water quality for indicators such as pH (increasing from 2.5 to 3.4), TDS (trending down to 400 mg/L) and sulphate (decreasing from 1800 to 200 mg/L).

Using this 6 year trend, an appropriate pit wall run-off composition was achieved by mixing 97% rainwater with 3% acid rock drainage / metal leaching (ARDML) type field water samples. The precipitation of minerals was allowed using the "Equilibrium_Phases"[1] option for calcite, alunite, jarositeK, malachite, ferrihydrite, gibbsite, magnesite and gypsum. If oversaturated, they precipitate and remove some concentrations of Al, Fe and SO_4 from the solution. This effectively meant that, upon precipitation along the pit floor, the solids became unavailable for further reactions.

[1] JarositeK formed in preference to ferrihydrite. So, although the model allowed for surface complexation onto the hydrous ferric oxide (HFO) surface, it did not take place due to the absence of ferrihydrite.

In particular the alunite and jarositeK phases had a slight, but not significant, effect on the modelled pH and SO_4 values. There was no significant impact on the trace metals concentrations due to the absence of hydrous ferric oxide (HFO) surfaces under these high SO_4 and low pH conditions.

The calibration and forward prediction results are shown in Figure 7, presenting an acceptable match between the modelled and measured signature parameters and trace metals, respectively.

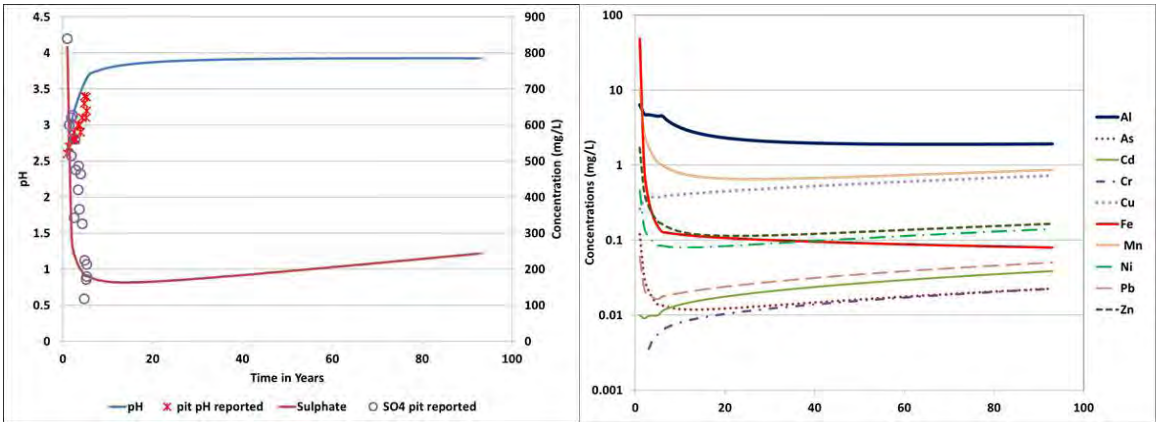

Figure 7. Long term predicted water quality at pit lake "M".

At pit lake "K" the 6 year field record indicated a downward trend from 1000 to 600 mg/L in SO_4, while the pH remained relatively constant at 2.71. Conventionally, when the pH of a pit lake remains relatively constant, the SO_4 is expected to increase or remain constant. The apparent contradictory behaviour of the measured pH and SO_4 complicated the calibration for the "K" pit lake.

The most representative wall rock runoff composition was achieved by mixing 70% rainwater with 30% ARDML type field water samples. It produced a reasonable fit to the SO_4 data, but the match with the pH data is poorer (even when considering the precipitation of jarositeK and alunite). The low pH values and the formation of jarosite phases will suppress the precipitation of ferrihydrite and, hence, prevent surface complexation and the sorption of trace metals.

The calibration and forward prediction results are shown in Figure 8, showing a slight over-prediction of sulphates and pH values. The trace metals are similar in order of magnitude.

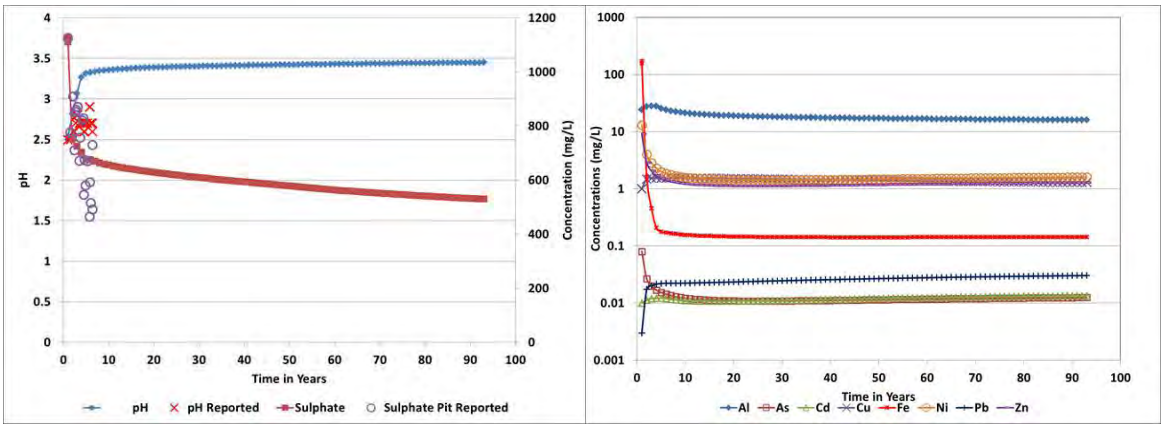

Figure 8. Long term predicted water quality at pit lake "K".

The "L" pit lake refilled quickly due to the storage of drained water from nearby operations, and natural groundwater inflow. The lake has a relatively good water quality with neutral to slightly alkaline pH values (7.3 – 8.1) and slightly elevated SO_4 (approximately 560 mg/L).

The results presented in Figure 9 rely on the inflow of a Ca-Mg / SO_4 type water with an average pH value of 7.7. Rapid filling prevented the generation of acidic pit wall run-off.

The simple mixing model confirms that relatively benign lake water qualities at "L" can be obtained over time if the dominant proportion of inflow is contributed by natural, alkaline groundwater rather than acidic pit wall run-off.

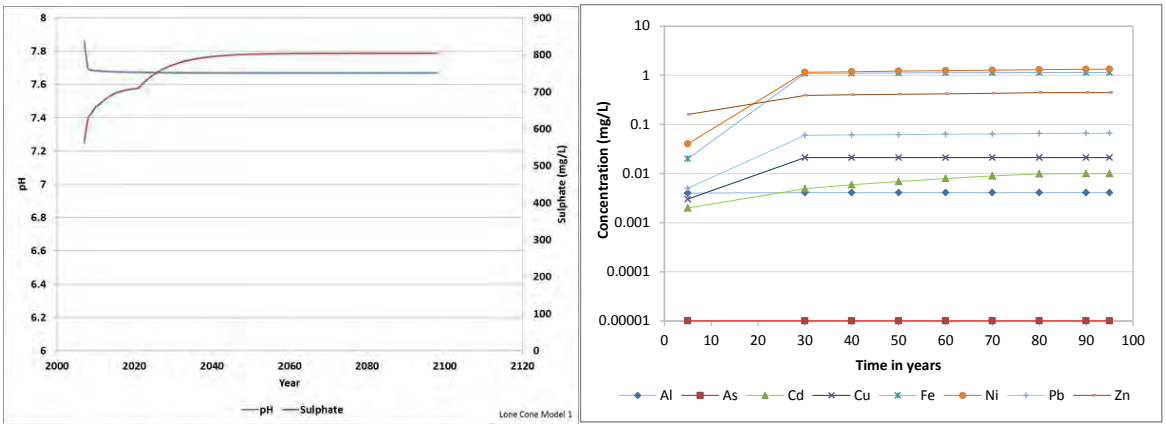

Figure 9. Long term predicted water quality at pit lake "L".

Pit lake chemistry predictions: pit wall interaction models

In the more complex models, rather than mixing two water types to obtain a representative pit wall run-off chemistry, we used the waste rock leach test results to calculate the following mineral / water reaction formula (partial representation):

(F)0.000474(Al2O3)0.000037(BaO)0.000004(CaCO3)0.324351(Fe2O3)0.000018(MgCO3)0.022222 …

… (ZnO)0.000015(As2O5)0.000004 PbO)0.000006(SeO3)0.000003(HgO)0.00000006

This partial formula represents a reactive leachate from a Banded Iron Formation, a common gold bearing horizon in central and southern Africa. As a check of the models, the formula was applied to reverse calculate the leachate composition of the NAG test for one specific sample, providing a calculated pH of 3.077 versus a measured pH of 2.3[2].

In addition to the reaction formula, the mineral amount that would potentially leach into the pit lake is also required for this type of simulation. We estimated this input parameter by multiplying the pit wall and pit floor surface area by a theoretical wall rock thickness. Based on the "M" and "K" pit lake water samples, the wall rock thickness would range from 5 mm to 20 mm, respectively.

Table 1 summarizes the results between the different simulations, indicating only minor differences in the pit lake composition predicted by the simple water mixing model and the more complex pit wall reaction model. The different years after closure are included for reference purposes.

Table 1. Current and predicted pit lake chemistry

Param.	Units	Pit Lake "K"			Pit Lake "M"			Pit Lake "L"

P	mg/L	<0.5	0.09	0.07		0.129	0.125	<0.005	0.068

[2] The difference is probably due to lower iron concentrations in the laboratory leach sample, whereby some ferric solid, ferrihydrite, $[Fe(OH)_3]$, schwertmannite $[Fe_8O_8(OH)_{4.8}(SO_4)_{1.6}]$ or jarosite formed and released more protons into the solution lowering the pH. It is likely that some acidity had been lost due to reaction with carbonate in the sample.

(1) Negative values calculated in PHREEQC

CONCLUSION

We recommend designing models based primarily on water balance components and available water quality data supported by mineralogical and leaching characteristics of the wall rock. Therefore, during the early stages of a mining project, the collection of site specific water monitoring data is as important as the more theoretical laboratory leach tests on solids.

Water mixing models to predict the pit lake chemistry behavior, when calibrated to known conditions measured in the field, can be acceptable substitutes for more complex mineral / water reaction models in circumstances where specific inflows dominate the water balance.

ACKNOWLEDGEMENTS

We extend our gratitude to AnglogoldAshanti who provided us with the data and the funding to develop the models presented in this paper. We also thank Dr. Dirk Vanhooydonck who reviewed the mathematical formulae used in the pit lake water balance.

Predicting Pit Lake Formation and Water Quality

David Arcos, Jordi Guimerà, Salvador Jordana, Eduardo Ruiz and Jorge Molinero
Amphos 21 Consulting, Spain

ABSTRACT

Pit lakes form when open pit mining operations are discontinued and dewatering ceases. The resulting composition of the water within the lake is related to the geology and mineralogy of pit walls, water flow rates and climate conditions. In some cases, these lakes will develop acid sulphate conditions with high concentrations of metals, thus constituting an environmental concern. Preventing such conditions from the early stages of the mine project allows a proper planning for mine closure, yet conditions can be predicted, allowing taking informed decisions.

In this work, open pit flooding has been simulated using COMSOL Multiphysics, a well-known commercial FEM platform, and water quality can be calculated by coupling the geochemical code PHREEQC code with the Java interface iCP. In the implemented model the height of the lake depends on the relationships between the groundwater water inflow rate of the lake, the elevation of the spillway, the water volume of the lake as a function of the height of the water and the evaporation rate. In its turn, the height of the lake variable is used as a Dirichlet boundary condition at the bottom of the open pit in a realistic hydrogeological large-scale 3D aquifer. The water quality can be determined by considering the geochemical processes in the interaction of water with the pit walls, as well as by considering the contribution from rainwater and the evaporation effect.

The resulting model is able to recreate transient pit lake generation and water quality. The simulations predict the rise of water in the pit lake as a function of time, the maximum elevation of the lake and the flow rate of the creek that could appear by overflow if the lake reaches the pit boundary. In terms of water quality, the simulation is able to predict the composition evolution with time of both the water entering into the lake and the lake itself, even after reaching a hydraulic stationary state. Results obtained show a good agreement with currently available field data. It is worth mentioning that the model could also calculate lake stratification due to thermal and/or ionic strength effects, although it has not been implemented yet.

Keywords: Pit lake, mine closure, modelling, hydrogeology, geochemistry.

INTRODUCTION

Excavated pits can have several depths and sizes, but all of them require environmental reclamation. One possible reclamation endpoint could be the creation of pit lakes (Gammons et al., 1999). Pit lakes are created by filling by water the open pit left after the completion of mining operations. This water filling can be done by artificial flooding or natural hydrological processes such as rain or groundwater inflow (Castro and Moore, 2000).

The increase in open-pit metal mining since the 1970s will lead to the formation of numerous pit lakes over the next 50 years. Many of these lakes could develop acid sulphate conditions with high levels of dissolved metals. Recommended approaches for remediation of these conditions include the addition of lime or other alkaline materials and the stimulation of sulphate-reducing bacteria. However, prevention rather than remediation is probably the preferable approach. Measures, like filling the pits with water as fast as possible to promote anoxic conditions within the lake preventing the oxidation of sulphides present in the pit walls, thus minimizing the formation of acids and dissolved metals (Castro and Moore, 2000).

Local hydrogeology determines how fast an open pit lake is formed in natural conditions. A generalized water balance for a pit lake can be summarized as the change in water storage in the lake, which results from the addition of inflows (direct rain, surface water runoff and streams, and groundwater inflow) and the subtraction of the outflows (evaporation, groundwater outflow, surface water outflow as a creek from the lake). The rate of groundwater input depends on the site geology, topography and climate. A rough estimate of groundwater inflow can be obtained by looking at the amount of water that was pumped during active mining operations. This can provide a useful estimation during the early stages of flooding but the rate will change as the pit fills with water and the hydraulic gradient towards the lake will decrease. On this context, water quality will be the result of the interaction of groundwater with the pit walls, especially to a depth where atmospheric oxygen can penetrate. Considering that flow rates decrease as water level rises and that sulphide oxidation reactions are kinetically driven, the quality of the inflow water will be worst with time. Thus, the quality of the water in the lake is dependent on the velocity of lake formation. In addition, other aspects that may affect water quality are the surrounding groundwater composition, the amount of rainwater (and/or evaporation) and the characteristics of the pit walls (sulphide amount and distribution).

