ORGANIZERS

The ICARD-IMWA 2015 was organized by SANAP and Gecamin, Chile.

South American Network for Acid Prevention (SANAP)

SANAP was created in 2008 in Brazil by a group of professionals and academics interested in the problems of acid rock drainage and in identifying solutions to prevent its impact.

Active primarily in Brazil, the main objectives are to develop training activities, information exchange amongst professionals, and support research in the prediction, prevention and control of acid rock drainage in the context of South America. SANAP is currently in a development phase and national chapters are being established, further strengthening the South American network within the already formed national networks in countries concerned.

SANAP is a member of the Global Alliance which brings together varying networks that have developed around the issue of Acid Rock Drainage.

Gecamin

Powering professional development for sustainable mining

Gecamin is a Chilean company with 17 years of experience organizing technical and international conferences for the mining industry. Our conferences aim to inform and inspire professionals from all over the world, fostering the exchange of best practices and innovative experiences.

Over 20,000 professionals have attended our events and have been trained in areas fundamental to the mining industry. These areas include: Geology and Mining, Mineral Processing, Hydrometallurgy, Sustainability and Environment, Water and Energy, Maintenance and Automation, and Human Capital.

Gecamin seeks to contribute to the sustainable development of the mining industry by openly addressing its most pressing concerns and by offering a platform for knowledge exchange that aims at identifying the most sustainable solutions.

In 2014, Gecamin organized 11 conferences and 12 courses, with a total of 922 technical presentations, gathering 2,947 delegates from 54 countries. Additionally, a total of 734 delegates from mining sites attended, and a book with the proceedings was published for each conference.

FOREWORD

On behalf of the ICARD-IMWA 2015 Organizing Committee, I am pleased to welcome all authors and participants to Santiago, Chile. For the first time in history, the International Conference on Acid Rock Drainage, ICARD, is being held in South America, a fact that demonstrates the interest of the local mining sector and its growing approach to responsibly address the problem of acid rock drainage. The issue is very important in Chile, especially in the context of the new mine closure regulation whose main objective is to guarantee the physical and chemical stability of closed mining facilities and waste deposits.

The decision to organize the conference together with the IMWA (International Mine Water Association) annual meeting is another important fact; illustrating that beyond the specific issue of acid drainage, responsible water management in the mining environment is of the upmost importance for the industry.

We hope that ICARD-IMWA 2015 will provide participants with an opportunity to exchange success stories but also to examine industry failures in the search of solutions for more sustainable mine water management. This is a fairly unique gathering in terms of a mix of academia, government and industry and allows for constructive analysis and discussions through in-depth research presentations. All papers have been peer-reviewed and we hope to have gathered the highest quality knowledge that embraces both applied research examples and case studies which might otherwise not find a place at conventional academic conferences. This convergence of research and practice was a key mandate for the Organizing Committee and I hope that these proceedings reflect the effort of both the authors and reviewers. I am confident that these proceedings will prove to be a useful tool in the daily lives of mining professionals.

Thank you for joining us in this conference.

Robert Mayne-Nicholls

CHAIR

10th International Conference on Acid Rock Drainage

and IMWA Annual Conference

PREFACE

ICARD-IMWA 2015, held from April 21-24, 2015 at the Grand Hyatt Hotel in Santiago, Chile, is the 10th International Conference on Acid Rock Drainage, organized this year in conjunction with the International Mine Water Association annual meeting. The Conference is hosted by the South American Network on Acid Prevention, SANAP, and by Gecamin, Chile.

Acid rock drainage and mine water management are now widely recognized by the mining industry as priority issues that should be addressed throughout the entire life of a mine; specifically, paying special attention to the long-term impacts. The main focus of ICARD and IMWA conferences has moved from prediction, analyzing and describing the different mechanisms involved, and developing models, to prevention and control, proposing and developing engineering solutions for reducing environmental impacts and minimizing risks. The conference slogan "Agreeing on solutions for more sustainable mine water management" reflects the effort undertaken to provide reliable solutions to the different problems related with water management in the mining environment.

ICARD-IMWA 2015 is organized to provide an international forum where mining professionals, operators, researchers and suppliers can meet to exchange, interact, analyze and discuss experiences and recent innovations in the area of sound and responsible mine water and effluent management. The objectives of the congress are to:

- Discuss the most recent advances and developments related to prediction, prevention and control of acid mine drainage.
- Bring together professionals committed to improving water management and minimizing mining impacts on surface and underground water.

These proceedings contain 220 abstracts of papers and posters written by authors from 24 countries.

The main topics addressed by the abstracts included in these proceedings are:

Geomicrobiology, biogeochemical cycles and biomining; Applied mineralogy and geoenvironmental units; Prediction of drainage flow; Prediction of drainage chemistry; Mine water and drainage collection and treatment; Cover design and performance; Scaling from laboratory to field studies; Reliable mine waste management; Reliable mine water operation; Mine dewatering; Mine water management for closure; Mine water geochemistry and Pit lakes.

The full version of the papers can be found on *gecaminpublications.com*

All papers published in these conference proceedings have been peer-reviewed by experts from around the world, whom we thank for their contribution by dedicating their time in reviewing, correcting and commenting on the articles.

We believe that these conference proceedings, as well as the conference program, will be of great interest to mine water and industry professionals.

Jacques Wiertz

TECHNICAL COORDINATOR

10th International Conference on Acid Rock Drainage and IMWA Annual Conference

All papers published in these conference proceedings have been peer-reviewed by experts from around the world, whom we thank for their contribution by dedicating their time in reviewing, correcting and commenting on the articles.

We believe that these conference proceedings, as well as the conference program, will be of great interest to mine water and industry professionals.

10th International Conference on Acid Rock Drainage

and IMWA Annual Conference

ACKNOWLEDGEMENTS

The Executive Organizing Committee acknowledges with gratitude the efforts of all the authors for contributing a large variety of high quality, detailed and innovative papers to the technical program. We also would like to thank the reviewers, the employees from Gecamin, and all those involved in the creation of these proceedings for their assistance. The support of the Organizing, Editorial and Technical Committees has been greatly appreciated, as has been the support of the ICARD-IMWA 2015 Chair, Co-Chairs and the Chairs of technical sessions.

The Executive Organizing Committee also wishes to thank the following sponsors (as of March 23, 2015 in the order in which they were confirmed) for their generous support:

Platinum: O'Kane Consultants

Gold: SRK Consulting

Silver: GEO-SLOPE International, Amphos 21, Andritz Ritz GmbH and GeoSystems Analysis

Proceedings: Minera Los Pelambres

Social: INAP and Golder Associates

Official Material: Hatch

Wi-Fi: Tetra Tech

Students: Minera Los Pelambres

Other: Miwatek

Institutional Partners: Fundación Chile, Sociedad Nacional de Minería (SONAMI), Chile; Consejo Minero, Chile; Servicio Nacional de Geología y Minería (SERNAGEOMIN), Chile; Instituto de Ingenieros de Minas del Perú (IIMP), and The Brazilian Mining Association (IBRAM)

Official Media: Nueva Minería & Energía, Chile

Media Partner: AreaMinera, Chile

Finally, we would like to thank all the delegates who attended the conference and exchanged their valuable knowledge and expertise, thus contributing to the great success of this 10th edition of the International Conference on Acid Rock Drainage and the Annual Conference of the International Mine Water Association, ICARD-IMWA 2015.

Executive Organizing Committee
10th International Conference on Acid Rock Drainage
and IMWA Annual Conference

PROCEEDINGS SPONSOR

We proudly acknowledge Minera Los Pelambres as the Proceedings Sponsor of the 10th International Conference on Acid Rock Drainage and The IMWA Annual Conference.

PLENARY PRESENTATIONS

International Network for Acid Prevention's Path Forward

Terrence Chatwin
International Network for Acid Prevention (INAP), USA

ABSTRACT

Expanded populations increase potable and agriculture water use, as well as all other needs for clean water including mining. These pressures have focused International Network for Acid Prevention's (INAP's) efforts to foster best practice to maintain water quality throughout the mining industry. In addition, INAP is committed to assist in building capacity of all stakeholders whether they be large or small operators, regulators or communities through relevant research, information transfer and continuous improvement of operational and remedial practice.

INAP is recognized for its effort in the prevention and mitigation of acid-rock drainage (ARD) through the publication of the GARD Guide, a global best practice guide for ARD prevention. A key element to the success of INAP has been their partnership and support by the Global Alliance, a network of regional orgainzation committed ARD prevention and sustainable mining. To increase INAP's influence and further promote these best practices, we are commited to expanding our partnerships not only with the Global Alliance; but with other like organizations including governmental and non-governmental agencies to educate stakeholders through short courses and on-line presentations. To support its use, we are producing an on-line PDF file of the GARD Guide to allow users to print hard copies of the document. We are also continually updating the GARD Guide with new and relevant information and best practice.

Recognizing the value of inputs from all partners and stakeholders, INAP hosted a "Path Forward Symposium" at the 9th ICARD, where excellent recommendations were proposed and compiled into a report that was used by INAP in its strategic planning process. We look forward to further outstanding suggestions from all stakeholders to assist INAP in its path forward in supporting the mining industry in its sustainable development.

Keywords: ARD, acid drainage, INAP, GARD Guide

INTRODUCTION

With the expansion of human population, the need for increased food, water, material and energy have increased. Each of these required resources places its own specific requirements on clean water. This rapid growth of and competition for water usage, as well as, unexpected drought in certain regions have raised water costs and forced many water users to focus on availability and true value of water. This increased demand combined with inadequate mine closure actions have resulted in an adverse perception of mining's impact on present and future water quality, which in turn has resulted in increased regulatory and societal pressures on the mining industry. INAP and its member companies have raised their review of water resource issues to the highest levels.