Once a pit lake has been filled to its ultimate surface elevation, there are many different hydrogeological scenarios for the lake, which can be considered important factors for “end use” decisions. For example, in an arid climate, it is very possible that evaporation will completely balance any water input terms. Such a lake is referred to as a “terminal” lake. A “flow-through” lake, on the other hand, will receive groundwater inputs from one side, but will lose groundwater to the other side. Flow-through lakes are especially common when the pit was excavated on a hillside with an initially sloping water table. Finally, if water inputs are high (such as in a wet climate, or where a stream is permanently diverted into the lake), then the final lake will probably have a surface water output. This could either be an engineered spillway or stream (Gammons et al., 2000). The effect on the water quality is also dependent on the behaviour of the lake once it reaches the ultimate surface elevation. In an arid climate, the excess evaporation will result in increasing the concentration of sulphate and metals in the water lake (Atkinson, 2002), resulting in the precipitation of sulphate minerals in the lakeshore. In “flow-through” lakes, the quality of the water will depend on the quality of entering groundwater, thus good quality groundwater will

result in improvement of the lake quality. Finally, in wet climate conditions, it could be expected that dilution result in increasing the quality of the water in the lake. Another aspect that must be considered is the role of emerged pit walls; if the amount of sulphides present is high, surface run-off can affect negatively the water quality in the lake, although tis effect needs to be assessed carefully.

To quantitatively approach pit lake formation and water quality, preliminary conceptual models are typically developed by: 1) compiling all available data (geologic, mineralogical, climatic, potentiometric, hydraulic testing, etc.); 2) evaluating the data to determine aquifer geometries, hydraulic boundaries, hydraulic parameters, groundwater movement, geochemical processes and other variables of interest; and 3) integrating this information into one or more working hypotheses that characterize the system.

Numerical simulations allow the validation of the conceptual models, as well as the quantification of the predicted effects on the pit lake, such as inflow and outflow rates, water quality and their dependency with time. To model this groundwater flow-lake system some specific modules as PITLAKE, LAKE, LAK2 (Moreno and Sinton, 2002) have been created for MODFLOW.

In this paper we will simulate this transient pit lake generation using COMSOL Multiphysics® (COMSOL, 2012). COMSOL provides generic partial differential equation (PDE) solvers and Algebraic Differential Equations (ADE) that are robust in handling coupled equations. COMSOL has developed several modules helpful for hydrologic applications, e.g., the Subsurface flow modules (COMSOL, 2012). However, singular implementations as the pit lake generation must be explicitly user defined. The geochemical processes are implemented with the PHREEQC code (Parkhurst and Appelo, 2013), which is coupled with COMSOL by means of iCP, a Java interface (Nardi et al., 2014).

METHODOLOGY

Groundwater system

The groundwater system is described by the flow equation (Bear, 1979), (nomenclature for all formulas can be found at the end of this publication):

$$S_e \frac{\partial p}{\partial t} = -\nabla q + Q \tag{1}$$

where the Darcy's flow (q) can be expressed by Darcy's law:

$$q = -K\left(\nabla p - \rho g\right) \tag{2}$$

Figure 1 shows a sketch of the hydrogeological system in the problem of interest.

The chemical part of the system is calculated through the code PHREEQC. One of the main aspects is related to the penetration depth of atmospheric oxygen ($10^{-0.67}$ bars partial pressure) into the rock in the unsaturated region, allowing the water to equilibrate with this oxygen pressure. In this zone sulphide oxidation can occur, so the primary minerals able to react are considered in the system allowing their dissolution following a kinetic rate. Secondary minerals are allowed to precipitate if they become supersaturated. Aqueous speciation is specifically considered in the code. Other geochemical processes such as sorption, cation exchange or solid solution precipitation can also be included in the calculations if needed. One important aspect is that mineral distribution in the rocks

around the pit is not uniform. Therefore, based on geochemical data and block model the mineral distribution in the system can be defined (Figure 2), allowing the definition of different mineral zones depending on their mineral content.

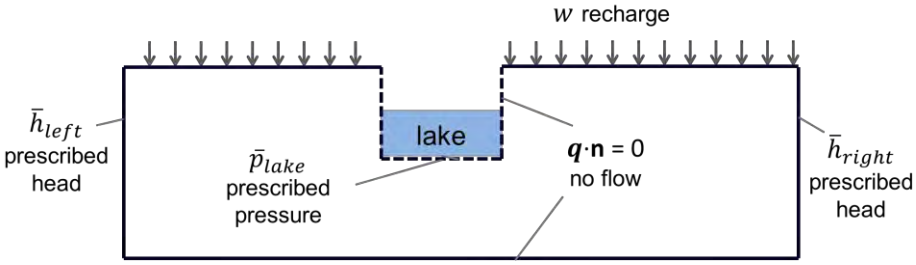

Figure 1 Sketch of the hydrogeological system in a synthetic problem

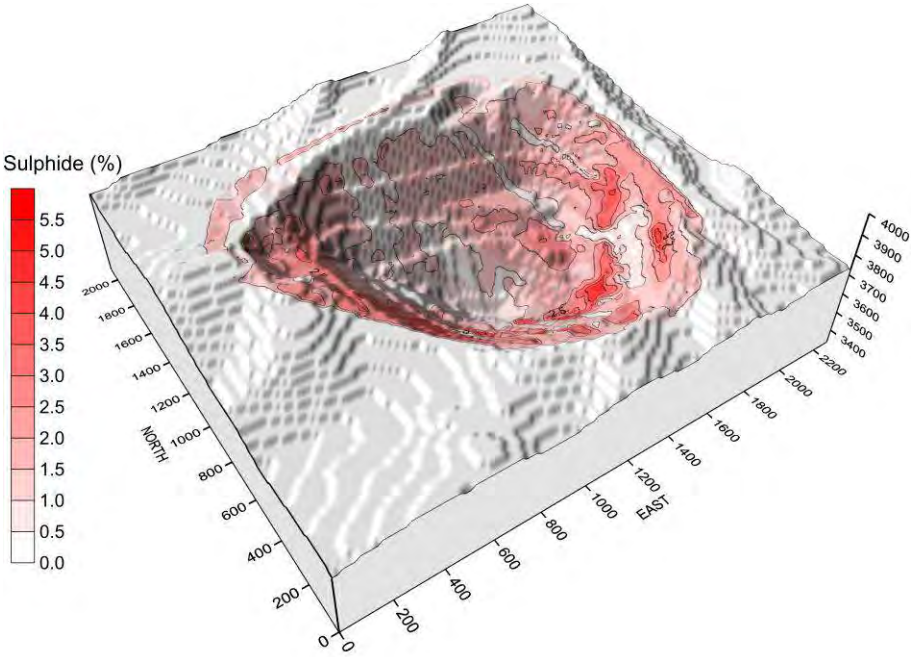

Figure 2 Sulphide distribution in the wall of a final open pit

Lake system

The volume water balance in the lake is described by:

$$\frac{d\left(V_{lake}\right)}{dt} = Q_{aq} - Q_{ev} + Q_r \tag{3}$$

The net groundwater flow rate from the aquifer to the lake is expressed by:

$$Q_{aq} = \int_{A_{\min}} \left(q \cdot n\right) dA \tag{4}$$

The evaporation outflow rate is calculated as:

$$Q_{ev} = E \cdot A_{lake} \tag{5}$$

The rain inflow rate is calculated as:

$$Q_r = w \cdot A_{lake} \tag{6}$$

Note that for simplicity here we only consider the rain that impacts straightforward to the lake surface, not the total of the lake hydrologic basin, but the model could also handle this condition with minor changes. Figure 3 shows the sketch of the lake system analysed in this problem.

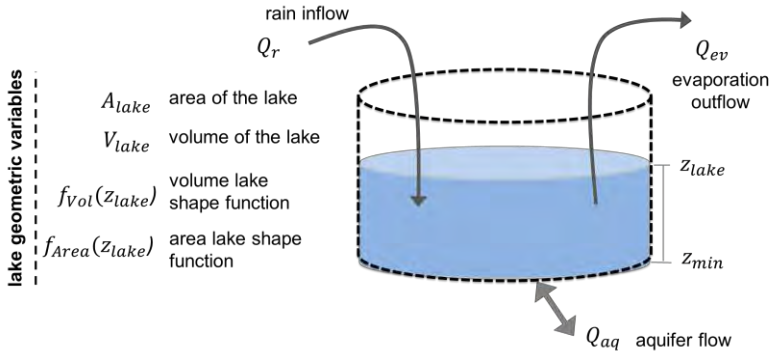

Figure 3 Sketch of the lake system in a synthetic problem

As in the case of the groundwater system, the interaction between lake water and mineral zones in the pit walls can occur. In this case the reactions are limited to the water in contact with the pit wall and sulphide oxidation is restricted to the near surface zone, where water with enough oxygen dissolved can be found. In addition to secondary minerals precipitated due to the water – rock interaction, they can also precipitate near the surface due to evaporation processes. However, this effect has not been implemented yet.

Analysis of the coupling used between underground and surface water

The groundwater and the lake system are coupled in both directions by the following terms (Figure 4):

- Equation 4 couples the lake system with the groundwater by means of the aquifer flow rate.
- The underground system is coupled by the Dirichlet boundary condition applied at the bottom of the lake,

$$\bar{p}_{lake} = \rho g z_{lake} \tag{7}$$

The natural evolution of the system tends to a steady state situation where the lake level is constant and the groundwater inflow rate is equal to the evaporation rate (Figure 5).

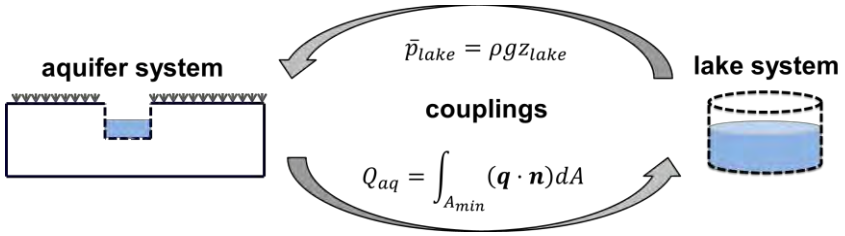

Figure 4 Couplings between the aquifer and the lake system

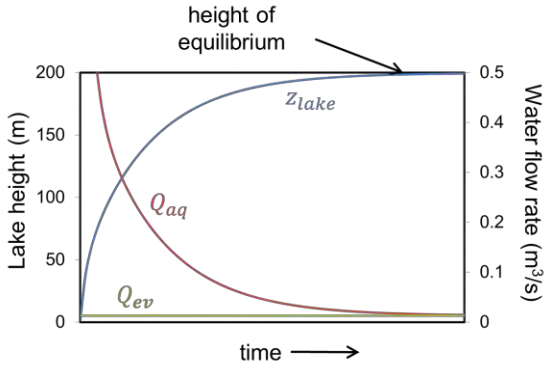

Figure 5 Expected behaviour of the system

This coupled problem has been solved by performing a Picard approach, solving the lake and the aquifer system iteratively until the solution has converged. The nonlinear system of equations of the lake has been solved by using a Newton-Raphson algorithm.

APPLICATION CASE

A pit lake generation in an open pit mine has been simulated using the abovementioned equation system. The mine, located in a temperate climate area, stopped the dewatering at the beginning of the 2000. Before that, the maximum dewatering flow rate was about 20 l/s.

The mine is placed onto a natural water divide and the topography has a gentle slope to both sides. The geology consists on a fractured crystalline rock with a significant alteration zone in the uppermost part. This shallow part formed mainly by sand, has a thickness of a few meters and constitutes the main aquifer (Figure 6).

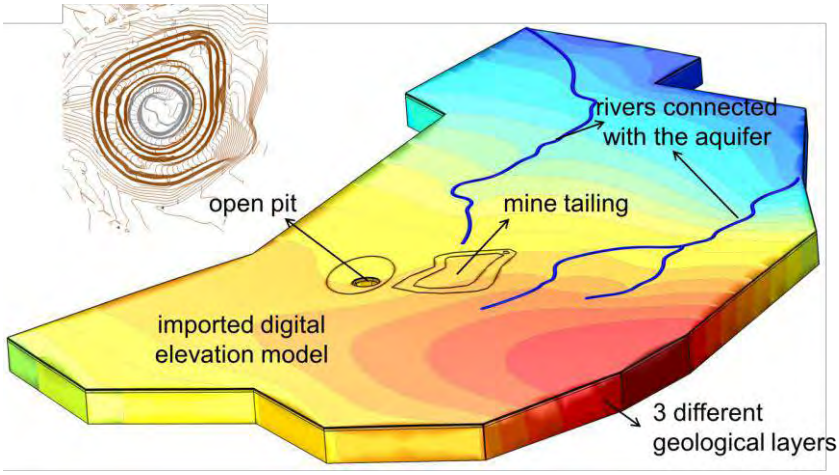

Figure 6 Hydraulic head distribution

Streams and creeks occur in the lowest areas. These streams flow permanently and have been set as fixed head (Dirichlet) boundary condition. Internal streams are ephemeral and they have been modelled by a mixed flow (Cauchy) condition. The upstream boundary, the highest one, has been considered as a prescribed head boundary, using available piezometric data. Remaining boundaries are considered impervious (no flow Neumann condition). Water recharge of 150 mm/y is prescribed on the top boundary, to account for infiltration of rainwater.

The final pit wall has been divided in geoenvironmental units (GEUs) according to the mineral contents, especially sulphides, and their geochemical behaviour based on previous geochemical tests (Table 1 and Figure 7). The primary minerals have been considered to dissolve following a kinetic rate. The reactive surface area of these minerals has been calculated based on rock porosity and assuming that water flows through fractures with a mean aperture of 0.02 mm. In this way, the rock surface in contact with a litre of water has been calculated, and then distributed between the different minerals according to their relative amount in the rock (Table 7). Secondary minerals are allowed to precipitate when they become supersaturated both in the rock (groundwater system) and in the lake (lake system). Other processes can be implemented, such as sorption or cation exchange, but they have not been considered in this case. In addition, the possibility of considering stratification of lake water due to ionic strength and temperature has not been considered. According to the COMSOL capabilities, it is possible to include this process in the model, but it has not tested yet.

Modelling stages were the following:

- Steady state flow model to simulate the conditions at the end of the period of activity of the mine. In this phase, the hydrodynamic parameters have been adjusted to fit site observations: the pumping dewatering rate and piezometer levels. During this stage the lake system is not active and a fixed head equals to the topographic value (zero pressure condition) has been considered at the bottom of the open pit.
- Transient model. The result of the steady state model of the previous stage has been used as initial conditions. At this stage the full system (lake and groundwater) is accounted to simulate the open pit lake generation.

In both stages the chemical composition of lake water depends on the geochemical processes occurring in:

- Pit walls: interaction of groundwater with defined GEUs; and
- Lake: water resulting from pit wall seepage and mixing with already existing lake water and rainwater, plus effects of evaporation.

Table 1 Mineral composition of the GEUs defined for the pit walls.

Minerals (wt %)	GEU 1	GEU 2	GEU 3	GEU 4
Pyrite	0.1	0.5	2.0	5.5
Chalcopyrite	0.0	0.02	0.1	0.7
Arsenopyrite	0.0	0.01	0.05	0.1
Sphalerite	0.0	0.01	0.03	0.2
Fe(III) oxides	0.1	0.5	0.5	2.5
Quartz	57	56	58	55
K-Feldspar	20	17	12	16
Biotite	0.8	0.8	0,5	0.8
Clay minerals	21	25	26	19

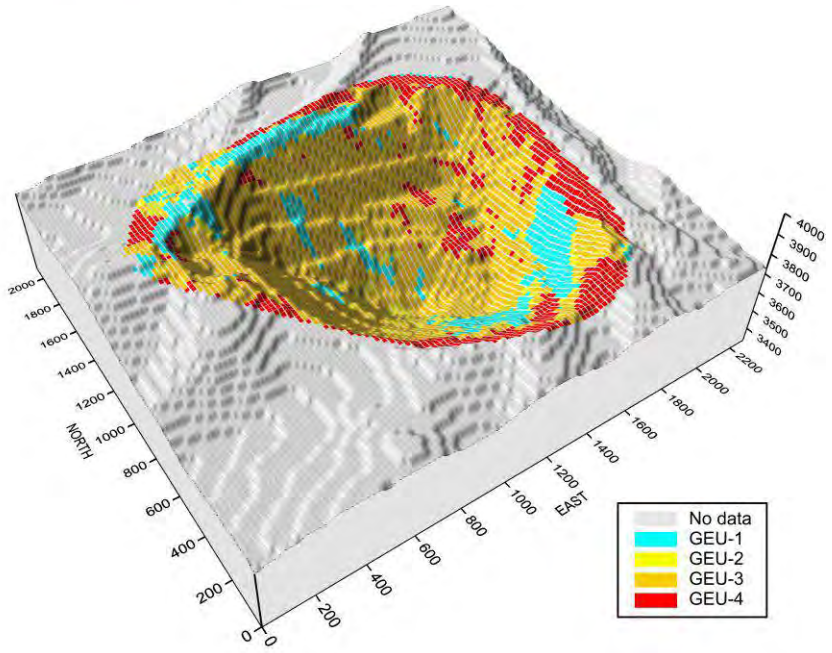

Figure 7 Distribution of geoenvironmental units (GEUs) in the final pit walls.

The domain has been meshed by means of nearly 700.000 tetrahedral quadratic elements. To improve the time and the accuracy of the non-linear calculation process the time steps and numerical convergence parameters has been adjusted for the transient simulation. In terms of chemical composition, it can be seen (Figure 9), that for the first 10 years of evolution (up to present) a major impact is not expected. However, after this time, it is expected that lake water became gradually more and more acidic and with higher metal concentrations.

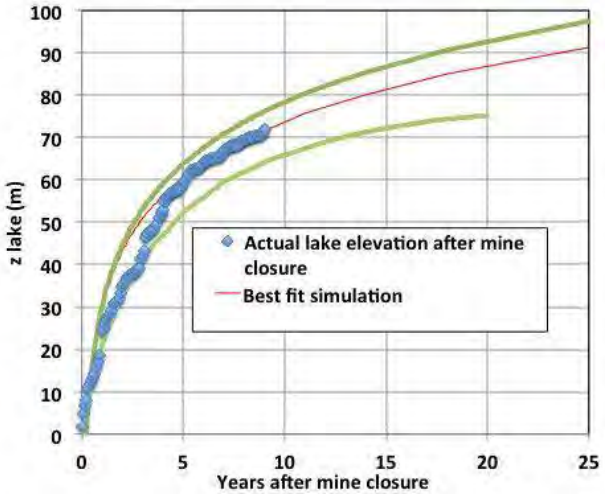

Figure 8 Sensitivity analysis (green lines) has shown permeability and storativity as most critical parameters for an accurate prediction

The mine operation counts with about 10 years of observation data available from the beginning of water rise in the open pit. These data have been used to calibrate the model and the best fit obtained reproduces satisfactorily the growth of the lake. A sensitivity analysis showed that the

response of lake level rise is very sensitive to the hydraulic parameters of the aquifer, to the recharge and evaporation rates and to open pit geometry (Figure 8).

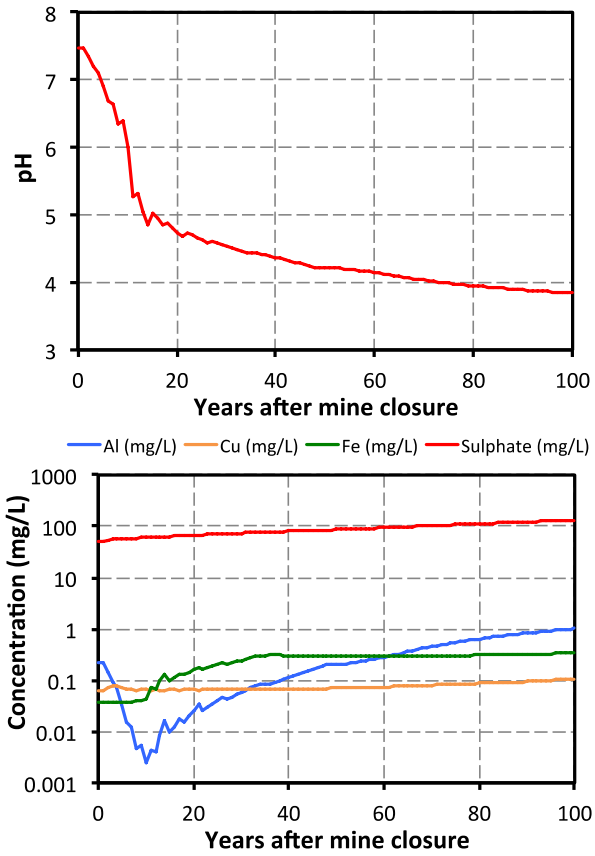

Figure 9 Predicted chemical evolution of the lake water.

For this particular mine, the computed results allows to conclude that at the final stages the lake will be a "flow-through" lake and also will eventually generate a stream through a spillway. All these results are very important for the management of effluents as they may be affected by old mining activities and may affect the environment.

CONCLUSION

The pit lake dynamics and quality can be modelled by the groundwater and lake coupled system developed in this work, as well as coupling hydrologic and geochmemistry processes. This system has been used in a real case and it reproduces satisfactorily the growth of the lake according the available data and predicts present and future water lake composition.

One of the most powerful aspects of the proposed formulation is its flexibility. The developed simulator admits all kind of open pit geometries since it is generalized for area and volume lake shape functions. In addition, other sources and sinks (even nonlinear ones) can be added easily in the lake water balance.

Important information that can be predicted by using this model is:

- The flow rate for dewatering and the lake height after closure,
- the time to generate a creek (if any) and its flow

- the lake and groundwater flow relationship: flow- through or terminal.
- the lake water composition, and its expected evolution with time.

The model presented in this paper constitutes a powerful pit lake prediction, especially when the environmental conditions claim for high accuracy.

NOMENCLATURE

A_{lake}	area of the lake (m^2)
A_{min}	minimum area of the lake (m^2)
E	evaporation rate ($m \cdot s^{-1}$)
g	gravity vector ($m \cdot s^{-2}$)
K	hydraulic conductivity tensor ($m \cdot s^{-1}$)
p	liquid pressure (Pa)
Q	source term ($m^3 \cdot s^{-1}$)
Q_{aq}	flow rate to the lake from groundwater ($m^3 \cdot s^{-1}$)
Q_{ev}	evaporation rate ($m^3 \cdot s^{-1}$)
Q_r	rain inflow rate ($m^3 \cdot s^{-1}$)
q	Darcy's flow ($m^3 \cdot m^{-2} \cdot s^{-1}$)
S_e	specific storage (m^{-1})
V_{lake}	Volume of the lake (m^3)
w	rain rate ($m \cdot s^{-1}$)
ρ	liquid density ($kg \cdot m^{-3}$)

ABSTRACT

Coal mine pit lakes may form at mine closure when voids formed through mining extractions have extended below groundwater. Internationally, acid and metalliferous drainage (AMD) is a common problem for coal pit lake water quality. Even if not acidic, pit lake water quality may become degraded gradually through dissolution of contaminants and evapoconcentration.

Contaminated coal pit lake waters can present significant risk to both surrounding and regional communities and natural environments. Pit lake waters may discharge into surface and groundwater; or directly present risks to wildlife, stock and human end users.

Riverine flow-through is increasingly being proposed to mitigate pit lake water contamination. This paper presents the motivation for, and key processes and considerations regarding a flow-through final lake hydrology. International case studies as precedent and lessons for future application are also described from a review of literature describing pit lakes that use or propose surface water inflows and discharge as key components of their closure and pit lake management designs.

Chemical and biological processes such as dilution, absorption and flocculation and sedimentation reduce solute loads from river and lake. We conclude that riverine lake flow-through may often be a valid mine closure strategy for pit lakes with poor water quality. Although, we caution that maintenance of existing riverine system values must be maintained first and foremost, we further suggest that decant river water quality may, in some circumstances, be improved; notably in examples of meso-eutrophic river waters flowing through slightly acidic pit lakes.

Flow-through closure proposals for coal pit lakes must be scientifically justifiable and follow a risk assessment approach. Due to the high-uncertainty, biotic and physico-chemical attributes of both upper and lower river and lake should be well monitored. Monitoring should directly feed into an adaptive management framework approved by key stakeholders.

Keywords: pit lake, mine closure, flow-through, AMD, salinity

INTRODUCTION

Due to operational and regulatory practicalities, coal pit lakes will continue to be common legacies of many mine lease relinquishments. Weathering of potentially acid forming (PAF) materials in pit lake catchments, such as pit wall rock, waste rock dumps, and tailings storage facilities, may produce acid and metalliferous drainage (AMD) that reports to rivers and pit lakes (Younger, 2002). AMD-degraded water quality in pit lakes may reduce regional environmental values and may present practically perpetual risks to surrounding communities and environmental values (McCullough & Lund, 2006; Hinwood *et al.*, 2012). As a result, mine closure guidelines and regulations increasingly require low risk long-term to surrounding ecological and social environments for closure practices to be acceptable (McCullough *et al.*, 2009a). Many currently operating or planned mines do not have available options for AMD avoidance (e.g. Wisotzky (2013) in place for a variety of historical and contemporary socio-economic and regulatory reasons (Hilson & Haselip, 2004).

Increasingly, beneficial end uses are also required for pit lakes either through regulatory requirements, or through other stakeholder aspirations such as communities, or interest or non-governmental organisations (NGOs) (Swanson, 2011). As a result, sustainable pit lake management aims to minimise short- and long-term pit lake liabilities and maximise short- and long-term pit lake opportunities (McCullough & Lund, 2006). Such management may be very costly and difficult to achieve in remote mining regions (Kumar *et al.*, 2011).

The hydrological setting of lakes is well known as a key factor for water quality (Straskraba, 1999; Kratz *et al.*, 2006). Furthermore, lakes are usually storage elements in river networks, reactors transforming many of water constituents and sinks for particles and dissolved water constituents, but may act temporarily also as source. Accordingly, design and management of the connection of pit lakes to river systems and to the groundwater have been applied as management approach for controlling water quality both in pit lakes and in rivers e.g., (Schultze *et al.* (2011)).

This review presents the findings of a search for literature describing coal pit lakes that used surface water inflows and discharge as key components of their closure and pit lake management designs. The experiences documented in the found literature are summarised, evaluated and generalised.

PIT LAKE HYDROLOGY

The pit lake equilibrium water balance and final depth is defined by the net effect of all its hydrologic components. For example, groundwater intrusion and seepage, catchment and direct surface water inputs and evaporative losses (McCullough *et al.*, 2013b). This net effect will determine whether the final pit lake water balance is terminal as an evaporative sink (Figure 1a), source (surcharged) (Figure 1b) and perched above local groundwater levels or flow-through (Figure 1c,d) and directly to ground and surface waters. Terminal hydrology is most common for pit lakes in net negative rainfall areas due to their constrained catchment size relative to natural lakes (Niccoli, 2009) and surcharge or flow-through for lakes in net positive areas. However, in climates of marked rainfall seasonality, pit lakes may even demonstrate a combination of terminal and flow-through system depending on season.

Flow-through pit lakes distinctly show discharge of water to the greater catchment. These pit lakes have a relatively net nil water balance where water entering them exits as either a through-flow

groundwater (Figure 1c) hydrogeology (may or may not be expressed as surface water down-gradient) or a flow-through surface water hydrology (Figure 1d).

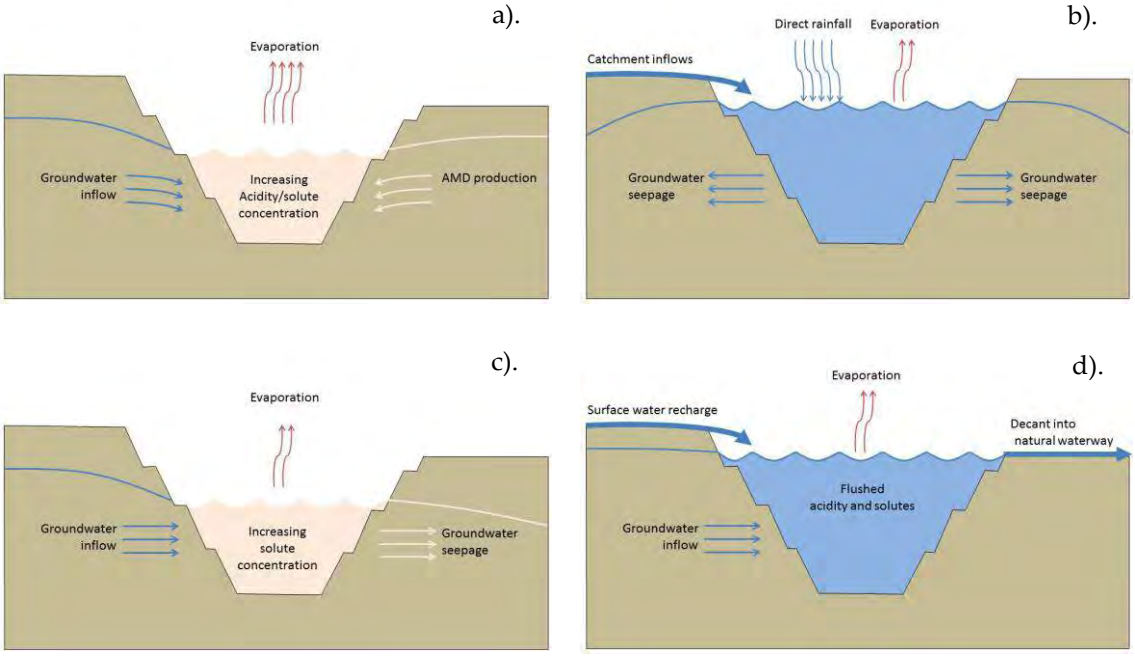

Figure 1: Conceptual equilibrium hydrogeological regimes for pit lakes. a) evaporative terminal sink, b) surcharged lake, c) groundwater through-flow system, d) surface water flow-through system

ENGINEERED PIT LAKE FLOW-THROUGH

There are a number of reasons for engineering a permanent diversion of river or other surface water into a pit lake, mostly related to maintaining or improving pit lake water quality:

a) because a surface drainage system was originally diverted around the pit void location and it is desirable that the system is diverted back into its 'natural' channel for mine closure for cultural or similar motivations;

b) the pit lake is proposed as a water reservoir, or for retaining and buffering high flows as flood protection for downstream;

c) higher quality (e.g., less acidic, lower salinity) river water is required to maintain a minimum pit lake water level or minimum water quality, or, conversely;

d) the pit lake is proposed as a treatment facility to improve water quality of the river.