Some forms that these pressures on the mining industry have taken are lower water discharge levels for dissolved metals and other contaminates. They have also resulted in higher bond requirements for mine closures and more stringent financial assurances for final closure options. Also in the United States (USA), there are limitations to how mine discharges can be treated post closure. Two states in the USA will not accept perpetual water treatment as a final closure option (Kempton et al., 2010).

Combining these pressures for clean water with the potential adverse impacts of acid rock drainage (ARD) and metal leaching can create significant problems for the mining industry. ARD is one of the most serious and potentially enduring environmental problems of the mining industry, as indicated by the high liability cost carried by many mining companies to cover potential liabilities of ARD and metal leaching. Effective prevention of acid drainage is a formidable challenge, to which INAP, the mining industry and its stakeholders have committed a strong effort to foster best practice to enhance water quality within its member's operations and throughout the mining industry. In addition, INAP is committed to assist in building capacity of all stakeholders whether they be large or small operators, regulators or communities through relevant research, information transfer and continuous improvement of operational, remedial and waste management practice.

Who is INAP?

INAP is an international network of mining companies dedicated to the prevention and mitigation of acid rock, saline and neutral drainage (ARD), (SD) or (ND) and metal leaching in the support of sustainable mining. INAP was formed in 1998 to coordinate and facilitate global research, information transfer and capacity building on the management of sulfide mine wastes, acid rock drainage and metal leaching (www.inap.com.au, 2014). Since then, INAP has grown into a proactive, global leader in the field

We have also organized workshops that address technical, economic, and societal and policy issues. These workshops provide a discussion forum of issues and result in identifying research needs and opportunities. Within these workshops, INAP works to link these issues with interested parties to develop possible solutions and initiatives.

INAP plays a strong supporting role in major ARD events. The International Conference on Acid Rock Drainage (ICARD) is sponsored by INAP every 3 years. At this time, I would like to

recognize the International Mine Water Association, who is partnering with INAP and the Global Alliance in sponsoring the Tenth ICARD/IMWA 2015 Conference. Our close relationship with IMWA is based on our shared objectives and our commitment to sustainable mining. We are pleased to share this venue with our "kindred spirits".

ICARD is a key platform for information transfer and discussion of ARD prevention and mitigation processes, mine waste management methodologies, developments in geochemistry, characterization, modeling and prediction and innovative treatment techniques. This forum is open to all mining industry stakeholders. Through this conference and focused workshop, INAP indentifies and promotes best practice in ARD prevention, supporting continuous improvement in mine waste management and closure, and seeking innovative solutions to critical ARD issues.

A major element of INAP is the identification and promotion of ARD prevention best practice. The most effective best practice tool INAP has produced is the Global Acid Rock Drainage Guidance Document (GARD Guide). The GARD Guide is a compilation and update of all of the ARD, AMD, ND and SD documents and compendia from across the globe. It includes information from not only hard-rock mining but coal mining as well. The GARD Guide was rolled out in 2009 at the Eighth ICARD as a web-based guidance document located at (www.gardguide.com), which is available and free for all to use. The original publication was compiled by an international team lead by Golder and Associates with many external academic and consulting authors. The web-based format was designed to facilitate updating and expanding the document, and it is readily available for those users connected to the web.

INAP's partners

There are eight regional partners that support INAP's goal of preventing ARD and metal leaching, which form the Global Alliance (GA). These organizations represent significant technical and regional expertise on ARD and metal leaching prevention, mitigation and mine waste management. These regional partners are listed below:

- Australia - The Sustainable Minerals Institute–Knowledge Transfer (SMIKT)
- Canada – The Mine Environmental Neutral Drainage Program (MEND)
- China – The Chinese Network for Acid and Metalliferous Drainage (CNAMD)
- Europe – The Partnership for Acid Drainage Remediation in Europe (PADRE)
- Indonesia - The Indonesian Network for Acid Drainage (INAD)
- South Africa – The Water Research Commission (WRC)
- South America – The South American Network for Acid Prevention (SANAP)
- United States – The Acid Drainage Technology initiative (ADTI)

INAP is also keen to engage other regional organizations focused on prevention and treatment of ARD and encourage them to join the GA.

A major activity of the GA members is to host or to assist in the planning of the ICARD. Each ICARD is hosted by a GA member or its associate. The Eighth ICARD held in Skelleftea, Sweden and was hosted by the Swedish Association of Mines (SveMin) and supported by PADRE. The Ninth ICARD was hosted by MEND, in Ottawa, Canada. The Tenth and current ICARD is being

hosted by Gecamin with support from SANAP. GA members in Australia (SMIKT) and in the United States (ADTI) have also hosted the ICARD.

In recognition of the strength of the GA, INAP hosts a reception at the ICARD for the GA where they can network and update one another on their regional activities. During this reception each member organization has an opportunity to inform the Alliance on their efforts and successes. INAP would also like to recognize recent relevant reports that have been published by Global Alliance members. In 2014, MEND published an excellent report on mining-impacted waters entitled, *Study to Identify BATEA for the Management and Control of Effluent Quality from Mines, MEND Report 3.50.1* (MEND 2014). The Water Research Commission of South Africa has published many articles and report that are available at their website (www.wrc.org.za).

Over the past six years, ADTI has been working on a set of five workbooks that have been published through the Society of Mining, Metallurgy and Exploration (SME). These volumes include:

- Basics of Metal Mining Influenced Water
- Mitigation of Metal Mining Influence Water
- Mine Pit Lakes: Characteristics, Predictive Modeling and Sustainability
- Techniques for Predicting Metal Mining Influenced Water
- Sampling and Monitoring for the Mine Life Cycle

All of the editors and many of the authors of these volumes are members of ADTI. This is an outstanding accomplishment for an organization that is composed totally of volunteers and is self-sustaining.

As well as the Global Alliance, INAP partners with many consultants, service providers, governmental, non-governmental organizations as well as local communities and other mining industry stakeholders. The next section of the paper will illustrate how INAP partners with many organizations with common interests to build capacity and transfer information to a broad range of mining industry stakeholders.

INAP'S CURRENT ACTIVITIES

We believe that the role INAP performs in its current activities not only demonstrates its commitment to the prevention and mitigation of ARD, but it also shows our willingness to be a transparent partner to achieve strong communications with and build capacity within our stakeholders. We also seek to foster best practice throughout the mining industry's waste and drainage management plans and continually improve operations and prevent ARD.

Research

In this paper, actions that INAP and its partners have organized and implemented to prevent and mitigated ARD and metal leaching will be presented. These actions have included a gap-driven research project that focused on a key industry need, mine-waste management. Typically, these

efforts concentrate on large-scale projects that require large collaborative efforts or large scale demonstration. An example of this large-scale project is the Diavik country rock instrumentation study in Northern Canada performed by the University of Waterloo, the University of British Columbia and the University of Alberta. Whereas, INAP's financial funding commitment was small compared to the total funding, we did represent a consortium of international mining companies, who assisted technical planning and review from its inception. INAP has supported this project for almost a decade. The lessons learned from this large-scale, long-term project has been very rewarding and valuable and has resulted in a substantial mine-waste management bond reduction for Diavik.

INAP is currently working with O'Kane Consulting and a group of international experts from Canada, Australia, and the USA to prepare a "Global Soil Cover System Design Guidance Document." The planning and organization of this project goes back to 2011 at the Seventh Acid and Metalliferous Drainage Workshop in Darwin. At a plenary session, Dr. Bruce Kelley, formally the Global Practice Leader - Environment at Rio Tinto Limited spoke on the management of mine wastes. As he pointed out, the biggest job of most mining companies is to manage their waste, since over 98% of the materials they handle consist of overburden, low-grade ore, mine waste and tailings. He described managing this waste as the elephant in the room. The discussion following that presentation resulted in an ad-hoc group of about 40 who stayed for an hour after the meeting discussing approaches to address this issue. By the next, morning a group had been formed to prepare and submit a proposal to INAP. The INAP Operating Committee welcomed the proposal and requested further review. Further discussion was carried on at the INAP Path Forward Symposium held at the Ninth ICARD in Ottawa in May 2012.

In 2013, INAP entered into an agreement with O'Kane Consulting (OKC) to prepare a guidance document on the design and construction of soil cover systems. In organizing the technical team, O'Kane Consulting and INAP felt the need for global input for this document. Consequently, a global technical advisory group (TAG) was formed to review and advise O'Kane on this project. Not unexpectedly, some of that original Australian Ad hoc committee are on this TAG. INAP has reviewed the first draft of the document and O'Kane and the TAG have responded to our suggestions and comments. This document is schedule for presentation at the Tenth ICARD in Santiago in 2015.

Capacity Building

A key element of INAP's strategy to prevent and mitigate ARD is to support the enhancement and development of technical and leadership capacity of mining stakeholders including regulators, small operators and exploration companies and communities, particularly in developing regions where training and experience is less available to stakeholders.

Since its publication, the GARD Guide has become such an integral part of INAP capacity building program. To promote the GARD Guide and train stakeholders in its use, INAP and its Global Alliance partners have sponsored and organized short courses across the globe. A GARD Guide short course was presented prior to the Tenth ICARD/IMWA meeting here in Santiago, Chile.

Those presenting include a member of the ADTI Steering Committee and another who was a supporter of the SANAP organization. INAP has been very pleased with outcome of these GARD Guide short courses. For example a few years ago, a GARD Guide short course was organized and presented in Turkey (Personal Communications Rens Verburg, 2013). Resulting from this short course, a committee was organized to translate the GARD Guide Executive Summary into Turkish. In addition to the GARD Guide Executive Summary being translated into Turkish, it has been translated into Spanish, French and German as well.