Surface water flow-through processes

Pit lake water balance largely determines whether lake water quality reach equilibrium or continues to evolve over time. A pit lake water balance with evaporation as the primary water loss function will typically lead to increases in solute concentrations compared to a flow-through system

where incoming water can continue to replenish and dilute and solute concentration effects that are occurring/have occurred in previous dryer seasons (Niccoli, 2009).

For lakes affected by AMD, lake acidification can continue after initial rapid filling and neutralisation of acidity by alkaline waters e.g., from a river diversion. The major sources of both acidity and alkalinity are surface and, groundwater inflows, biogeochemical alkalinity generation inside the pit lake including its sediment and elution of side walls and shore material and final pH will reflect the net result of all geochemical contributions (Müller *et al*., 2011).

Solute and acidity concentrations are usually higher in pit lakes containing AMD (Banks *et al*., 1997) than in river waters (Meybeck, 2005). Consequently, flow-through by river water typically will result in dilution (likely to be insignificant for acidity, but potentially significant for salinity) and acidity neutralisation (which may be significant).

The reaction of river water bicarbonate with pit lake acidity is the most important chemical reaction removing lake acidification. It is accompanied by the precipitation of dissolved iron and aluminium as the main contributors to acidity. The success of metal removal may be limited since some metals require pH above 8 for removal (e.g., manganese, zinc). However, co-precipitation with iron and aluminium are also important mechanisms of the removal of substances from the lake water during neutralisation and in particular phosphorus and trace metals (Lee *et al.*, 2002; Kopacek *et al.*, 2005).

Acid pit lakes with high phosphorus loadings show increased algal biomass which may then lead to improvements in water quality through phytoremediation (Fyson *et al*., 2006) and sulfate reduction of decaying organic algal cells (Wendt-Potthoff *et al*., 2012). However, Totsche *et al.* (2006) demonstrated that artificial eutrophication, through stimulation of primary production, is limited by phosphorus fixation to iron minerals in the lake sediment. Although Schultze *et al.* (2011) considered the contribution of rapid river filling to phytoremediation to be small, in the case of ongoing lake flushing with river water, the contribution of primary production may become a much more important alkalinity-generating process over longer time scales.

In conclusion, flow-through pit lakes systems can contribute a number of important processes to improve and maintain pit lakes water quality over long-term scales (Table 1).

Table 1: Benefits and risks of flow-through pit lake closure strategy for pit lakes

Pit lake advantages	Limitations / Risks
Dilution of elevated solute concentrations in lake waters e.g., salinity, contaminants	Incoming flows may contribute solutes to the pit lake
Neutralisation of lake acidity by river water alkalinity	
Chelation and sorption of lake metals by river nutrients such as C and P (Fyson *et al.*, 2006; Neil *et al.*, 2009)	River water may introduce contaminants such as nutrients, organic pollutants and/or toxic metals (Klemm *et al.*, 2005)
Import of aquatic organisms through inflowing waters accelerating pit lake colonisation and establishment of a representative aquatic biotic community (Peterka *et al.*, 2011)	Aquatic communities may be riverine species and not representative of proposed lake ecosystems. Pest species may be established in pit lakes due to connectivity (Stich *et al.*, 2009; Kosík *et al.*, 2011)

River water can contribute much needed organic carbon and phosphorus to foodwebs of new pit lakes and especially for acid pit lakes (McCullough *et al.*, 2009b)	Lakes may become eutrophic following excess nutrient imports through river water (Hupfer *et al.*, 1998)
Acidity generation by interaction between lake water and lake sediment may be limited due to a fast accumulation of benthic sediment (Dessouki *et al.*, 2005)	Nutrients may be buried under inorganic sediments or in a monimolimnion and become unavailable (von Sperling & Grandchamp, 2008; McNaughton & Lee, 2010)
Provides nutrients stimulating primary production as an approach for pit lake neutralisation (Tittel & Kamjunke, 2004)	Only likely to be important over longer terms due to phosphorus fixation to iron and aluminium in water column and lake sediments (Kleeberg & Grüneberg, 2005; Kopacek *et al.*, 2005)
Inflows may provide a source of organic material which contributes organic carbon as a substrate for sulphate reduction in the lakes' sediment (Salmon *et al.*, 2008)	Only likely to be important over longer terms as sulfate reduction is a relatively weak alkalinity-generating process (Wendt-Potthoff *et al.*, 2012)
Meromixis may be stabilized (Boehrer & Schultze, 2006) allowing for save burial of hazardous mine waste and treatment of AMD (Pelletier *et al.*, 2009)	Meromixis may result in enrichment of hazardous substances (metals, H_2S, CO_2, methane) in the monimolimnion affecting the entire lake water body in the case of limnic eruption or other reasons for long-term instability of chemical stratification (Sanchez-España *et al.*, 2014)

Since diversion of river water is a substantial impact for the river, respective aspects have to be considered. Beside legal, economic and social aspects (e.g. existing rights for water use) there are also ecological advantages and risks as shown in Table 2.

Table 2: Benefits and risks of flow-through pit lake closure strategy to rivers

Advantages to rivers	**Limitations/risks to rivers**
Decreased suspended and dissolved contaminant loads, especially nutrients (McCullough *et al.*, 2013a)	Decreased pH and alkalinity. Increased solute contaminants such as heavy metals, ammoniacal nitrogen (McCullough *et al.*, 2012)
Extends riverine aquatic habitat	May form physical or chemical migration barrier to movements of aquatic life
Reduced flood incidence and extended base flow duration	Altered hydrological regime reducing flood peaks required for biology and for scouring and shaping river channels
	Reduced overall river flow volume as a result of greater seepage and evaporation

Although water quality in a river may benefit from diversion through pit lakes (Table 2), there may also be substantial risks for the river. They should be avoided by adequate management. Typically, impacts resulting from acidification of pit lakes will not affect the downstream river if flow-through is established following acidic pit lake water neutralisation and the precipitation/co-precipitation of metals. The amount of water diverted from a river into a pit lake can often be best managed by limiting diverted flow to the pit lake. This will depend on the hydrological situation in the river and should be directed to maintaining hydrological patterns downstream as necessary for sustaining river end uses. The barrier function of a pit lake for migrating organisms can be mitigated by

connecting the pit lake via bypasses to the river. This strategy may therefore allow for relatively simple management of flow-through, and, in this way, for balancing positive and negative effects of the flow through approach.

Lowest risk for downstream rivers will be presented when the river is already degraded. For instance, we do not recommend flow-through as leading practice for pit lake closures with high downstream river water quality and end uses. The strategy has worked particularly well in the Lake Kepwari pit lake situation (see EXAMPLES,) as the river channel was able to be maintained in its historical course and river water quality was already degraded (McCullough *et al.*, 2012; McCullough *et al.*, 2013a). This reduced risk of AMD on downstream river values. Similarly, the monitoring period has validated the closure approach.

Poor water quality could affect both the ecological communities that might come into contact with the surface water of the pit lake and the down-gradient groundwater system at flow-through pit lakes (McCullough *et al.*, 2013b). River flow timing such as hydroperiod of when water flow is elevated (or even available in seasonal/ephemeral rivers) may also be important for triggering biological responses such as fish spawning events.

Effects of climate change on flow-through hydrology

Climate is the single most important factor on the hydrologic processes associated with a pit lake (Niccoli, 2009). Changes in climate (e.g., temperature, rainfall, wind, precipitation amount and distribution) will affect the individual hydrologic components over a short period of time whilst ground water inflow responses are generally and ultimately generated from precipitation recharge. Pit lakes with significant interaction with a groundwater system will tend to be buffered against short-term climatic changes, however, long-term climatic changes will still be reflected in ground water inflows over the long-term.

The water balance may be affected so grossly in a dryer climate that reduced pit lake water levels lead to cessation of flow through and lakes then become terminal sinks. In comparison, a wetter climate will most likely result in elevated pit lake water levels leading previously terminal pit lakes to become flow-through to either ground or surface waters. However, it is difficult to make broad statements about how climate changes will affect the status of a pit lake (i.e., if it will change from a flow-through to a terminal pit lake or vice-versa) because climate changes will affect all the components of the hydrologic system. Because of this, the effect on water balance for each pit lake resulting from climate change must be evaluated on a case-by-case basis.

EXAMPLES

There are examples for beneficial application of pit-lake flow-through strategy in different countries. Lake Senftenberg (Germany) was neutralised and kept neutral (Werner *et al.*, 2001). Flushing of pit lakes will be the future strategy for many German pit lakes (Luckner *et al.*, 2013). To reach this goal, the connection of naturally separated river basins is already in practice and is discussed to be extended in Germany in future (Koch *et al.*, 2009). The Muldereservoir, a pit lake in Germany, traps considerable amounts of toxic trace elements (ranging from 16% for zinc to 90% for cadmium) from Elbe River and its tributaries into the North Sea (Zerling *et al.*, 2001; Klemm *et al.*, 2005). Moser and Weisser (2011) reported the successful neutralisation of a pit lake in Austria by diversion of river water. Lake Kepwari and Collie River (Western Australia) form a further example

for the successful application of the flow-through strategy (McCullough *et al.*, 2012; McCullough *et al.*, 2013a).

CONCLUSIONS

Flushing with river water has proved to be a very useful strategy for management of some pit lakes internationally. A fundamental prerequisite for the use of river water and mine water for filling and management of pit lakes is the water availability. Water scarcity may be a limiting factor for flow-through solutions to pit lakes that currently function as terminal lakes due to regional water availability. That is, the applicability of filling and flushing of pit lakes with river water and mine water strongly depends on the climate and the intensity of the use of water downstream the pit lakes. In the case of limited water availability, floods may be the only options for the filling of pit lakes under such arid conditions and this method may be evaluated similar to the practices in Germany. However, the ecological needs of the river system downstream the pit lakes have to be kept in mind, including the flow magnitude and variability of the flow rate under such conditions.

The water quality of the used river water also has to suit the requirements of the planned use of the pit lakes. Otherwise, treatment of the river water, the mine water or the pit lake may be necessary. Of more importance, priority should be given to river water quality and end uses and the maintenance, or improvement, of existing water values (McCullough & Pearce, 2014). River water quality should generally not be presented with risk of degradation by pit lake flow-through, which will limit opportunities to this strategy to pit lakes of early better water quality and/or rivers of relatively lower water quality. Ideally, hydrological and geochemical modelling will precede a trial period of flow-through which then validates the model expectations to stakeholders' satisfaction.

Some pit lakes can also be used as reactors under certain conditions for instance, removing nutrients from river water and in turn precipitating metals from lake water. Nonetheless, hydro-chemical processes will vary between operations and sites based on the specific geological, hydrological and climate characteristic of each lake and its inflow/outflow characteristics. Developing flow-through systems must be based upon reliable data and accurate predictions of water balance and water quality e.g., from deterministic models. Nevertheless, abatement of acidification and salinisation as the import of alkalinity and freshwater, is typically the key driver to use flow-through as a closure strategy for pit lakes.

Nucleation Seeding to Promote Chemical Precipitation of Hardness and Alkalinity from Mine Pit Lakes

Allison Haus and Mehgan Blair
BARR Engineering, USA

ABSTRACT

Several flooded taconite mine pits in northern Minnesota contain circum-neutral water with elevated concentrations of sulfate, hardness (dominated by Mg) and alkalinity, which together contribute to overall total dissolved solids and specific conductivity, and are of increasing local regulatory concern. Two of these mine pit lakes (pit lake "A" and pit lake "B") are meromictic, stratified both thermally and chemically. The deepest and densest water in the pits rarely, if ever, mixes with the overlying, more dilute water. Geochemical modeling suggests that both lakes are increasingly supersaturated with respect to calcite and aragonite with depth; it has been well documented that high concentrations of magnesium can act to kinetically inhibit precipitation of calcium carbonate. Reducing alkalinity and hardness via a passive strategy may be achieved by reducing the barrier to precipitation: nucleation. Nucleation seed crystal precipitation from concentrated bottom waters was initiated via four different processes, including evaporation, heating, lime addition, and salt addition. Precipitated seed crystals were then introduced to more dilute top water while alkalinity and hardness were monitored. Spontaneous precipitation of hardness and alkalinity was successfully achieved by heating deep pit water and exsolution of CO_2. This process is hypothesized to be responsible for the "white bathtub ring" that edges the pit lakes.

Keywords: hardness, carbonate, alkalinity, nucleation

INTRODUCTION

In some former taconite (iron ore) mine pits on the Mesabi Iron Range in northern Minnesota, oxidation products from trace sulfides are neutralized by relatively abundant carbonates, including siderite and ankerite. The resulting pit lake water quality has circum-neutral pH, but can contain elevated concentrations of sulfate, hardness and alkalinity. Together, these elevated salt concentrations increase total dissolved solids (TDS) and specific conductance, and are of increasing local regulatory concern. Sulfate, specifically, is strongly regulated in the state of Minnesota, where the water quality standard in water used for wild rice production is as low as 10 milligrams per liter (mg/L). The potential may exist to passively reduce salt concentrations by pairing strategies that promote sulfate-reducing bacteria (SRB) to reduce sulfate with strategies that reduce alkalinity and hardness. Non-mechanical strategies that result in reductions in alkalinity and hardness by encouraging chemical precipitation are explored herein.

BACKGROUND

Hardness and alkalinity in wastewater is typically removed via active processes such as ion exchange, membrane separation or chemical precipitation. Chemical precipitation occurs when the solubility product of calcite increases such that supersaturation occurs (Nancollas and Reddy, 1971). It may be possible to induce chemical precipitation of calcium carbonate in a relatively passive way in mine pit lakes by modulating solution parameters that directly influence saturation state.

The solubility expression and corresponding solubility product for calcite can be represented as:

$$CaCO_3 \leftrightarrow Ca^{2+} + CO_3^{2-} \quad K_{SP,\,calcite} = 10^{-8.48}$$

The driving force, or associated change in Gibbs free energy, of the calcite precipitation reaction is determined by the solubility constant of calcite (K_{SP}) and the ion activity product Q:

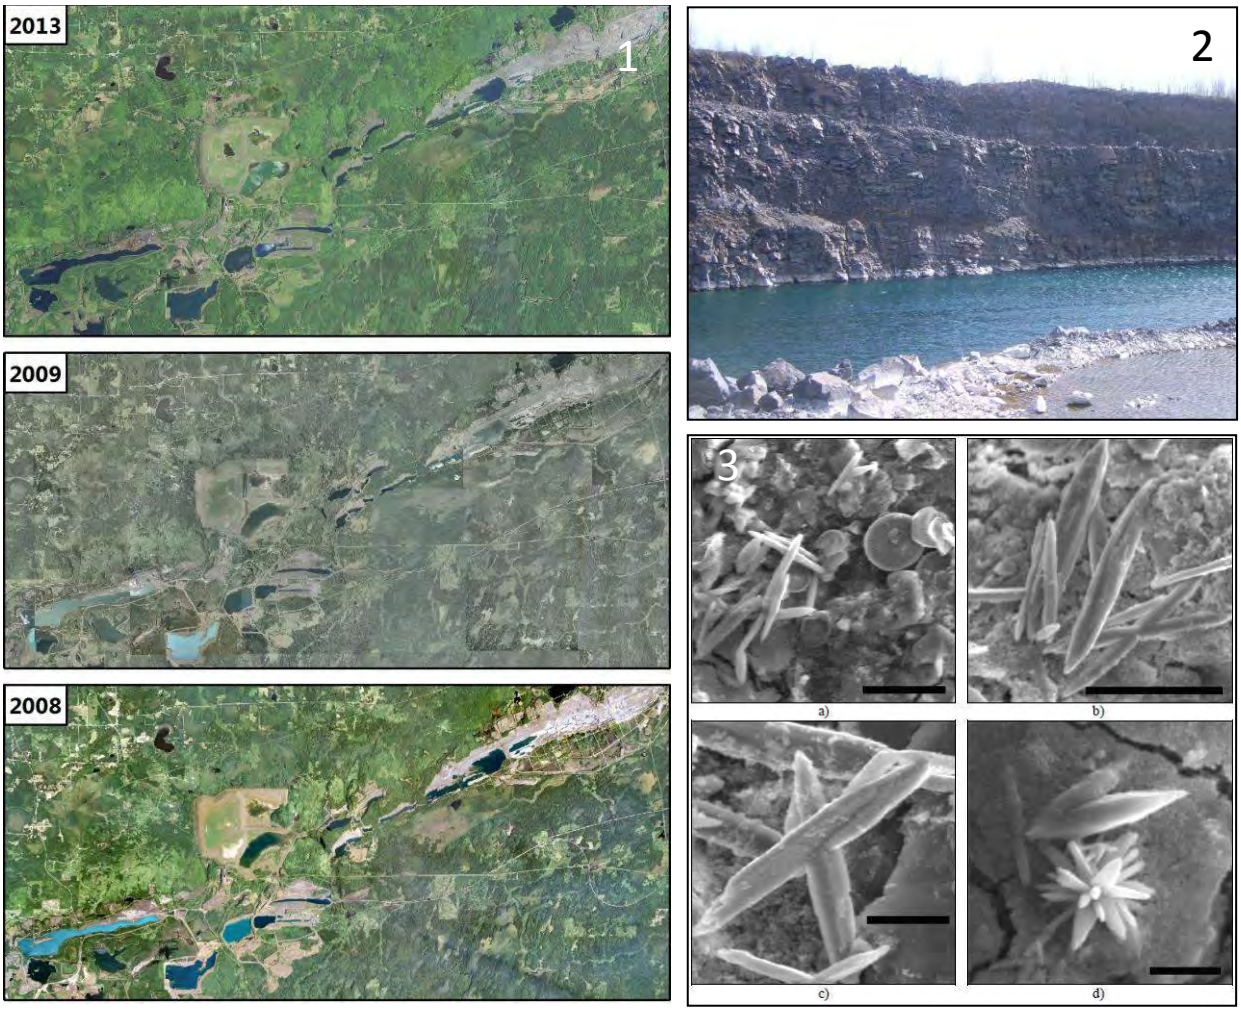
$$\Delta G = \Delta G^0 + RT \log (Q/ K_{SP}),$$

where R is the gas constant (8.314 J/mol K), and T is the temperature in Kelvin. The ion activity product, Q, is the product of the real concentrations of Ca and CO_3^{2-} in solution. When Q is greater than the K_{sp}, the solution is supersaturated, and precipitation of calcium carbonate is thermodynamically favorable. Several solution parameters can act to modify saturation state by increasing the carbonate concentration. For example, as pH increases, the carbonate equilibrium shifts to the right, meaning carbonate (CO_3^{2-}) concentrations increase, as does saturation state of calcite. Similarly, CO_2 influences saturation of calcite because of its control on pH. Finally, carbonates demonstrate retrograde solubility: as temperature increases, they are more likely to precipitate. Taking advantage of these relationships may facilitate passive chemical precipitation.

The water quality at several northern Minnesota taconite mine pit lakes is supersaturated with respect to carbonates, but there may not be adequate "driving force" to overcome the barrier to nucleation (Teng et al, 2000). The barrier to precipitation may be removed when a nucleation seed is presented to solution, thereby promoting precipitation in systems with lower driving force. This type of "nucleation seeding" strategy may result in alkalinity and hardness reductions in systems supersaturated with respect to carbonates. A form of this strategy has been used successfully to remove metals and TDS and to regulate pH for more than a decade at a 20-acre mine pit lake in Duck Town, Tennessee (Chermak, 2004). The pit lake water has elevated acidity and dissolved metals and is treated by adding lime to water highly concentrated in metals and TDS, such that nano-particulate iron-oxides begin to form. This water is then introduced to the more dilute pit lake, and metals within the pit lake water precipitate on the iron-oxide particulates, which then settle out at the bottom of the pit lake as sludge.

Precipitation of metals was kinetically limited in the Duck Town mine pit lake by a barrier to nucleation. Once the pit lake water was seeded with crystals that provided surface area, metals precipitated out. The following suggests that similar treatment might work at several of the flooded taconite mine pits to remove alkalinity and hardness:

- Water with the highest TDS occurs at the bottom of stratified pit lakes.
- Preliminary geochemical modeling of the quality of water in the mine pit lakes indicates that the water is supersaturated with respect to carbonates, both calcite and aragonite.
- Aragonite ($CaCO_3$) has been identified by X-ray diffraction (XRD) as an authigenic precipitate at the bottom of one of the mine pit lakes, and in the adjacent rock stockpiles.
- Occasional spontaneous formation of carbonates may be responsible for observed phenomenon within the pit lakes: the presence of a white "bathtub ring" surrounding several of the lakes, and periodic "whitings", when pit lake water color, which is normally dark blue, changes to a bright turquoise color.



Figures 1, 2, 3 **1)** Aerial images of pit lakes during summer months (different years) capture color of individual lakes, normally dark blue, changing to turquoise during "whitings". Width of images above are approximately 40 km**. 2)** Top right picture shows Pit Lake "A", including the remnant highwall (approximately 37 meters high) and a white "bathtub ring" in foreground**. 3)** SEM Micrographs of aragonite crystals in a taconite mine pit lake sediment sample. a) and b) show single blades and clusters. c) a twinned crystal. d) single blades and a radiating cluster of aragonite crystals. SEM images- scale bar: a) 1,500X; 20 μm scale b) 4,000X; 12.5 μm scale c) 6,000X 5 μm scale; d) 3,500X; 10 μm scale.

We investigated, through modeling and bench-testing, whether it is possible to induce chemical precipitation of carbonates, thereby decreasing concentrations of hardness, alkalinity, and, by extension, TDS and specific conductivity from the pit lake water, with little mechanical input.

METHODOLOGY

The investigation consisted of two phases: experimental modeling in the geochemical software Geochemist's Workbench (Bethke, 2008) (GWB) and laboratory testing to explore a) if precipitation of $CaCO_3^{2-}$ from very concentrated pit water can be promoted, and, if successful, b) whether

alkalinity and hardness removal from the more dilute pit water will occur through precipitation onto seed crystals.

Water from Pit Lake "A" was collected from two depths (1 and 20 meters) corresponding to the two stratified regions of the meromictic lake: the mixolimnion, the uppermost portion of the water column that behaves as a holomictic or normally mixing lake, and the monimolimnion, or lower isolated portion of the lake. The monimolimnion is generally colder, more anoxic and saltier than the upper water column. The location of the chemocline was determined in the field, based on the temperature and salinity gradient. Chemical analyses of these water samples were conducted and the data are presented in Table 1.

Table 1 Initial Water Chemistry

Parameter	**Units**	**Pit A Deep-20 m**	**Pit A Shallow-1 m**
Calcium	mg/L	165	60.5
Iron		0.196	ND
Magnesium		293	171
Manganese		14.1	0.0211
Alkalinity, bicarb		474	205
TDS		2360	1230
Sulfate		1370	732
Temperature	°C	6.6	19.3
Conductivity	µS/cm	1870	1420
pH		7.52	8.7
Calcite Saturation	Log Q/K_{sp}	0.4198	1.0889
Aragonite Saturation	Log Q/K_{sp}	0.2844	0.9443

Phase 1: Reaction modeling in GWB

GWB was used to model reactions aimed at increasing saturation state with respect to calcium carbonate phases, based on the Pit Lake chemistry data (Table 1). The thermodynamic constraints

for mineral reactions were based on the Lawrence Livermore National Laboratory database provided within the GWB platform. Calculations of saturation were based on equilibrium state. The system was assumed open to atmosphere and the CO_2 endpoint was modeled at atmosphere (log $P_{CO2} = 10^{-3.4}$).

Phase 2: a. Promoting formation of calcium carbonate

In the laboratory, several clean jars (rinsed once with dilute acid, then 3 times with tap water, then 3 times with DI water) were filled with 500 mL of deep pit water (Pit A Deep – 20 m) and left open to atmosphere (some evaporation occurred). Carbonate precipitation was encouraged from concentrated pit water by 1) evaporation over three days and heating to room temperature (20 °C) (control), or 2) heating to 45 C. In the heated trials, jars were placed atop a hot plate. For the control, they were placed simply on the bench top. Neither trial was stirred. All of the tests were repeated 5 times, with concurring results.

b. Measuring removal of hardness and alkalinity through continued precipitation

When seed crystal formation was observed from the deep pit water trials, the precipitate was harvested using a screen sieve. Two quantities of this material was then introduced into 500 mL (each) of the more dilute shallow pit water: 1) 0.01 mol, and 2) 0.02 mol seed crystal (determined by dry mass) harvested from the deep pit water experiments. In comparable trials, small quantities of other materials that had the potential to either increase saturation state, or to act as seed crystals, were added to 500 mL (each) of shallow pit water: 1) 0.01 mol ground lime, and 2) 0.03 mol of commercially available fine-grained aragonite. These four trials were compared to a control trial which was subjected to evaporation and heating to room temperature (20 C).

During each trial, a multi-parameter water quality meter (YSI 556 Multi-Probe Meter) was used to measure specific conductivity, pH, dissolved oxygen, and oxidation-reduction potential. Alkalinity was measured using an alkalinity titration kit. At the conclusion of the experiments, six samples were selected for chemical analysis of hardness (Mg and Ca) and alkalinity. In the lime trial, where sludge formed at the bottom, the supernatant water was decanted off the top of the solid and sent for analysis. In trials where calcite crystals formed at the top, water for analysis was collected from below the floating crystals.

RESULTS AND DISCUSSION

The deep water (Pit A Deep – 20m) contained higher alkalinity, more dissolved constituents, and had a higher conductivity and TDS than the shallow pit water (Pit A Shallow – 1m), as shown on Table 1. Despite containing more than more than twice the concentration of alkalinity and approximately 2.5 times as much calcium as the shallow water, the geochemical equilibrium model predicted that the saturation state of calcite was lower in the deep pit water than it was in the shallow pit water. The solubility of CO_2 increased with decreasing temperatures; more CO_2 was

dissolved and the pH was lower in the deep pit water relative to the shallow pit water. Both temperature and pH exerted a strong influence on calcite saturation state (Figure 4).

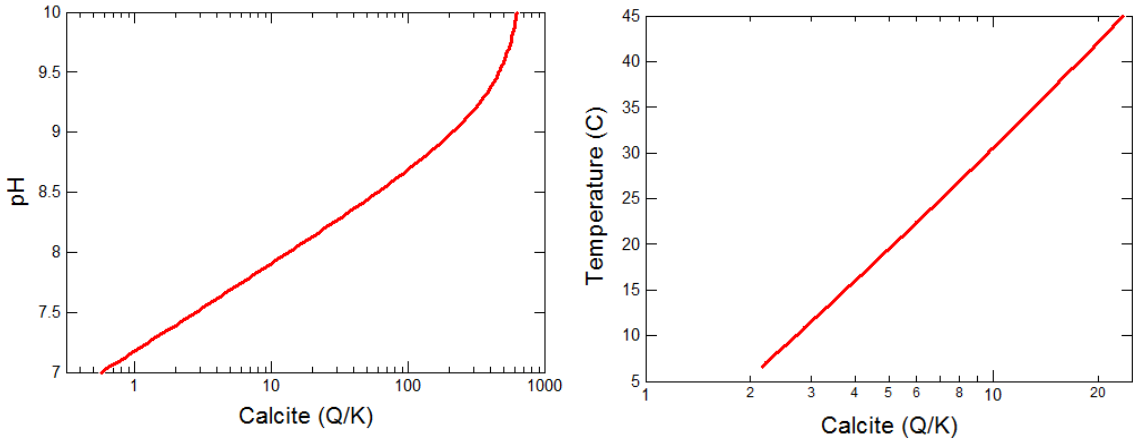


Figure 4 Predicted saturation state of Pit A Deep – 20 m water, as a function of A) pH, and B) temperature (°C).