To assure that there are global opportunities for short courses on the GARD Guide in remote locations, INAP has also entered into an agreement with EduMine for an internet GARD Guide course which is presented within the EduMine web-based educational program.

Since its roll-out in 2009, the GARD Guide has been updated three times. The original version of the GARD Guide was compiled by an international team of consultants and academics lead by Golder and Associates. Since that first version, the following organizations and consulting firms have participated in additions and upgrades to the GARD Guide:

- Natural Resources Canada - Canada
- Environmental Geochemistry International - Australia
- Earth Systems - Australia
- EcoMetrix Inc. - Canada
- Knight Piesold / Sovereign Consulting Inc - USA

As you will note from this list, they are geographically diverse, and they were not part of the original GARD Guide production team. INAP desires that the entire mining consulting and service community recognize and support the best practices compiled in the GARD Guide. If there are best practices or relevant case studies that have not been include in the GARD Guide, let us know, so together, we can correct the oversight.

One of the modifications that GARD Guide users have requested is the addition of more case studies of actual mining operations. Many of the recent upgrading editors and reviewers were requested to include brief case studies that would focus on specific best practices and illustrate how they can upgrade the operations or express lessons learned from less effective actions. Numerous case studies have been added from a variety of climatic and geochemical regimes. INAP thanks these consulting firms and governmental agencies for their efforts to broaden the GARD Guide perspective and strengthen its value to our stakeholders.

INAP has received numerous requests for a GARD Guide hard copy. Consequently, INAP and its service providers have formatted the GARD Guide as a printable PDF file thus allowing users to print all or sections of the GARD Guide has a hard copy. This printable version of the GARD Guide is found at www.gardguide.com and is presently available to all stakeholders.

Many organizations use and reference the GARD Guide. INAP was pleased that the U.S. Environmental Protection Agency (US EPA) translated to Spanish and appended the executive summary of the GARD Guide to the Central American Free Trade Act *EIA Technical Review Guideline: Non-Metal and Metal Mining* (US EPA, 2012). The GARD Guide is also referenced in the

US EPA CLU-IN webinar on mining – resources and is linked and referenced in the Interstate Technology and Regulatory Council (ITRC) web page on mining waste treatment technology selection (www.itrcweb.org/miningwaste-guidance/other_resources.htm) (ITRC viewed 2014). The GARD Guide will also be referenced in future mining guidance documents prepared by International Finance Corporation (IFC) (Personal communication, John Middleton, IFC, 2013).

I also met with Dr Anthony Hodge, the president of International Council for Mining and Metals (ICMM) and we discussed how INAP and ICMM could team to support our joint water management and conservation programs.

Another key partnership that INAP is seeking to enhance is teaming with universities and research centers. These centers of learning and research train future miners, engineers, planners, managers and regulators for the mining industry and develop innovative ARD mitigation methods.

In a recent discussion with a mining engineering professor, it became apparent how important it is emphasize sustainable mining and ARD prevention to all technical disciplines including those that explore, develop, construct, operate and close a mining operation. To achieve this shared responsibility of preventing ARD and maintain clean mining discharges, requires the engagement of all mining industry stakeholders.

Not only do our academics train the students, but they are on the cutting edge of innovative research to produce the new tools to prevent, model, predict and mitigate ARD. Hence, it is important that INAP and our collaborative partners are teaming with universities and research centers. I know ADTI has had a university consortium as a key element of their program. I believe that this should be implemented in all Global Alliance organizations to engage universities in our programs and objectives and to keep us informed of new and relevant tools and programs that are being developed within the academic community. This connection is of particular interest in the field of biogeochemistry where new tools are developing on a regular basis.

One activity that INAP and the Global Alliance is implementing to strengthen its ties with the academic community is the new program to recognize brief (four to five page) case study based on published work of current investigations or operations. As discussed earlier, case studies are a very effective tool to illustrate best practice principles. By limiting the length of the case study, we believe that they can be focused on a specific practice relevant to ARD prevention, and that they can be harvested from the current literature describing current operations or research activities. Students can seek out mentors in either academic or operational venues and create lasting relationships. In addition, these case studies will be useful for illustrating best practice and lessons learned for future students. The results of the first Case Study Competition will be presented at the Tenth ICARD in Santiago. We believe that it will be successful in not only developing useful and relevant case studies, but it will also develop lasting inter-generational relationship that will strengthen the mining industry.

Sulfate Treatment Workshop

Through INAP and ADTI members, a Sulfate Treatment Workshop was organized and presented in Salt Lake City on February, 27-28, 2014. One hundred and ten delegates from five different countries attended this meeting. The program included a broad ranging panel discussion with six separate presentations. An additional twenty-one presentations or case studies and innovative processes were given. At the conclusion of the program, five breakout sessions were held to discuss future efforts. Following the technical program, a field tour of the Kennecott reverse osmosis plant, which treats sulfate-bearing groundwater, was held. As well as recognizing ADTI's crucial support, I would also like to recognize the workshop's sponsors – Veolia Water, Golder Associates and Arcadis, US.

Path Forward Symposium

Recognizing the value of inputs from all partners and stakeholders, INAP hosted a "Path Forward Symposium" prior to the Ninth ICARD. The INAP path forward symposium was attended by over 70 ARD experts from across the globe. The program consisted of seventeen presentations on innovative ARD technologies and other ideas relevant to ARD prevention. The symposium format allowed each presenter five minutes to present his/her idea followed by two minutes for questions and answers. Needless to say, a lot of information was disseminated in a short period of time. It was like an extended "elevator presentation." These talks were then followed by detailed discussion by focus groups. The themes of the four discussion groups included: 1) Biogeochemical processes and tools, 2) Mine-waste management, 3) Innovative treatment technologies and 4) Stakeholder engagement. Following the breakout sessions, a short summary meeting was held to organize and compile the discussion points and findings. These findings were disseminated to the attendees. A second summary session was convened following the ICARD to focus on some of the salient points made at the symposium. At this session many excellent recommendations were proposed and compiled into a report that was discussed at the INAP Strategic Planning Meeting held in November 2013. This strategic planning meeting was facilitated by Dr. Dirk van Zyl, a well respected consultant and professor at the University of British Columbia.

INAP PATH FORWARD

Based on the suggestions made at the Path Forward Symposium and inputs and recommendations by INAP Operating Committee members at the INAP Strategic Planning Meeting in Vancouver, BC a strategic plan was developed to facilitate our planning and future programs. This plan focus on four themes 1) building capacity within INAP, its partners and industry stakeholders, 2) strengthening our communication links with our member companies, our Global Alliance and other stakeholder partners; 3) implementing ARD prevention best practice throughout the entire mining industry; and 4) maintaining continuous improvement. For INAP to be successful in meeting these goals, we need to develop closer ties with our existing and future partners.

Good communications is critical to maintaining quality partnerships and accomplishing our goals. Superior communication combines a well designed message with focused listening and understanding by both parties. Comprehending concerns and desires are often crucial to successful project implementation. Because of the importance of the ARD prevention concept, we often focus

on the message. But to assure successful projects, INAP will work on understanding the needs of our partners as strongly as we focus on project implementation. I believe this approach will lead to stronger partnerships and more shared successes.

Sharing information and experience was a theme that was heard consistently within the planning meeting and path forward symposium. This concept has been exemplified by INAP members as they hosted our Operating Committee (OpCom) meetings. Our last OpCom meeting was hosted by Freeport McMoRan Copper and Gold and held in Tucson, AZ. Following the meeting, we toured the Sierrita and the Bisbee mining sites. During the tour, we observed three water-treatment pilot-plants that were treating discharges from the Sierrita operations. We also toured an innovative water management operation located on the Bisbee tailings management facility. At the end of the tour, one of our experienced OpCom members expressed, "I learned a lot from this tour."

At a separate OpCom meeting, INAP heard a presentation on the Rio Tinto ARD Risk Management Protocol. This program has been operating at Rio Tinto's mining and processing facilities over the past decade and it is based on Rio's corporate-wide review and audit program. The design and implementation of this ARD review program was first presented at the 7th ICARD in 2008. Since that time, the experiences of nearly one hundred audits have been included in the risk management data base covering facilities in a variety of commodities and operating units. Many INAP members have similar programs, and we believe that these resulting discussions on ARD risk management will be informative and valuable to all and help promote the mission of INAP.

Other topics we are looking forward to discussing are developing and implementing ARD management plans throughout the mine-life cycle, working with exploration groups and junior companies to develop early waste characterization data and engaging communities to address their concerns and develop sustainable mining.

CONCLUSIONS

ARD management and prevention is critical to the success and reputation of the mining industry. To achieve these goals, measurement and ongoing improvement of the ARD management plan are necessary throughout the life of mine. Successful implementation of the ARD management plan relies on commitment from company management and the systematic use of ARD management tools including partnering with all stakeholders. We believe that by partnering with all mining industry stakeholders, we will be more successful in achieving our joint goals of preventing ARD and supporting sustainable mining.

Finally, the prevention and mitigation of ARD is becoming more technically viable and more widely applied through the efforts of all mining stakeholders including mining operators, consultants, researchers and suppliers; regulatory agencies; NGOs and the environmental community. We would like to thank all of INAP's partners in this important endeavor to prevent ARD and metal leaching in mining-impacted waters resulting in more clean water for all of us.

Acid Rock Drainage Best Management Practices: A Great Success Story at the Margajita River, Pueblo Viejo Gold Mine, Dominican Republic

Carlos Tamayo, Rodolfo Espinel, Tim Kahl, Benoit Bissonnette and Jorge Lobato
Barrick Gold Corporation, Dominican Republic

ABSTRACT

The Margajita River is about six kilometers long, skirting Barrick's Pueblo Viejo mine before winding its way into Hatillo reservoir, one of the largest fresh water bodies in Dominican Republic.