The results of field and lab measurements from the laboratory experiments are presented in Table 2. Spontaneous precipitation of carbonate occurred with every test of Pit A Deep water (Figure 5). In the control experiment, as water equilibrated with atmospheric CO_2 and room temperature (~20 C), saturation state increased with increasing temperature and pH until precipitation of carbonate occurred after three days. Precipitation occurred more rapidly when Pit A Deep water was heated further: after four hours heating to 45 C. The increase in conductivity in the Pit A Deep water also reflected this temperature increase; conductivity of water increases by about 2-3% with every degree C. The precipitate formed at the water surface, coalesced into larger clumps with time (or application of heat), and settled to the bottom of water column with time (~2-3 days after formation in the control).

Little change in water quality was observed when carbonate seed crystals, precipitated from the Pit A Deep water, were introduced to the Pit A Shallow water. For example, conductivity remained fairly constant across almost all tests. Significant reductions in hardness, alkalinity, and specific conductivity were observed only in the lime addition test, which also experienced coincident increase in pH increase and saturation state. The formation of sludge at the bottom of the glass is also consistent with carbonate precipitation after the addition of lime.

Figure 5 A) Precipitate that formed from the deep pit water control over a period of 3 days. B) Groups of precipitated crystals that occurred at the surface during heating of the deep pit water.

Table 2 Experimental Results: Laboratory and Field Measurements, and Model Predictions

		Pit A Deep - 20 m			Pit A Shallow - 1 m					
Test	**Units**	**Start**	**Control**	**Heat to 45 C**	**Start**	**Control**	**0.01 mol lime**	**.03 mol Arag**	**.01 mol Seeds**	**.02 mol Seeds**
Calcium	mg/L	165	113	--	60.5	60.8	26.2	60	63.3	64.2

pH		7.52	8.43	8.02	8.7	8.53	9.08	8.4	8.39	8.4
Field alkalinity	mg/L as $CaCO_3$	860	780	640	540	520	280	400	400	480
Precipitate Evident		none	yes, see fig 3A	yes, fig 3B	no	no	sludge	few at surface	no	no
Calcite Saturation	Log Q/K	0.33	0.96	1.93	1.01	0.79	2.03	1.63	1.16	1.51
Aragonite Saturation	Log Q/K	0.19	0.82	1.79	0.87	0.65	1.89	1.48	1.30	1.37

Experimental results were modeled in GWB, and predicted saturation state post-reaction is plotted in Figure 6. The results indicate that precipitation of calcium carbonate occurred only during those tests during which the predicted saturation index increased by a factor of two or more (colored red in the figure. Tests in which no precipitate formed are colored blue). Though predicted saturation state is lower in the Pit A Deep control than it is in three of the Pit A Shallow tests, the relative change from the initial saturation state was greater in the Pit A Deep tests, and this change correlates with observed precipitation. All tests and controls were supersaturated with respect to calcite; only tests where the change in driving force was greater than 2 led to precipitation.

An additional factor that may explain the continued resistance to precipitation in the shallow pit water is inhibition due to high concentrations of Mg and sulfate in solution (Berner, 1975). Kinetic inhibition due to Mg can sometimes be overcome by a larger driving force (ΔG), such that precipitation can proceed. Generally, reactions with larger Gibbs free energies are more likely to proceed spontaneously than are those with smaller free energies (Langmuir, 1997). In either case, driving up saturation state to >2 via the addition of lime was the only test that successfully led to precipitation of calcite from the shallow pit lake water.

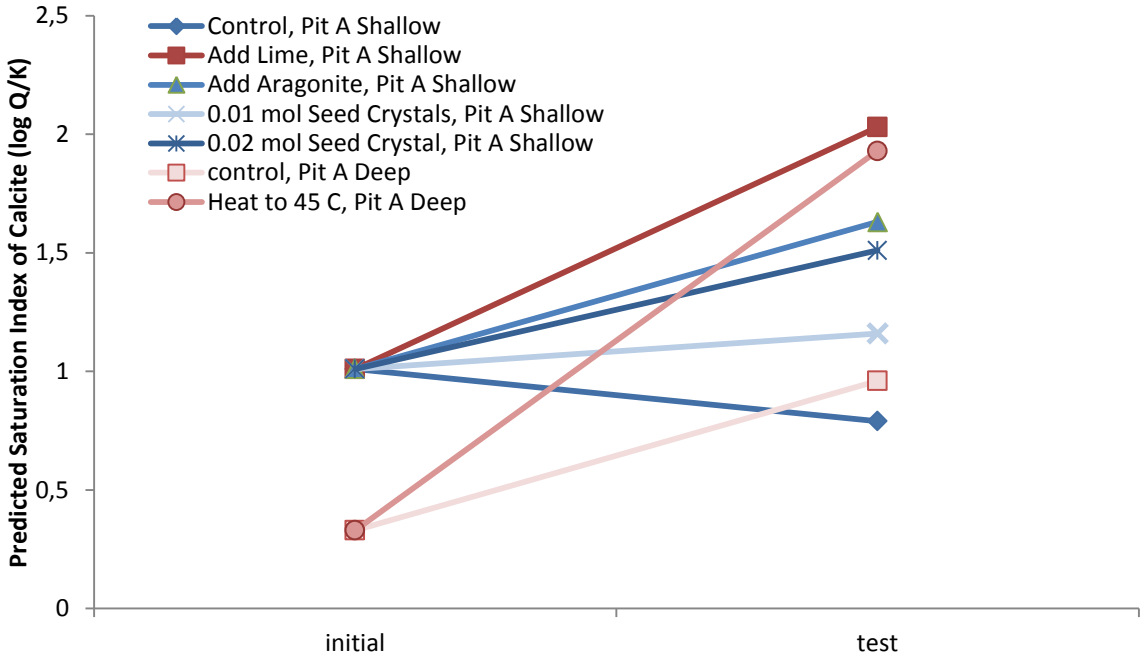

Figure 6 Predicted saturation with respect to calcite for Pit A Deep and Pit A Shallow, in initial waters and in each test. Precipitation of calcium carbonate was observed in tests shown in pink and red; precipitation did not occur in any of the tests colored blue. Precipitation occurred in both tests from the Pit A Deep water, during the control experiment and when the water was heated to 45 °C, and it occurred more rapidly and to a larger extent in the heated test. Lime addition was the only test that resulted in the precipitation of carbonate from the Pit A Shallow water.

CONCLUSION

Calcite precipitation occurred from the deep pit water in the control when it was removed from cold storage: changing temperature of deep pit water and allowing CO_2 to exolve increased saturation to the point of precipitation. This suggests that one potential treatment strategy to remove alkalinity and hardness is to pump the deep water to the surface and allow it to equilibrate with atmospheric conditions. The "whiting" events that have been observed at surrounding pit lakes demonstrate this process on a much larger scale, possibly due to turnover of the mixolimnion, which brings deeper, more saturated water to the surface. As saturated water equilibrates with atmospheric conditions, calcium carbonate precipitates, temporarily coloring the pit lakes a bright turquoise-blue. Test results predict that about 25% of the hardness and alkalinity

in the Pit A Deep water may be removed by pumping to the surface. The effect of pumping on pit lake hydrodynamics and stratification has not been investigated at this time.

Precipitation of hardness and alkalinity from shallow pit water was not achieved with the addition of nucleation seed crystals. It is possible that the quantity of seed crystals introduced to the dilute surface water didn't present enough surface area for additional precipitation to occur. Furthermore, adding a larger quantity of seed crystals could act to increase saturation state enough relative to the initial state to overcome the barrier to precipitation. Reductions in hardness and alkalinity in the shallow pit water was achieved by addition of a small amount of lime, a conventional wastewater treatment approach used to decrease water hardness.

Addition of Bulk Organic Matter to Acidic Pit Lakes May Facilitate Closure

ABSTRACT

Macro nutrients (C, N, P) are essential for sustaining freshwater ecosystems. However, acidic pit lakes are often nutrient-poor as low pH levels and metal complexation (by Al, Fe and Mn) reduces dissolved P and C concentrations. In contrast, N is often not limiting as it is readily available from groundwater and blasting residues.

The Collie basin in Western Australia has a lake district of eleven acidic coal mine pit lakes (pH 3-7, low metals/metalloids and sulfate concentrations). Our previous researches at – microcosm, mesocosm and field scale demonstrated low C and P concentrations limit algal productivity. Addition of organic matter (in the form of terrestrial leaf litter) offered potential bioremediation benefits including habitat creation, sediment formation, the potential for sulfate reduction, and slow release of macronutrients to promote algal growth.

We tested the effect of organic matter additions of straw, lawn clippings and eucalypt leaves on acidic pit lake water and sediment in 1,200 L replicated mesocosms. We regularly measured water quality in each mesocosm over a year and concluded by measuring the development of macroinvertebrate communities. The highly labile C found in lawn clippings stimulated algal biomass, macroinvertebrate diversity and abundance, and improved water quality. Straw and eucalypt leaves did not alter water quality substantially but did increase abundance of macroinvertebrates.

Additions of nutrients, particularly as bulk organic matter increased macroinvertebrate abundance but also altered species composition from carnivorous highly mobile opportunists found in the controls to a range of herbivores/omnivores, while not necessarily altering water quality substantially. The presence of labile C (particularly in the grass) was able to increase algal biomass and improve pH. If conservation values are important for closure of pit lakes and eutrophication is not a risk, then addition of bulk organic matter (particularly labile forms) should be considered in closure plans. Organic matter could be actively added or passively through the catchment. As environmental improvements were seen in all treatments, adding many readily available organic matter types to pit lakes, may be helpful to achieving closure objectives associated with biodiversity.

Keywords: Macroinvertebrates, algae, ecosystem development, succession

INTRODUCTION

Natural lakes are increasingly degraded and lost through human activities. However, pit lakes resulting from the flooding of open-cut mine pits post-mining are creating new lakes (McCullough & Etten, 2011). Pit lakes can pose an environmental hazard to regional groundwater and surface waters, and nearby aquatic and terrestrial ecosystems (McCullough & Lund, 2006). Initially, pit lakes are geochemically controlled usually through acid and metalliferous drainage (AMD) from oxidation of sulfidic minerals in and around the lakes degrading water quality by increasing acidity, sulfate and metal/metalloid concentrations (Koschorreck & Tittel, 2007). Compared to natural aquatic systems, acidic pit lakes typically have greater depth, poor bankside stability, limited organic sediments, limited riparian vegetation cover and diversity, and low rate of allochthonous inputs (Van Etten, 2011; Lund *et al.*, 2013). The ecological development of pit lakes is poorly understood, but primary succession in terrestrial systems is largely driven by accumulations of organic matter and this is likely to be case in pit lakes. Poor water quality and low ecological values of acidic pit lakes may significantly reduce beneficial end use options for the lakes which might be otherwise possible.

Acidic pit lakes typically have low nutrient concentrations; especially of phosphorus and dissolved inorganic carbon, which may limit algal biomass (Nixdorf *et al.*, 2001). Although phosphorus is highly soluble under low pH conditions, it tends to co-precipitate with iron and aluminum in the water column or bind to the sediment (Kapfer, 1998). Dissolved organic carbon concentrations in the water are also often low due to limited allochthonous materials entering the lake from the catchment (Lund & McCullough, 2011). Acidic pit lakes often have adequate concentrations of nitrogen (left from blasting residue), but this nutrient predominantly exists as ammonia due to limited nitrification at low pH (Nixdorf *et al.*, 2001). Algal primary production is fundamental for lake ecological development leading to the establishment of a functional mature aquatic ecosystem (Kalin *et al.*, 2001; Lund & McCullough, 2011; McCullough & Etten, 2011). Additionally, algal biomass provides a substrate for in-lake alkalinity generation by microbes, and a binding site for metals (Dessouki *et al.*, 2005).

Carbon additions to a pit lake can also provide conditions and substrates suitable for the growth of sulfate reducing bacteria (SRB) (Frömmichen *et al.*, 2003). As SRB effectively reverse the AMD processes, they can substantially improve water quality in AMD affect pit lakes (McCullough & Lund, 2011). Furthermore, elevated metal ions may also be removed by direct sorption and complexation to internally-generated or added organic matter (Fyson *et al.*, 1998). Bioremediation by SRB activity shows some potential in the newer pit lakes in Collie which have higher sulfate concentrations (Read *et al.*, 2009). Readily available bulk organic materials such as mulch, hay, manure (cow) and sawdust have been found to be potentially useful for bioremediation in Collie (Thompson, 2000; Lund *et al.*, 2006). The comparatively low sulfate concentrations in Collie pit lakes ultimately limit the ability of SRB to improve the water quality of an entire pit lake but may produce local improvements within specific habitats within the lake (Lund *et al.*, 2006).

Closure criteria for pit lakes waters tend to focus on meeting water quality objectives for slightly disturbed environments (McCullough & Pearce, 2014). It is typically difficult to achieve such water quality closure criteria and active treatment of poor water quality is expensive and ongoing. In Collie pit lakes, there is a suggestion that additions of organic matter encourages algal growth and macroinvertebrate diversity and abundance despite little change in water quality (Lund *et al.*, 2006). We believe that with organic matter additions, there are broader opportunities for pit lakes to achieve biodiversity outcomes and ecological development trajectories to still meet closure criteria

defined by environmental values. Therefore, the aim of this project was to determine the effect of bulk organic material addition (straw, eucalypt leaves, and lawn clippings) on mine pit-lake water quality and aquatic biodiversity.

METHODS

Study site

The Collie pit-lake district is located within the Collie coal basin within the Collie River catchment. Collie township lies nearly 160 km south-southeast of Perth, and is the center of coal mining in Western Australia (Zhao *et al.*, 2009). The Collie Basin covers an area of approximately 225 km^2. Collie coal is a sub-bituminous coal with a relatively low sulfur content (0.3-0.9%), and low caking and ash (4–9%) properties (Le Blanc Smith, 1993). Low amounts of acidity are generated through pyrite oxidation, ferrolysis and secondary mineralization. This acidity is sufficient to generate low pH in pit lakes due to the low buffering capacity of the surrounding rock. There are currently 11 pit lakes in Collie; an overview of the entire lake district is provided in Lund *et al.* (2012). WO5H is one of the larger and more acidic lakes and was chosen as the source of water and sediment for this study.