As far back as most people in the communities could remember the waters of the Margajita River were colored a dark, ominous red – a product of acid rock drainage (ARD) from the old waste rock dumps and facilities from previous mining operations. The local inhabitants called it 'blood' river.

For decades, the stream was highly acidic (pH below 3) and metal concentrations exceeded Dominican water quality standards by orders of magnitude.

Pueblo Viejo Dominicana Corporation (PVDC), a joint venture between Barrick Gold Corporation (60%) and Goldcorp (40%), started commercial operations at this gold mine in January 2013. PVDC efforts to clean-up the Margajita water were an extraordinary challenge. A comprehensive approach for ARD management throughout the mine-life cycle was planned and is currently being executed. This approach follows management principles for ARD mitigation and prevention as described at the Global ARD Guide developed by the International Network of Acid Prevention (INAP).

PVDC spent lots of effort to clean-up this brownfield mining site and in implementing best industry management practices. ARD water is collected in two different areas on site and used as much as possible as high pressure cooling water for the autoclave process. ARD water is treated at the onsite Effluent Treatment Plant (ETP) prior to final discharge into Margajita. Approximately 40,000 cubic meters of water is treated daily. Management practices and careful operation of the ETP have brought dramatic improvements to Margajita River. Communities now see evidence and extraordinary results of high quality water being returned into the river. Also, fishing has returned upstream at the confluence of the river to Hatillo reservoir.

ABSTRACT

Given the social conflicts that arose around Conga mining project (gold-copper), the Presidency of the Council of Ministers of Peru commissioned an independent international expert's report, to analyze all hydrological aspects included in the Environmental Impact Study and in the responses to the presented allegations.

The studies have addressed surface water and groundwater, in terms of possible interference with the quality and quantity, from the pre-mine situation, through the mining operation and after mine closure.

The hydro-climatology of the Andean area where the project is located has been reviewed concluding that the interference conditions would be significant only during the dry seasons due to a structural deficit of water outside the mining project. The mitigation measures have been studied and completed. Mitigation is acheived mainly through construction of surface water storage reservoirs, for replacement of affected volumes, with the possibility of ensuring higher low water flows, and with the implementation of collecting boreholes to ensure water supply to surrounding community users.

The designed water storage will allow increasing the availability of water in the required period and better management of water resources for the affected users. The loss of four existing small lakes as a consequence of the project implementation does not affect existing area water supplies.

There are no aquifers in entity that may be affected by the project, and there are well known hydrogeological disconnects between permeable materials. It is for these reasons that the groundwater is not considered as significant alternative for water supply, while sub-surface water, captured by sub horizontal bore-holes can be improved.

From the bacteriological point of view, the quality of groundwater in pre mine conditions is often deficient, as a result of livestock and lack of sanitary controls contamination. Groundwater exceeds the maximum level of heavy metals in some analyses as well.

The international expert's report recommends a set of participatory water management controls, to ensure compliance with provisions and proposals.

CONTEXT

In January 2012 the Presidency of the Council of Ministers of Peru commissioned an independent international expert report to the authors of this paper. The objective was to analyze the water component of the Environmental Impact Study (EIS) of the Conga Mining Project whose approval had been questioned by different groups opposed to it.

The Conga Mining Project is located at the Andes range, with an average elevation over 4000 m above sea level, east of Yanacocha Mine and 73 km northeast of the city of Cajamarca (Fernández Rubio, López García, Martins Carvalho, 2012). The owner of the project is Minera Yanacocha S.R.L. (MYSRL) (Figure 1).

Figure 1 Location of Minas Conga near Cajamarca, Peru

The geology of the area includes Cretaceous sedimentary rocks, Miocene's volcanic rocks, Eocene/Miocene sub-volcanic and plutonic formation and alluvial, and Quaternary fluvio-glacial and moraines sediments.

Mineralization was found in two cupriferous porphyry deposits (Chailhuagon and Perol) with 0.28% copper and 0.72 grams per ton gold grade. Mining operations are planned for 14 and 19 years, respectively with projections for extraction of 504 Tm of mineral and 581 Tm of low grade mineral and waste rocks.

The project is located within the Marañón river basin, a major watershed of the Amazonian basin and extends over a minor percentage of the headwaters surface of five microwatersheds: Alto Jadibamba (9%), Chugurmayo (0.4%), Alto Chirimayo (8%), Chailhuagón (2%) and Toromacho

(2%). The area affected by the project is minimal as compared to that apportioned to agriculture, the activity that produces the largest negative impact on the biodiversity.

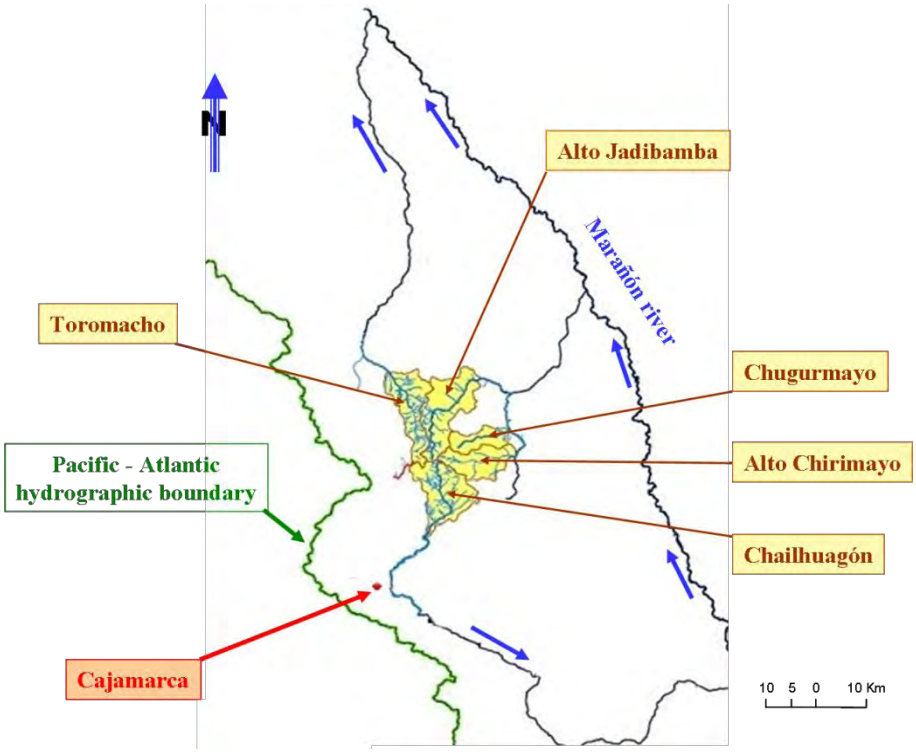

Figure 2 Conga Project footprints and micro-watersheds

SCOPE OF THE EXPERT REPORT

The basis of the report focuses on four major tasks: analysis of the available information; evaluation of the proposed prevention; mitigation and compensation measures; and, finally, proposal of complementary solutions to increase water availability to the downstream users. The report was completed, as expected, in forty days of intensely dedicated work.

The basic groundwork was the analysis of the 18 volumes of the EIS (Knight Piésold Consulting, 2010a) plus the 15 volumes of response to the observations received (Knight Piésold Consulting, 2010b), for a total of around 27,000 pages. These analyses were complemented with on-site surveys and studies, helicopter flights and multiple meetings with technical staff from public and private institutions that provided invaluable additional information as well as with social groups, associations and local residents. The product of these tasks was a 261 page expert report formally submitted to the Presidency of the Council of Ministers of Peru on April 13th, 2012.

The authors greatly appreciate the support provided by David Lorca Fernández, Project Manager of FRASA Consulting Engineers (Spain) and Tiago Carvalho, Production Assistant at TARH – Terra, Ambiente e Recursos Hídricos, Lda. (Portugal).

THE CONGA PROJECT INFRASTRUCTURE

The Conga project includes a number of facilities and specific infrastructures, extending over an area of less than 2,000 has (Figure 3).

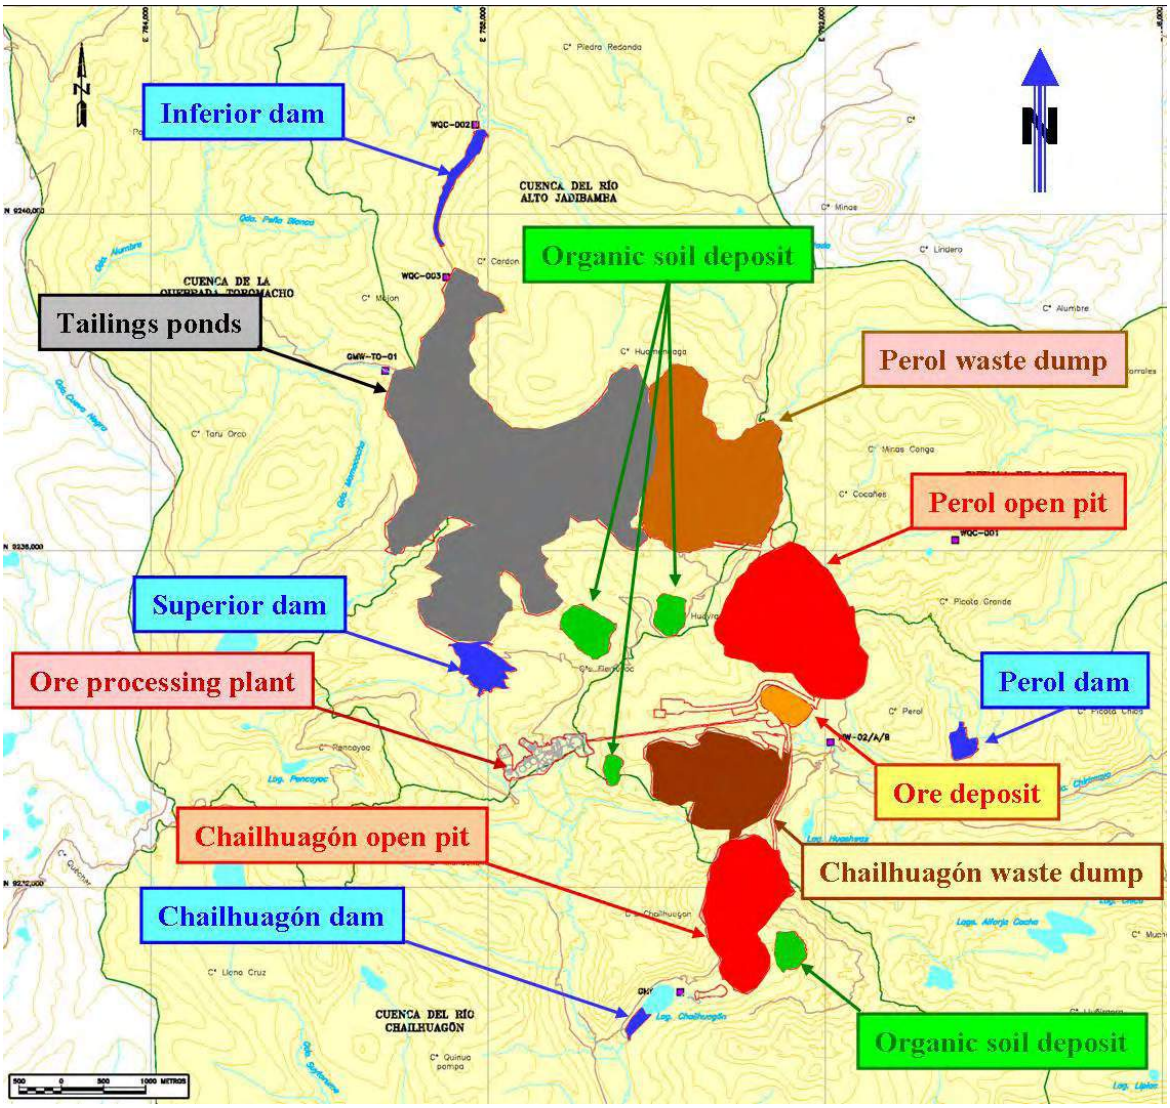

Figure 3 Main infrastructures of the Conga project

In addition to the two open mining pits (Perol and Chailhuagon), two wastes and low grade rocks dumps are provided. Chailhuagon waste dump is expected to not produce acidity, given the presence of abundant carbonate rocks; so its drainage, after passing through control and settling sediments facilities, would be released without issue. Perol is anpotential acidic water producing deposit, will be built upon relatively low permeability materials, but if necessary, a secondary system of interception and collection of water, or waterproofing work will be installed. In any case the natural drainage waters will be discharged by runoff to the tailings deposit, and pumped to the designed water treatment plant.

The planned thickened tailings are stored in sub-aerial conditions, under the protection of two dams (Figure 4), with planned capacity for 315 Mm^3, occupying an area of around 700 has. These dams will rise gradually, as required by the volume of waste; the upper dam will be permeable to retain the solid tailings, and filter the water; the downstream will be waterproof, to retain the effluents that will be pumped to the acid water treatment plant, designed for a flow of 850 m^3/h. Treated, good quality water, will contribute to the Inferior reservoir, to meet the demand of affected users in the months of drought, while the sediments of the treatment (4.45 Tm/h of mud) will be stored in the tailings deposit.

The planned infrastructure also includes: organic soil stockpiles for use in rehabilitation work; ore stockpile to be processed; and the ore processing concentrator plant (with capacity to 92,000 Tm/day), with no use of mercury and cyanide. Natural runoff waters will be directed to solids sedimentation pools or to the tailings deposit, used in the concentrator plant or the grinding, or pumped for their treatment and temporary storage in the reservoirs, in the case of low quality water.

It should be noted that it is necessary to remove two lagoons (Perol and Mala), for excavation of the open pits (Figure 4), and two others (Azul and Chica) which will be covered by a waste dump.

Figure 4 International Experts Team of the Conga Project water component in the Perol lagoon (from left to right: Luis López García, Dr. Civil Engineer; José Martins Carvalho, Dr. European Geologist; Rafael Fernández-Rubio, Dr. Mining Engineer).

As compensation has projected the construction of four regulating reservoirs, of which three (Inferior, Perol and Chailhuagon) will be used to store runoff in rainy period, which compensate for affections that can cause the mining project in the surrounding micro-basins. The fourth reservoir (Superior) will serve the needs of the project and, once finished the mining operation, will supply water to the surrounding users.

Table 1 Storage capacity, current and future, of the water bodies associated with the mining project

Original lagoon	Capacity (Mm^3)	Reservoir	Capacity (Mm^3)
Perol	0.8	Perol	0.8
Chica	0.1	Superior	7.6
Azul	0.4		
Mala	0.1	Chailhuagón*	1.6
Chailhuagón	1.2		
		Inferior	1.0
Total	**2.6**		**11.0**

* Originally: 1.43 Mm^3

In any case, the water runoff decrease will be small, given the low dimension of the subtracted area, and taking into account the decrease in rainfall above the elevation of the "optimum rain" (Fernández Rubio, Lorca Fernández & Novo Negrillo, 2014).

SURFACE WATER ON THE CONGA PROJECT

As expected, the surface water component of the Conga project is extensively analyzed in the EIS. The database used is correct but, as usual in undeveloped, small, isolated high mountain areas, is somewhat limited. The methods used are generally adequate, although some minor discrepancies on the procedure or the analysis of results, without significant influence on the conclusions of the EIS, were detected and should be accounted for in future updates. The impact of the project on the surface water is properly assessed and the mitigation measures proposed are correct, even if the expert report recommends some additional complementary improvements.

The mitigation measures are based on the construction of four reservoirs, three to recover the low flow loss derived from the occupation of part of the collecting watersheds and one to insure the availability of water for the mining operations that will also serve to increase water availability in the area after the mine closure. The reservoirs will store excess water runoff during the humid season and make controlled releases of mitigation flows during the dry season. It has been proved that the current estimated low flows can be fully recovered and even supplementary water to downstream irrigation users could be provided by the reservoirs. Therefore, the project will certainly not negatively affect the downstream users. It may however positively affect users, since the excess water of the humid season can be stored and used to fulfill their dry season needs (Figure 5).

The report points out that if the reservoirs are used to increase water availability downstream and not only to release mitigation flows, they must be operated by a participative management board where all stakeholders are represented: mining company, water authorities and water users, basically agricultural. In this way, the two-fold objective of providing mitigation flows and

increasing water availability to improve local agricultural output could be achieved with minimum conflicts.

The report points out that if the reservoirs are used to increase water availability downstream and not only to release mitigation flows, they must be operated by a participative management board where all stakeholders are represented: mining company, water authorities and water users, basically agricultural. In this way, the two-fold objective of providing mitigation flows and increasing water availability to improve local agricultural output could be achieved with minimum conflicts.

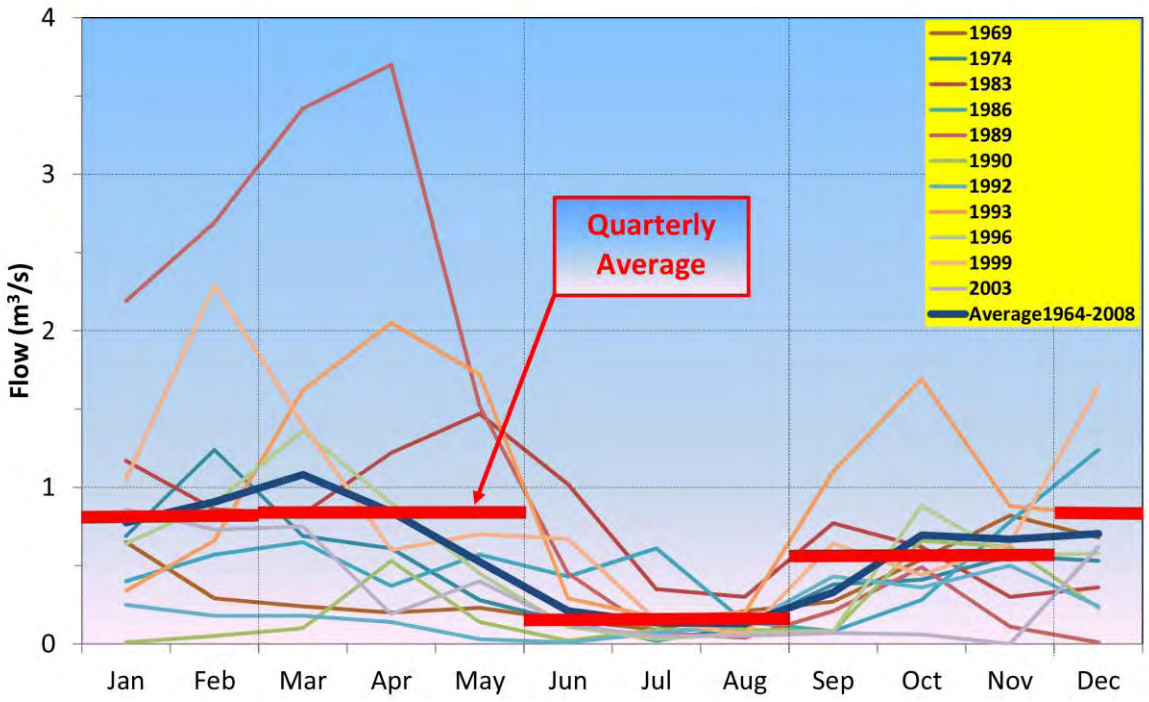

Figure 5 Monthly flow in selected years of the 1964-2008 period in Alto Jadibamba river.