Experimental Methods

In September 2012, SCUBA divers collected sediment from WO5H (top 0.2 m) in 20 L plastic containers at 2-3 m depth. In addition, a water tanker was used to collect ~12,000 L of WO5H water from the lake. Both water and sediment were taken to Perth within 24 h of collection and immediately transferred to mesocosms. The mesocosms were designed to mimic the littoral (<1 m deep) zone of WO5H. Twelve fiberglass mesocosms (diameter – 0.76 m and height – 0.80 m) with an individual capacity of 1,200 L were used for the experiment. Sediment was first added to all the mesocosms to a depth of 100 mm, followed by the WO5H water. Utilizing a randomized block design, three replicates of four treatments were randomly assigned. The treatments consisted of no additions (control), and additions of straw, eucalypt leaves and grass clippings. Grass clippings were obtained locally from a lawn mowing contractor, eucalypt leaves (*Eucalyptus* sp.) were obtained at Edith Cowan University, Joondalup campus during tree pruning operations, and straw was obtained from a pet supplier. All materials were allowed to dry in the sun for 2—3 days, before 3 kg was weighed and added to the appropriate mesocosm. This resulted in a layer approximately 50 mm deep for grass, and 0.3—0.4 m for eucalypt and straw across the bottom of the mesocosms (Figure 1). The mesocosm water volume was maintained at approximately 950 L, by rainfall and additions of reverse osmosis water to control for evaporation.

The mesocosms were monitored for changes in physico-chemical parameters initially every week for 6 months, then monthly until day 210, then at 3—4 month intervals for a total experimental duration of 421 days (18/9/2012—13/11/2013). A Datasonde 4a multi-parameter probe (Hydrolab, USA) was used to measure water temperature, pH, oxidation reduction potential (ORP), electrical conductivity (EC), dissolved oxygen saturation (DO), chlorophyll *a* and turbidity. Water samples were collected on five occasions (days 1, 38, 71, 113 and 421) from the surface (0.1 m deep) of each mesocosm. An aliquot of the water sample was filtered through 0.5 μm filter paper (Metrigard, Pall, USA), part of the filtered samples were acidified using analytical grade nitric acid (to achieve a pH of <2, approximately 1% w/v) for metal analysis (Al, Ca, Co, Cu, Fe, K, Mg, Mn, Na, Ni, and Zn) on

ICP–AES (Varian Vista-Pro, USA). Anions (SO_4^{2-} and Cl^-) were analyzed on filtered samples using ion chromatography (Metrohm 761 Compact, Switzerland). Ammonia/ammonium (NH_4-N), NOx-N (nitrate and nitrite) and filterable reactive phosphorus (FRP-P) in filtered and total nitrogen (TN-N) and total phosphorus (TP-P) on unfiltered samples were analyzed on an auto-analyzer (Skalar, USA). Dissolved organic carbon (DOC) was measured as non purgeable organic carbon and total organic carbon (TOC) in filtered samples using a TOC analyzer (Schimadzu TOC–V CSH, Japan). All analysis followed methods in APHA (1999).

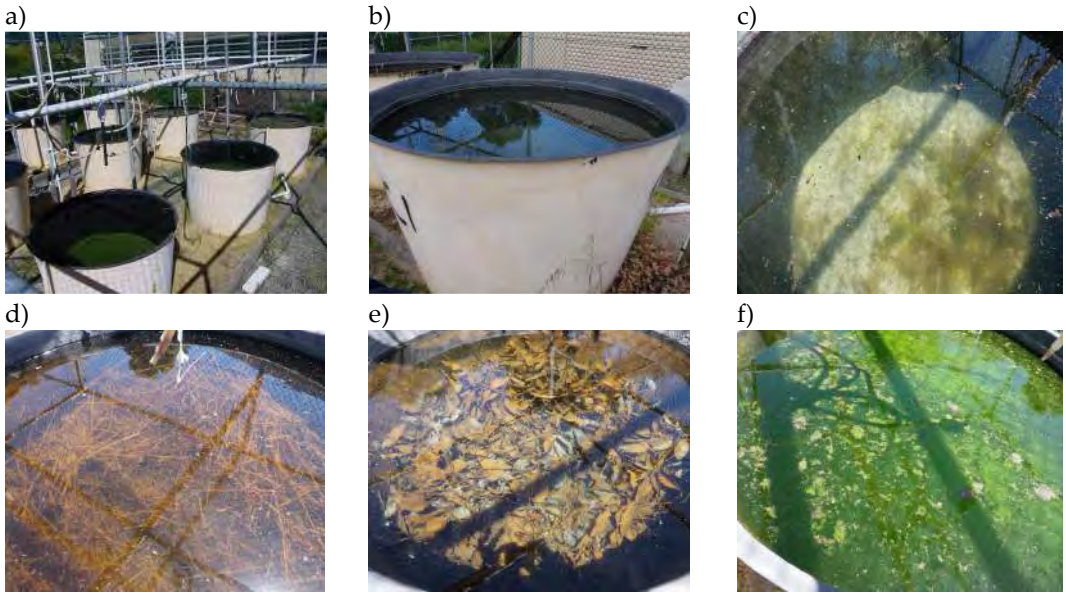

Figure 1. Photographs of the mesocosms in October 2012, showing a) experimental setup b) individual mesocosm, c) control, d) straw, e) eucalypt leaves and f) lawn clippings.

To avoid major disruption to the mesocosms, two surface small sweeps of the mesocosms for collection of macroinvertebrates were undertaken on days 38 and 86 using a small aquarium net (~500 µm mesh, 0.1 x 0.15 m). This was followed on day 421 by a sweep covering as much of each mesocosm as possible with a (0.22 x 0.22 m, 500 µm mesh) sweep net. Samples were preserved in 70% ethanol, sorted using a Bogarov trap and then counted and identified to broad taxonomic groups under a Olympus SZ-STU2 stereo microscope.

Water quality data from five water sampling occasions (days 1, 38, 71, 113 and 421), was ordinated using principal components analysis (PCA) in PRIMER (v6). We used a two-way ANOSIM on normalized data to determine if water quality was significantly different among treatments and times (excluding day 1, just after the treatments were added). We then analyzed treatments just for day 1 to establish that initial water quality parameters were similar across all mesocosms, regardless of treatment. Analyzed parameters included only those where more than half of the samples were above the detection limit – any values below detection were replaced with half the detection limit. Missing data were replaced by the average of any other data for that specific time and treatment, and auto-correlated parameters were reduced to a single parameter.

RESULTS AND DISCUSSION

Water Quality

At the beginning of the experiment (day 1), water quality among mesocosms was not significantly different (Global R = 0.145, P > 0.05), regardless of treatment (Figure 2). After day 1, treatments were significantly different overall (Global R=0.714, P<0.05) and between all treatment pairs (all P < 0.05, although straw x eucalypt R = 0.296, P = 0.04). Throughout the experiment, water quality among controls remained close to day 1 samples, with a slight divergence at the end of the experiment in day 71 (Figure 2). This shift is probably due to dilution by rainfall. The treatments separated from the controls on days 38 and 71, where grass generally was different to the other two treatments. On days 71 and 113, the treatments were similar to each other but distinct from the controls.

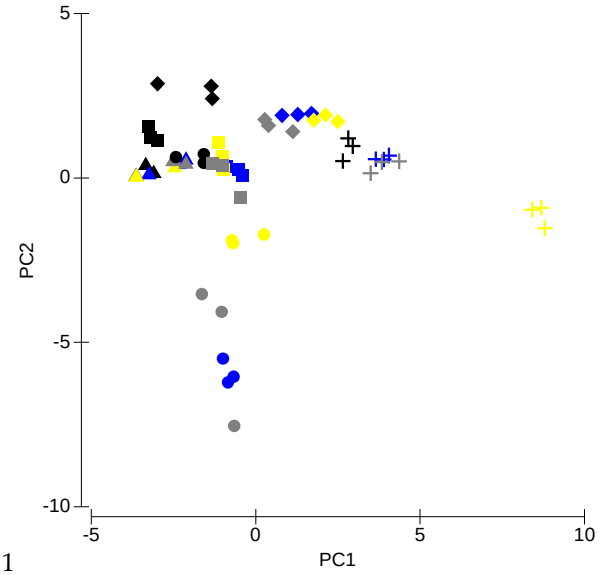

Figure 2. PCA of water quality data in mesocosms with acidic mine water over 14 months of incubation with bulk additions of carbon, 33.3% of the variability is associated with the first principal component axis (PC1) and 17% with PC2. *A priori* groups are time (by symbol) and treatment (by color). ▲ day 1, ● day 38, ■ day 71, ◆ day 113, + day 421, black = control, blue = straw, grey = eucalypt and yellow = grass)

There were significant differences (Global R=0.877, P<0.01) between all sampling times (excluding day 1). Temperature of the mesocosms followed seasonal trends peaking at just over 30 °C (summer) and dropping to just less than 16 °C (winter). There were no important differences in temperature between any of the mesocosms. No evidence was seen of stratification in the mesocosms, presumably due to the shallow depth and wind driven mixing. Conductivity (mean±SE, 1.5±0.01 mS cm^{-1}) follows a similar seasonal trend to temperature, reflecting largely evapoconcentration effects in summer (days 74-163) and dilution by rainfall in winter (days 256—347). Two notable trends were a slight increase in conductivity (of ~100 mS cm^{-1}) in the eucalypt treatment on days 60 and 64, and the lower conductivity from day 22 onwards in the grass treatment (of ~100 mS cm^{-1}) compared to the control and other treatments. No water samples were taken around days 60 and 64 so it is unclear what triggered the increase in conductivity for eucalypt leaves. The consistently lower conductivity seen for grass suggests binding of ions to leaves or ion precipitation may have been responsible.

The control remained aerobic (>60% saturation) throughout the experiment, but by day 20 dissolved oxygen in all treatments was less than 30% saturation (although grass by day 40 had started to return back to control levels). All treatments had returned to levels of dissolved oxygen similar to the controls after day 200. Biological oxygen demand caused by decomposition of the added organic matter was most likely responsible for reduced oxygen levels. Higher chlorophyll *a* concentrations in the grass-treated mesocosms are presumed to have increased oxygen concentrations as a result of photosynthesis. ORP follows the initial decline observed in dissolved oxygen for all the treatments, however by day 60 ORP in all treatments had returned to levels seen in the controls. On day 22, the mesocosms with straw had ORP of <-400 mV, the level at which methanogenesis (methane production) is possible, although by day 29 it had increased to >-103 mv.

pH was very stable at just over 3 for the entire experiment in eucalypt, straw and control treatments (Figure 3). Our previous mesocosm experiments using Collie pit-lake water have found pH has increased to circum-neutral in controls over the course of the experiment. At the time, we hypothesized that groundwater may be responsible for maintaining pH stability *in situ* (see Salmon *et al.*, 2008; Kumar *et al.*, 2011a). The current study used sediments collected from greater depths, 2-3 m compared to <1 m in the other studies, which may be more representative of lake sediment. It is possible that sediment processes in these sediments may be responsible for pH regulation (as per Peine *et al.*, 2000). Alternatively, the difference could be related to which lake the sediment was taken from i.e. WO5H compared to Lake Kepwari.

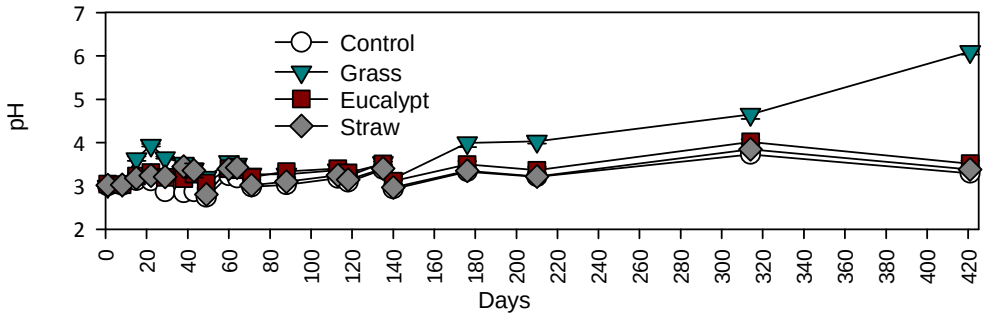

Figure 3. Mean (± SE) pH found in experimental mesocosms containing acidic mine-lake water collected from days 1 to 421.

Chlorophyll *a* concentrations were very low in the controls at <3 μg L^{-1}. Grass stimulated chlorophyll *a* production peaking at 332 μg L^{-1} more than the other treatments; however eucalypt and straw also increased chlorophyll *a* slightly between days 60 and 140 compared to the control. It is likely that alkalinity generation by algae was partially responsible for the lawn clippings after day 140 increasing pH to >6 by the end of the experiment.

Variation in Mn, K, Na, Mg, and Ca concentrations were minimal among treatments but declined slightly over the course of the experiment likely due to dilution with rainwater (Figure 4). Concentrations of Al, Co, Ni and Zn dropped by an average of >40% over the experiment in all treatments and control, although declines were lowest in the control and highest for the grass treatment (>95%). Copper was low in all treatments (mean = 0.755 mg L^{-1}) but appeared to increase slightly over the experiment in the control (peak = 5.5 mg L^{-1}), the most likely source being release from the sediments On day 38, Fe concentrations decreased for both controls and grass (mean = 0.9 mg L^{-1}) from an initial mean of 3.4 mg L^{-1}, and increased for eucalypt and straw (mean = 18.7 mg L^{-1}). By day 71, Fe concentrations were <1 mg L^{-1} in all treatments and control. The day 38 peaks are

not easily explained by ORP/anoxia induced release from the sediment and this suggests that the Fe might have been released directly from the eucalypt leaves and straw in these treatments.