Reservoir capacity must be adequate according to the hydrological characteristics of the microwatersheds that receive moderate rainfall but show a significant runoff excess in humid periods, and must take into account an eventual agricultural water demand. Therefore, it is recommended to update the hydrological studies using the data collected at the local hydrometeorological stations built by the project after publication of the EIS. It should be based on a revision of the rainfall – runoff model and, if possible, develop specific models for each microwatershed. Thus, the mitigation flows required could be adjusted and the availability of supplementary water for agricultural users would be a function of reservoir capacity as defined.

Recommendations of the expert report emphasize the need for future real time control of the evolution of the hydrologic variables and the application of the actions proposed on the EIS. Thus, the institutions with responsibility on water resources administration —basically the Ministry of Mines and Energy and the Ministry of Agriculture through the National Water Authority— can verify the degree of compliance with the proposals of the EIS and insure that correcting measures

are employed, if necessary. This systematic control will improve the hydrological knowledge of the area and provide transparent information to the local population and institutions.

Therefore, it will be necessary to build and operate a complementary hydrometeorological observation network and design adequate protocols for the collection and analysis of data and the drafting of monitoring reports.

This network should include continuous river flow gauging stations at the outlet of the five microwatersheds, since the stations installed in 2004 were destroyed in vandalistic attacks. The information obtained will be critical for the improvement of the rainfall – runoff models discussed prior. Moreover, it is recommended that at least one unaffected watershed is also gauged, in order to define the natural changes that might take place in the hydrologic regime of the area, not attributable to the mining operation.

Again, these various controls must be participative, involving institutions of the administration, local universities and communities and social groups implicated in the management of the water resources and especially the users of water for irrigation, primary consumers of the area.

The protocols for systematic handling and information must define the frequency and extent of the analysis and reports to be executed, the warning thresholds for emergencies and their associated actions. Dissemination procedures for the information obtained should be established based on the need for transparency and simplicity.

The EIS concluded that the proposed reservoirs, designed to provide only the mitigation flow, would generally be at full capacity, either during mining operations or after closure. Therefore, they are undersized in their capability for regulation of the natural runoff, so any technical and economical feasible capacity increase would augment the availability of water during the dry season and, consequently, the positive impact of the project. This is not the objective of a mining operation but, if properly managed, it would greatly improve the relations with the local population.

GROUND WATER ON THE CONGA PROJECT

A conceptual hydrogeological model and a numerical model were carried out within the EIS. These models have to be recalibrated and validated with the suggestions arising from the Expertise including also the new data to be supplied by the hydrogeological monitoring to update the ground water resource management. With this approach a better estimation of the qualitative and quantitative impacts on the existing micro basins will be achieved.

A complete integration of all data of the hydrogeological inventory is recommended, including its geo-referentiated location, defining the water points to be considered in a future monitoring network (springs and wells) down gradient of the main mining installations. This the future monitoring network will include controlling measurements in adjacent basins not affected by the project.

The deep ground water circulation is quite low in the volcanic rocks and even in the existing limestone units as they are confined between aquitards. The investigations carried out in the EIS and our field investigations did not demonstrate the occurrence of karst aquifers and fissured deep systems. The occurrence of fissured semi confined or confined aquifers are possible in limited sectors but they can allow the propagation of influenced levels, and mass transport over considerable distances after the closure and flooding of the main mining excavations. However, the hydraulic continuity between aquifers is not significant or is not present.

The available information allows for the conclusion that area ground water are mainly present in cutaneous (skin) aquifers and in alluvial and fluvioglacial deposits, all located at shallow depths and only following the seasonal precipitation. This ground water temporally feeds lagoons and the surface water runoff of ravines, gorges and rivers (Figure 6). Ground water recharge was estimated at about 34 mm/years, approximately 3% of the average annual rainfall.

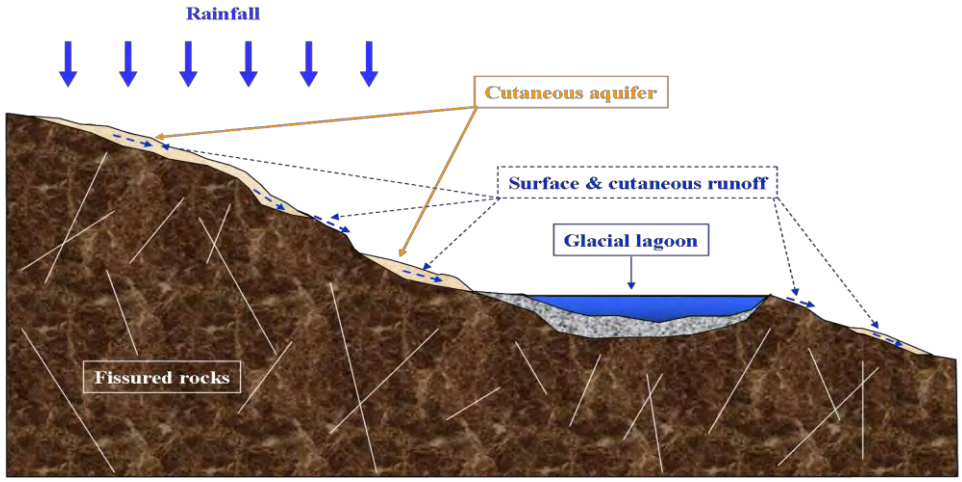

Figure 6 Hydrogeological context.

The main groundwater resources are located inside cutaneous shallow aquifers and its management shall be done in conjunction with surface water. Ground water resource is small and does not allow its systematic utilization for irrigation.

Additionally to the prevention, mitigation and compensation measures adopted by the EIS, the Experts suggested the execution of an appropriate vulnerability to contamination mapping to support technically the protection and mitigation activities for the future waste dumps and tailings dam. The design of wellhead protection zones for ground water sources used for public supply, considering chemical and biological contamination, is also suggested.

The Expertise also proposes the exploitation of the numerical model as a management tool considering the main mining project structures operation and its closing. The conclusions must be taken in account to the wise management of water resources and on the design of preventing and corrective activities, even considering that the Expertise classified the impacts as marginal over the discontinuous hydrogeological units ("aquifers") of the volcanic basement and of the interbedded limestone.

Among the mitigation and compensation measures, in addition to the surface reservoirs to be constructed, alternate water exploitation structures should be considered, such as sub-horizontal boreholes. This, offers better water management capabilities than springs, and the "rain sowing water" (managed aquifer recharge, MAR) in the cutaneous (skin) hydrogeological units using recharge channels (the well-known "acequias amunadoras" of the San Andrés de Tupicocha in the Peruvian Andes), very efficient and with great social acceptance.

WATER QUALITY

Comprehensive information on water quality, from analysis of accredited laboratories, from Cajamarca, Lima and Ontario (Canada), using standard process control and quality assurance is included in the EIS. According to these data we can highlight the following subjects.

Quality of surface waters in the pre-mine state

The water quality in lakes, streams, rivers and canals is studied in the EIS from historical data, for the five micro-watersheds located in the area, including various studies and controls developed for the Conga project, since 2003 until 2009.

The general characterization achieved, concerning composition of surface water, is considered adequate and its extension to more control points is recommended, for better knowledge of the pre-mining state, keeping track of spatial-temporal quality during the mining operation. It is also recommended to select referential points in similar basins unaffected by proposed mining activities.

In the EIS, analytical data are considered in the framework of national environmental quality standards for water (ECA), established by the Ministry of Environment and specifically, with Category 3, corresponding to irrigating high and low stem vegetables and to animal drink, as this is the primary use of these surface waters.

As for the quality of superficial water in the pre-mining state, the following could be highlighted:

- The major chemical facies is calcium bicarbonate, correspondent to low salinity waters, as a result of the low solubility of lithological materials where these waters flow; although some samples are calcium bicarbonate-sulfated and others are calcium sulfated.
- The pH measured in the field, for most samples, is higher than 7, even reaching 9; occasionally there are values between 6.5 and 7, and in wetlands ("bofedales") pH becomes very low (from 3.0 to 6.4 with medium values of 3.1 to 4.2).
- The total dissolved solids range from less than 3 mg/L to 302 mg/L, values that can be classified as low.
- The minimum alkalinity values were recorded in wetlands (<1.0 to 12 $CaCO_3$ / L, with a mean value of 1.3), which shows the poor quality of these waters. In the remaining tests, variable values were observed, surpassing 202 equivalents of $CaCO_3$ / L. In some ponds and irrigation canals values below 20 were measured, reflecting its poor quality for maintenance of animal life.
- The sulfate content may be considered low (<0.5 and 42.9 mg/L), although the presence of pyrite (especially in mineralized rocks), confirms its no-reactiveness, as a result of being under water and, therefore, without oxygen.
- In general, the recorded concentrations of heavy metals (Al, As, Cd, Cu, Fe, Mn, Ni, Pb, Sb and Zn), are low (sometimes even below detection limits) without values exceeding ECA´s Category 3, although in some analysis relatively high contents are observed, deriving from the presence of particulates, either in suspension or settled.

- In relation to the biological quality, content in fecal and total coliforms often exceed the limits set by the ECA for Category 3, especially in rivers, but also in channels, and samples exceeding the limits of these pathogens are frequent in water for human consumption, resulting in ill conditions for livestock and human activity.

Groundwater quality in the pre-mine state

EIS discusses the composition and quality of groundwater in the project area and its surroundings, from periodic analyzes by several laboratories, especially since 2009.

Since these waters are used primarily for human consumption, its quality was evaluated using the ECA standards, established by the Ministry of Environment for Category 1 - Subcategory A1 (water which may be turned potable with simple disinfection). The results were processed using statistical techniques and graphical displays, also using standard geochemical modeling programs. The results provide a good contribution to the knowledge of the characteristics, composition and behavior of groundwater quality.

Among the notable aspects, these can be highlighted:

- The majority chemical facies are calcium bicarbonate, although there are sodium-potassium calcium, and other chemical facies.
- The pH is generally neutral to alkaline, although there were analysis with very high values (over 11), possibly due to grouting additives used in drilling holes.
- Total dissolved solids is usually very low to low, but there are values higher than 4,000 mg/L.
- Most metals regulated for human consumption are below the maximum established values; however, in a series of water samples from wells the values were exceeded regarding the contents of Al, As, Fe, Hg, Pb and Mn in different sampling campaigns, a situation attributable to natural geochemical background, from a geological area that has received deep mineralized fluids.
- Values for total and fecal coliforms are generally low, although in some groundwater were obtained values that exceed the limits established by ECA regarding fecal coliforms, which highlight the human or animal influence.
- In terms of dissolved oxygen, DBO and DQO, some samples do not meet the ECA standards.

Quality of contact water in the mining and post-mine stage

Forecast for water quality that could be drained on a mining operation, always has a degree of uncertainty, especially for water in contact with reactive rocks (presence of pyrite and oxygen).

For an approximated value, a number of studies and hydro-geochemical leaching tests (including tests in humidity cells) were conducted in the EIS, to predict future water quality. For safety reasons, it is planned in the EIS to submit to water treatment all potentially quality-affected water. These changes in water quality are expected to be higher in waters in contact with rocks from the Perol open pit, as it presents pyrite and marcasite that, when exposed to this environment, would

be the main generating source of acidity, having little material to support natural neutralization except from Chailhuagón open pit where limestone is present.

Regarding the reactivity of the tailings in the presence of water and oxygen, and given its small grain size, no doubt they will be acid generating materials, which may incorporate: As, Cu, Mo, Sb and Zn . Therefore, an operating facility of acidic water treatment in the long term is included in the project design.

The process plant for mineral treatment will not use cyanide nor mercury, and reagents used for the differential flotation of targeted metals, will be in part, recovered and reused in the process, in a closed circuit. Another portion of reagent content will be incorporated into the produced concentrates, destined for export and transported by truck; and a third fraction will remain in the deposit, designed with zero discharge.

In the EIS it is proposed a sub-aerial disposal for the thickened tailings. To avoid the need for a very prolonged treatment of acidic waters, alternatives such as underwater tailings storage exist, avoiding the generation of acid waters and dramatically reducing the need for treatment, but requiring water, while it reduces the storage volume, which would require having a second tailings storage area.

RECOMMENDATIONS

The expert report proposes some improvements related to the infrastructures planned, whose feasibility must be confirmed after the necessary detailed studies. If proven possible, they could reduce the negative impacts identified in the EIS and increase the positive impact of hydrologic and environmental measures.

Moreover, the report emphasizes the opportunities to improve the expertise on the hydrologic behavior of high altitude Andean systems provided by the project. It would also enhance the environmental and hydrologic management practices in such areas.

Accordingly, the expert report recommends starting investigation, as soon as possible, of several aspects that could environmentally improve the design of some infrastructures:

- Optimize the conservation conditions of organic soils recovered from different areas of facilities in the provided storage (piles), for better preservation of its seed bank.
- Properly maintain humic materials from the dismantling of wetlands (“bofedales”), for later use in rehabilitation work.
- Evaluate technical and economically alternative relocation or displacement of the wastes and low grade Perol rocks dumps, to avoid cover the Lagoons Chica and Azul.
- Study the possibility of encapsulating residues from the treatment of acidic waters, in a secure deposit.
- Analyze the suitability of employing biotechnological passive methods of treatment of acid water, and in particular wetlands with planting of reeds (“totoras”) (Fernández Rubio, 1991).
- Analyze the possibilities for the increase in capacity of the designed reservoirs, in order to optimize the management of the water resources generated in the project area by. More specifically:

  - Expand the capacity of the Inferior reservoir to increase the availability of water during the dry season.
  - Expand the capacity of the Perol reservoir, if there is evidence of the need for supplementary water to the downstream users.
  - Expand the capacity of the Chailhuagón reservoir, to its feasible maximum to benefit downstream users (MYSRL has already undertaken this proposal). Thus it would happen in a current capacity of the lagoons of 1.2 Mm^3 to a current availability of reservoirs of 11 Mm^3.
- Build or improve intake structures for water supply of small urban populations that currently use natural springs, through sub-horizontal boreholes allowing control of the outflow.
- Systematically implement the "Water Earth Technology" (WET), or "rain sowing water" using recharge channels (the well known "acequias amunadoras" of the Peruvian Andes), to "collect water" through the "water harvesting" downstream during the dry season.

However, the need for a realistic framework that avoids the creation of false hopes must be emphasized. There is a strong risk of encouraging the misleading idea that a mining project has to solve the structural shortages of water during the dry season.

The recommended actions could be a first step towards the development of the water resources management system of the microwatersheds that should be complemented by the Peruvian National Water Authority through the Watershed Management Plans currently being drafted.

AKNOWLEDGMENTS

To the members of the various institutions that made our work easier by providing all the required means: Óscar Valdés Dancuart (President of the Council of Ministers); Jorge Humberto Merino Tafur (Minister of Energy and Mines); Manuel Pulgar Vidal (Minister of the Environment); Luis Ginocchio Balcázar (Minister of Agriculture); Mariano Castro S.M. (Deputy Minister for Environmental Management, Ministry of the Environment); Gabriel Quijandría Acosta (Deputy Minister for Development Strategic of the Natural Resources, Ministry of the Environment); Manuel Castro Baca (Director General of Mining Environmental Affairs, Ministry of Energy and Mines); Hugo E. Jara Facundo (Chief National Water Authority, Ministry of Agriculture); Jorge Luis Montenegro Chavesta (Director of Water National Authority, Ministry of Agriculture); Susana G. Vilca Achata (President Board of Directors, Geological Mining and Metallurgical Institute (INGEMMET)); Gustavo Adolfo Luyo Velit, Víctor Santiago Carlotto Caillaux and Flucker Peña Laureano (Geological Mining and Metallurgical Institute, Ministry of Energy and Mines); Milagros Verastegui Salazar (Ministry of Environment); Roque Vargas Huamán (Ministry of Energy and Mines); Amelia Díaz Pabló (President of the National Service of Meteorology and Hydrology of Peru (SENAMHI)); Julio Ordóñez Gálvez, Oscar Felipe Obando, Juan Fernando Arboleda Orozco y Waldo Sven Lavado Casimiro (Directors of the SENAMHI).

To those that provided liaison, coordination and logistical support: María Elena Juscamaita Arangüena (General Secretary, Presidency of the Council of Ministers); Tábata Dulce Vivanco del Castillo (General Secretary, Ministry of Energy and Mines); Marina Vilca Tasayco (Director of the General Administration Office of the Presidency of the Council of Ministers); Víctor E. Caballero Martín (Chief of the Office of Management of Social Conflicts, of the Presidency of the Council of Ministers); Walter Obando Licera (Adviser of the Office of Management of Social Conflicts, of the Presidency of the Council of Ministers; Technical Coordinator of the Expert Team); Martín Carbajal Zegarra (Adviser to the Office of Management of Social Conflicts, of the Presidency of the Council

of Ministers); Rodrigo Prada Vargas (Adviser to the Office of Management of Social Conflicts, of the Presidency of the Council of Ministers); Luis Alberto León Flores (Head of the Office of Administrative Affairs, the Presidency of the Council of Ministers); Lourdes de Souza Ferreyra Odar (Secretariat of the Office of Management of Social Conflicts, of the Presidency of the Council of Ministers); Michael Acosta Arce (Environmental Engineer of the Ministry of Energy and Mines); Miluska Eran Bodero (Assistant of the Ministry of Energy and Mines); Wendy Alfaro Wall (Assistant of Technical Support, Ministry of Energy and Minas); Raúl González Neira (Technical Support Engineer of the Ministry of Energy and Mines); and Sofía Mescua (Photographer).

To the technical staff of consulting companies that worked at the EIS, who provided complementary information and handled our requests for clarification (alphabetically ordered): Carlos Aguilera M. (Process Engineer. Fluor); Michael K. Herrel (Geochemist. Golder Associates); Alfredo Híjar (Environmental Consultant); Rafael S. Dávila (Principal, General Manager. Golder Associates); Simon Mansell (Senior Project Manager, Schlumberger Water Services); Mayra Medina (Consulting. Metis Gaia Consultores); Nathan Nadramija (General Manager. Metis Gaia Consultores); Xavier G. Panozo M. (Project Manager. Knight Piésold Consulting); Roberto Parra (Environmental Consultant); Abelardo de la Torre Villanueva (Asesores Técnicos Asociados, S.A.); Javier Torrealva (Lider Grupo Hidrotecnia. Golder Associates); and Mario Villavisencio (General Manager. Knight Piésold Consulting).