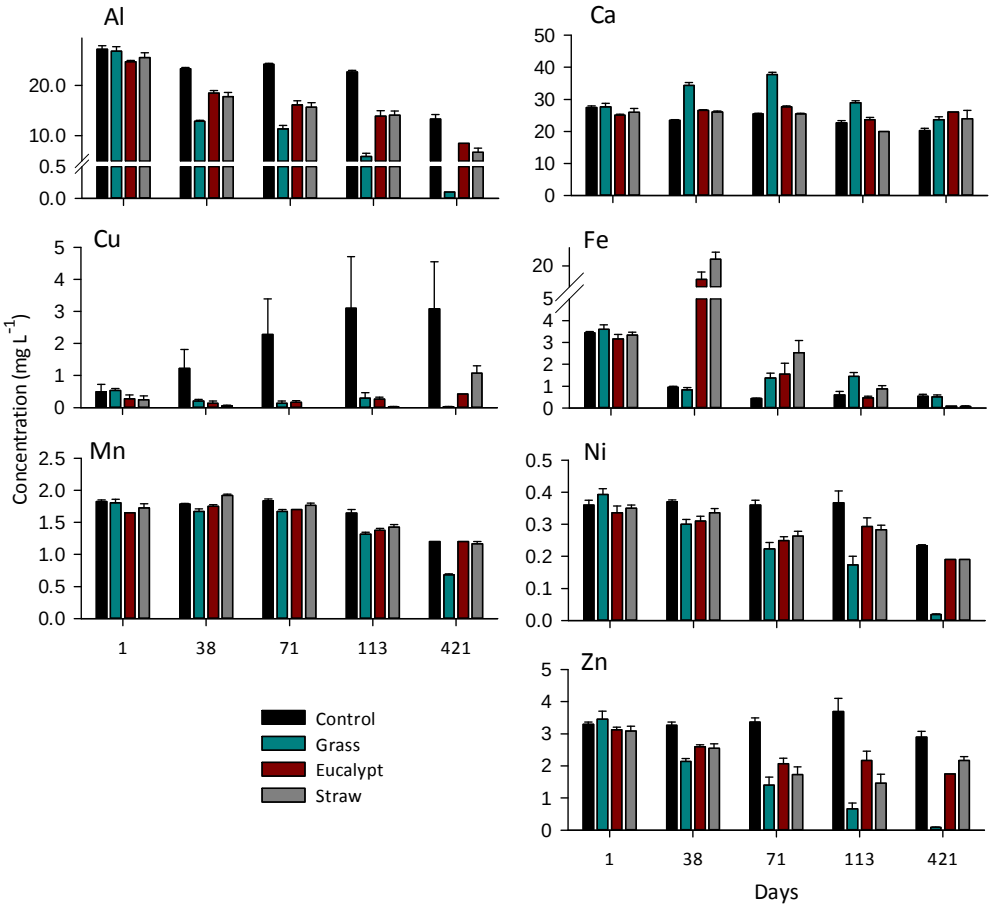

Figure 4. Mean (± SE) concentrations (mg L^{-1}) of select metals found in experimental mesocosms containing acidic mine-lake water collected from days 1 to 421.

Nitrification of ammonia to nitrate does not occur below pH 3 (Jeschke *et al.*, 2013) and initially the mesocosms were at pH 3. On day 1, NH_4-N was present at a mean concentration of 517 µg L^{-1}, with NOx-N concentrations at 68 µg L^{-1}. Ammonification from the likely rapid breakdown of the grass produced exceptional high NH_4-N concentrations in the grass treatment in days 38 and 71 exceeding 6000 µg L^{-1} (Figure 5). Over the course of the experiment, slight increases in pH appear to have allowed for nitrification of ammonia to NOx, evidenced by the overall decline in mean NH_4-N concentration to 69 µg L^{-1} and slight increase in NOx to 88 µg L^{-1} with differences between treatments probably dependent on algal and possible sediment uptake. Kumar *et al.* (2011b) has shown that algal growth in Collie pit lakes is limited primarily by P availability. Although bulk organic matter is not typically rich in P, it does provide a potential source. Initially in the mesocosms FRP concentrations were <14 µg L^{-1} and total P was below the detection limit of 20 µg L^{-1}. FRP remained very low throughout the experiment (<20 µg L^{-1}) with the exception of a mean of 63 µg L^{-1} recorded for eucalypt on day 38. As the experiment progressed, total P increased above detection limits for all treatments, however on days 71 and 113, reached over 3500 µg L^{-1} in the

grass treatments. As FRP concentrations in the grass treatments remained low, it is likely that algal biomass was responsible for the high total P values. The apparent ability of grass to release P is an important additional benefit of using this material within a pit lake. However, the decline in total P on day 421 to near start conditions, suggests that P release from the organic material was exhausted. The highest peak concentrations of DOC and TOC were from eucalypt and straw (mean of 30 and 40 mg L^{-1} for TOC respectively) on day 38, however these quickly dropped to <10 mg L^{-1}, with grass having the highest overall concentrations of DOC and TOC (mean 3.4 and 8.0 mg L^{-1} respectively) after day 38.

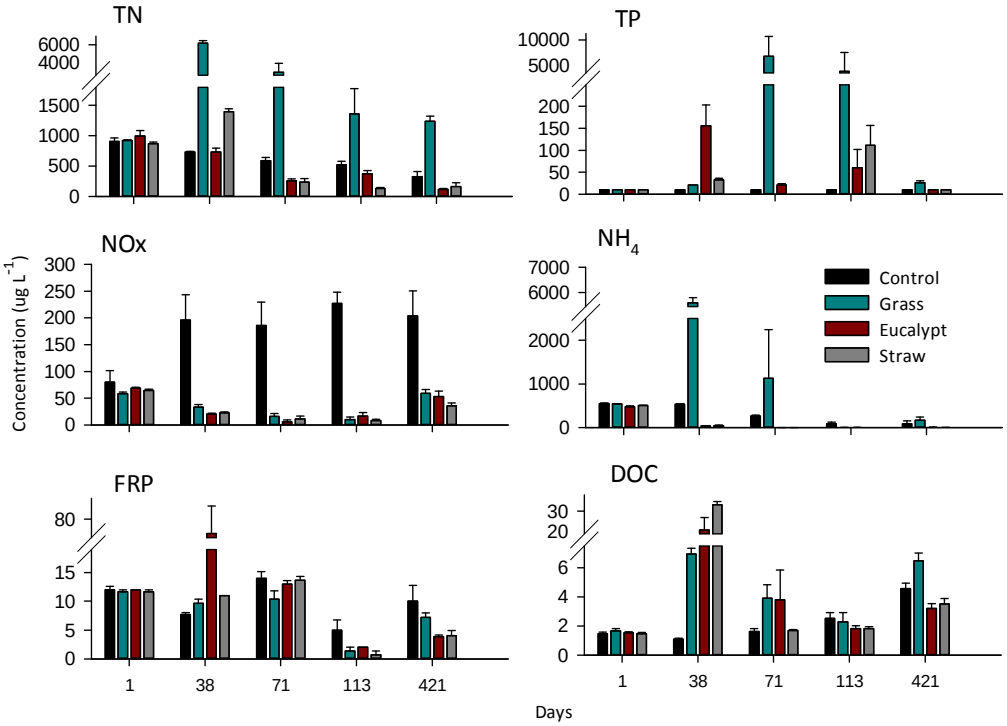

Figure 5. Mean (± SE) concentrations of nutrients in experimental mesocosms for days 1 to 421.

Chloride concentrations were consistent between treatments and as a conservative ion appeared to only change in relation to evapoconcentration and dilution by rainfall (Figure 6). Sulfate concentrations declined in all treatments and the control from mean of 830 µg L^{-1} on day 1, with the control only showing a slight decline (mean 422 mg L^{-1}) and the highest declines seen for grass (mean 112 mg L^{-1}) on day 421 (Figure 6). This suggests that sulfate reduction/secondary mineralization was occurring in all the mesocosms (Triantafyllidis & Skarpelis, 2005), but adding C enhanced SRB activity and that the more labile the C the stronger the effect. Algae were observed growing in all of the mesocosms, which would have contributed labile carbon to the sediment. The grass treatment produced a phytoplankton bloom, measured as chlorophyll *a*, but the controls only produced benthic algae.

Biota

On day 38, all the mesocosms were dominated at the surface by mosquito larvae (Culicidae), with similar abundances and species. By day 86, saw the mosquito larvae replaced by Chironomidae larvae and pupae and Ceratopogonidae larvae and pupae with the occasional Coleoptera adult. All

mesocosms were very similar in species and abundance, although this may be an artifact of the limited sampling that was possible at this time. At the end of the control contained a large proportion of Coleoptera and mites (~40%) compared to the treatments (<2%). The presence of these hardy predatory species is common in pit lakes (Proctor & Grigg, 2006). Eucalypt and straw in contrast were dominated by Chironomidae (>95%), which are also hardy and common to many pit lakes. Grass was different with approximately 15% of the taxa recorded being Culicidae. Total abundance of macroinvertebrates increased with the treatments, with increases over the control of four fold, eight fold and 48 fold for eucalypt, straw and grass respectively. All the taxa collected were most likely colonists from nearby water bodies rather than introduced with the organic material or present in the water or sediment.

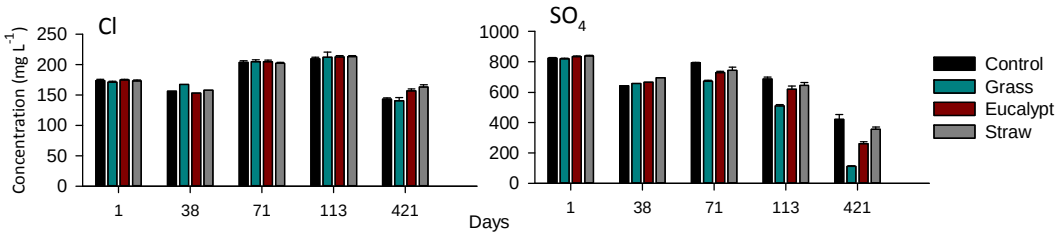

Figure 2. Mean (± SE) concentrations of Cl and SO_4 in experimental mesocosms from days 1 to 421.

CONCLUSIONS

Adding organic matter to highly acidic pit lake waters such as found at WO5H, resulted in no change in pH using more refractory C sources, but subtle improvements in other measured water quality parameters. Some of this improvement is likely due to secondary mineralisation and the sulfate reduction by SRBs. The more labile C produced by the grass treatment ultimately had the biggest impact on water quality and increased pH to 6. The grass also increased macroinvertebrate abundance. Although the taxa diversity (at this low level of taxonomic resolution) does not appear to have increased significantly in any of the treatments; there was a shift away from the predator dominated taxa seen in the control to more herbivorous/omnivorous taxa. Abundance of taxa also increased substantially in the treatments, particularly for the grass. These results suggest that when organic matter is added to pit lakes, more labile carbon sources may provide greater environmental value improvements. However, the results suggest that even refractory C sources such as straw have at least some environmental benefits. Although the quantities of organic material used in this study were very high (approximately 6 kg m^{-2} dry material) compared to what might be achievable in the field, benefits are still likely at lower levels. As these organic matter additions are targeting biodiversity rather than treatment of water quality per se, restricting the material to the littoral zone would likely achieve positive benefits without requiring unrealistic quantities of material. Using pit lake catchments to help supply organic matter to the lakes (see Lund *et al.*, 2013) may be one way to achieve sufficient inputs of carbon over long term to compensate for biotic/abiotic losses. This increasing carbon enrichment may allow even an acidic pit lake to develop ecological values, as an alternative to water quality-driven closure objectives.

ACKNOWLEDGEMENTS

This research has been funded by the Australian Coal Association Research Program (C21038) and Premier Coal Pty and Griffin Coal Pty. The support of Edith Cowan University in providing

infrastructure support is greatly appreciated. In particular, the authors wish to thank Dr Digby Short and Colm Harkin at Premier and Paul Irving at Griffin for their support. The invaluable assistance of Lorraine Wyse, Michelle Newport, Frazer McEnhill, Jay Gonzalez and Eddie Gazzetti with fieldwork is greatly appreciated.

Pit Lake Rebound Modeling, a Fully Integrated Approach Using FEFLOW

Alexia Carpentier and Robin Dufour

DHI Peru

ABSTRACT

An essential component of a mine closure plan is the prediction of the groundwater table rebound and the potential formation of a pit lake at the end of mine life. The time period over which the groundwater levels rebound needs to be estimated and the estimated inflows to the pit lake are needed for estimating the geochemistry and resulting water quality of the pit lake.

Pit lake formation is generally estimated using a simple water balance approach: the inflows to the pit lake are estimated from groundwater inflow or outflow, direct precipitation on the lake surface, runoff from the pit walls and direct evaporation from the lake surface. The water balance is dependent on the lake water level which controls the area of exposed pit wall and lake surface area. The rate of pit lake filling is therefore directly dependent on the pit lake water level. This internal dependency on the rate of pit lake filling is non-linear and complicates the modeling process in time varying (dynamic) models. This complex pit lake modeling challenge is difficult to solve using the general industry approach of simple spreadsheet based water balance calculation methods. Consequently the water balance is estimated by either splitting the pit rebound model process into various disconnected (independent) sub models or by simplifying the water balance process using separated groundwater and surface water models.

A more comprehensive and reliable approach is to couple the various ground and surface water models into a single integrated model where the feedback between pit level and water balance is inherent. DHI have developed a module (plug-in) for the FEFLOW model that combines the pit rebound model processes with the groundwater model. The plug-in allows for the continuous update of the pit lake level as a boundary condition (recharge) to the groundwater model on a time step basis. This paper describes the process of coupling the pit lake and groundwater models and demonstrates the application of such a model.

Use of Pit Lake Water Quality Prediction as a Tool to Support Management of Mine Closure Decisions

Luciano Santos
Pimenta de Ávila Consultoria e Projetos Ltda., Brazil

ABSTRACT

Current best practice dictates that all mines should be 'designed for closure'. This paper describes a water quality model approach used as a tool to predict a pit water quality in a future porphyry copper mine in southwest region of Brazil. The objective of the geochemical modeling effort was evaluating the future environmental impacts associated with water from the pit lake and also to assist in planning the rapid filling of pit lakes with other sources of water in the post-closure phase, in order to attempt the required quality levels for future use.

Based on the expected inflows to the pit lake (groundwater seepage, waste rock seepage and precipitation) in relation to the annual evaporation from the pit lake surface, a geochemical pit lake predictive model was developed using a PhreeqC approach. Precipitation of a large number of geochemically credible mineral phases was assessed by the mixing of all inputs to the pit lake. Also precipitation of ferrihydrite and adsorption onto this phase were simulated.

The predicted ranges of water qualities of pit lake, for the scenario without pumping from the rivers around the future mine to the pit (base case) are predicted to be moderately acid (pH ~4.5). All chemical parameters concentrations are expected to be bellowing the local effluent quality standards, with the exception of copper, and manganese. From all geochemically credible mineral phases included in the model, amorphous gibbsite, ferrihydrite, Schwertmannite, Barite and malachite were found as having the potential to precipitate.

Simulations considering rapid filling of the pit using the water from rivers around the future mine was also modeled. Four simulations were conducted using pumping rates of 1,500m^3/h, 2,000m^3/h, 3,000m^3/h and 5,000m^3/h. The results for rapid filling shown that this approach was a good one to achieve desired limit that is similar to water quality standards for all parameters using pumping rates higher than of 3,000m3/h. The final pH modeled for pumping rate of 3,000m^3/h is ~5.5.

Due to the use of many simplifying assumptions the pit lake water qualities necessarily cannot be considered highly quantitative. However, the model shows to be useful in evaluations of strategies for pit lake water quality management.