Finally, to all those who answered to our call for meetings both in Cajamarca and Lima, to incorporate their invaluable information to the expert report (alphabetically ordered): Narda Alarcón Rojas (UPAGU); Hugo Arévalo Escaró (PROESMIN); Nicole Bernex (Pontificia Universidad Católica del Perú); Luis Céspedes Ortiz (General Manager. Chamber of Commerce and Production of Cajamarca); Antenor Floríndez Díaz (ONG CUENCAS); Cristian H. Gálvez Ruiz (Director. Chamber of Commerce and Production of Cajamarca); Héctor Garay Montáñez (Universidad Particular Antonio Guillermo Urrelo (UPAGU); Ever Glicerio Hernández Cervera (Regional Governor Cajamarca Region); José J. Huamán Mantilla (PSI SIERRA – MINAG); José Carmelo Martínez Lázaro (Bishop of Cajamarca); Mirco H. Miranda Sotil (Advisor to the High Direction of High Water Authority); Rosa Olivera González (AGRORURAL – MINAG); Telmo Ramón Rojas Alcalde (ONG CUENCAS); Hugo Loli Salomón (Director of Committees. Chamber of Commerce and Production of Cajamarca); Francisca Torres Hernández (Josemar Consultores EIRL).

OFFER

Those interested in obtaining further information, not for commercial use, may ask for the complete expert report (in Spanish) and a power point presentation (rfrubio@gmail.com).

Mine Planning and Acid Rock Management

Dean Williams[1], Jim Fowler[1] and Dirk van Zyl[2]

1. *Kinross Gold, USA*
2. *University of British Columbia, Canada*

ABSTRACT

Mine planners face a number of obstacles to good management of acid generating materials. Too often the consequence of these obstacles is the generation of acid drainage, long-term water treatment, and possibly environmental impact. This paper reviews leading practice approaches to mine waste characterization drawing on the GARD Guide and mine planning from Kinross Gold Corporation's G4 resource characterization approach. Key obstacles to mine waste characterization and planning are discussed and solutions suggested.

Keywords: Mine planning, acid rock, management, characterization, life cycle

INTRODUCTION

Acid mine drainage and the need to manage acid generating materials is a well-documented problem of which mine planners are well aware. Nevertheless success in avoiding acid mine drainage through good management from start to finish of a project is mixed. Mine planners face a number of obstacles to good management of these materials, which this paper will discuss.

Mine planning is used in this paper to indicate the task of converting resources to economic reserves. This is a complex task that includes a large amount of information of variable detail and accuracy. The information includes metal content, processing costs, capital requirements, metallurgical properties, geotechnical characteristics, hydrogeological characteristics, as well as geochemical properties, etc. Mine planners are generally judged on their ability to optimize the economic value of a mineral deposit to allow the company to evaluate the overall feasibility of proceeding with a project. This task is often associated with very tight time schedules that require quick decision-making, in many cases with incomplete data or interpretations.

This paper explores the obstacles that mine planners face in developing good management strategies for acid generating materials. It focuses on the following three aspects:

- Incomplete geochemical characterization
- Integration of geochemical characterization into mine planning
- Long-term ARD management

Leading practice approaches will be identified as well as the obstacles faced by the mine planner to implement these practices. Recommendations will be made of how the practices can be improved.

LEADING PRACTICE

GARD Guide

Much has been written on the topic of geochemical characterization during the mine life-cycle. The Global Acid Rock Drainage Guide (GARD Guide, www.gardguide.com) provides a description of ARD characterization and prediction techniques (in Chapters 4 and 5) that can be used in developing the information required for mine planning and evaluation. A phased assessment approach is promoted that provides sufficient data at all stages of the mine life-cycle (exploration, pre-feasibility, feasibility, construction, operation, closure and post closure). Leading practice environmental management requires that the potential for acid drainage be identified early in the mine life-cycle. The overall characterization aims to identify the distribution and variability of key geochemical parameters, including sulfur content, acid neutralizing capacity and elemental composition and their influence on acid generation and element leaching.

The components of the characterization include (the information below draws on the GARD Guide, refer to it for more details):

- Sample selection from each geological material that will be mined and exposed and from each waste type. Selection of representative samples should consider material type, spatial

representation, compositional representation, and focused vs. random sampling. Standard operating procedures should be developed for the geological logging and the collection and documentation of sample selection. The GARD Guide recommends that the number of samples depends on the amount of disturbance, the compositional variability within each material type and the statistical degree of confidence that is required for the assessment.

- Laboratory and field testing to characterize the acid generating and metal leaching potential of mine materials, including static and kinetic tests:
    - Static tests:
        - Chemical composition (whole rock and elemental analysis)
        - Mineralogical analysis
        - Acid base accounting (ABA)
        - Net acid generation (NAG)
        - Water extraction (batch extraction) tests with solution assay
    - Kinetic tests:
        - Humidity cell leach testing
        - Column leach testing
        - Field column or rock pile testing to obtain information about material reactivity under ambient site conditions

The results from these tests, together with climatic, hydrologic, and hydrogeologic information for the site, provide a basis for predicting the potential for acid generation and metals leaching. With this information mine plans, including management strategies and environmental impact assessment, can be developed. This geochemical characterization process is depicted in Figure 1 from the GARD Guide (Figure 5.5).

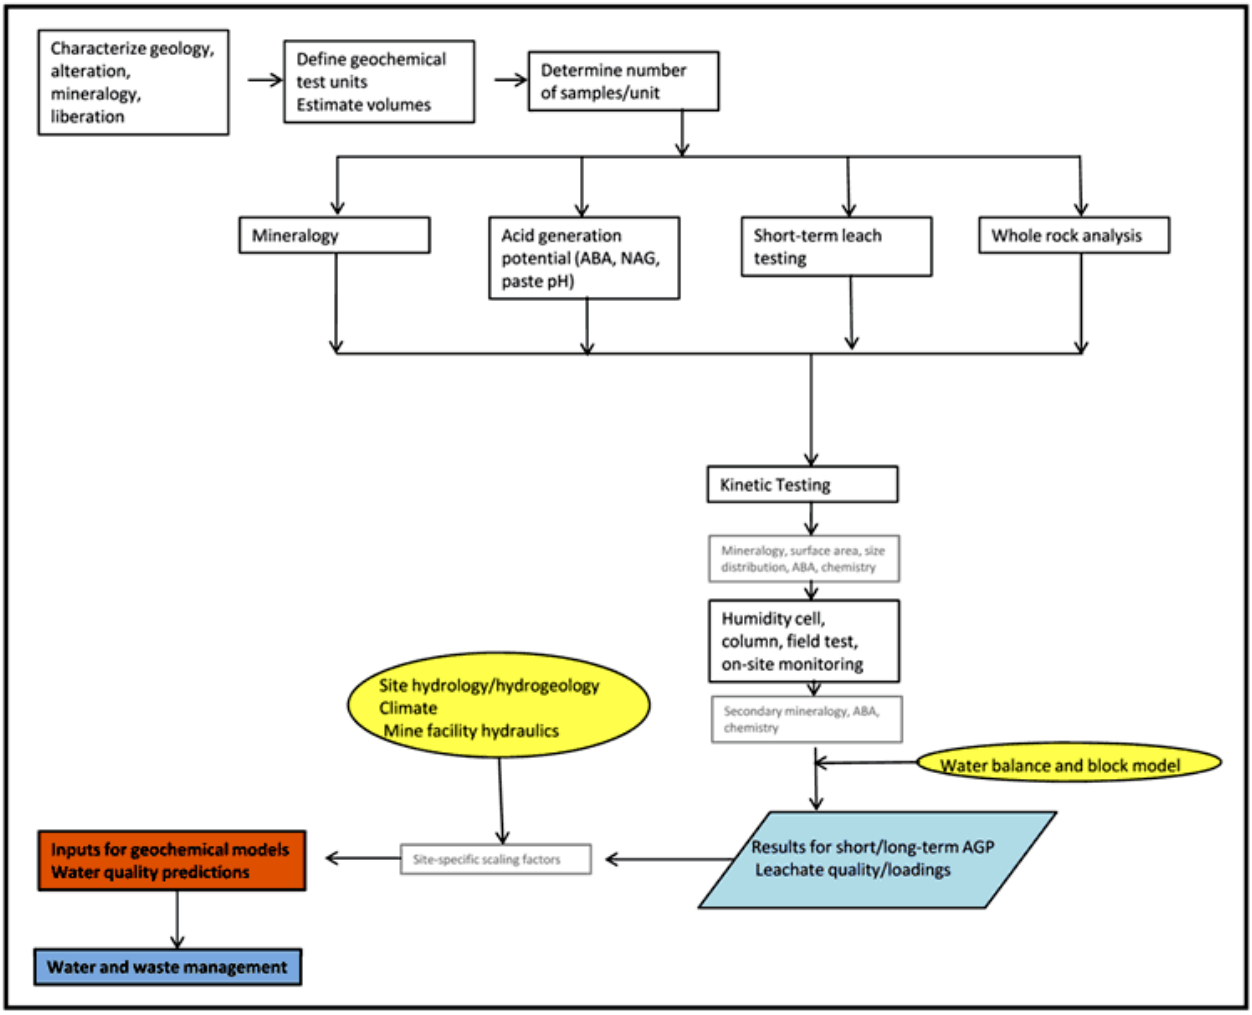

Figure 1 Geochemical Characterization Program

Kinross G4 Approach

An example of how geochemical information can be considered in mine planning is Kinross Gold Corporation's (KGC) in-house system for resource modeling referred to as G4 (Sims, 2014). Resource modeling using G4 draws from a database that includes four components:

- Geologic (G1)
- Geochemical (G2)
- Geometallurgical (G3)
- Geotechnical (G4)

Detailed correlation analysis is used to assess the 'G' components and populate the resource model with key variables. These variables; in addition to density, grade, and process characteristics; include elemental characteristics, acid base accounting, and hydrogeologic information. Scorecards are used to measure the maturity of all data bases with respect to project maturity. Target Maturity stages are:

- Initial Project Setup

- Initial Drilling
- Infill Drilling
- Scoping Study
- Pre-Feasibility Study
- Feasibility Study
- Operations

Figure 2 illustrates how the G4 feeds into the Resource Block Model and Mine Optimization

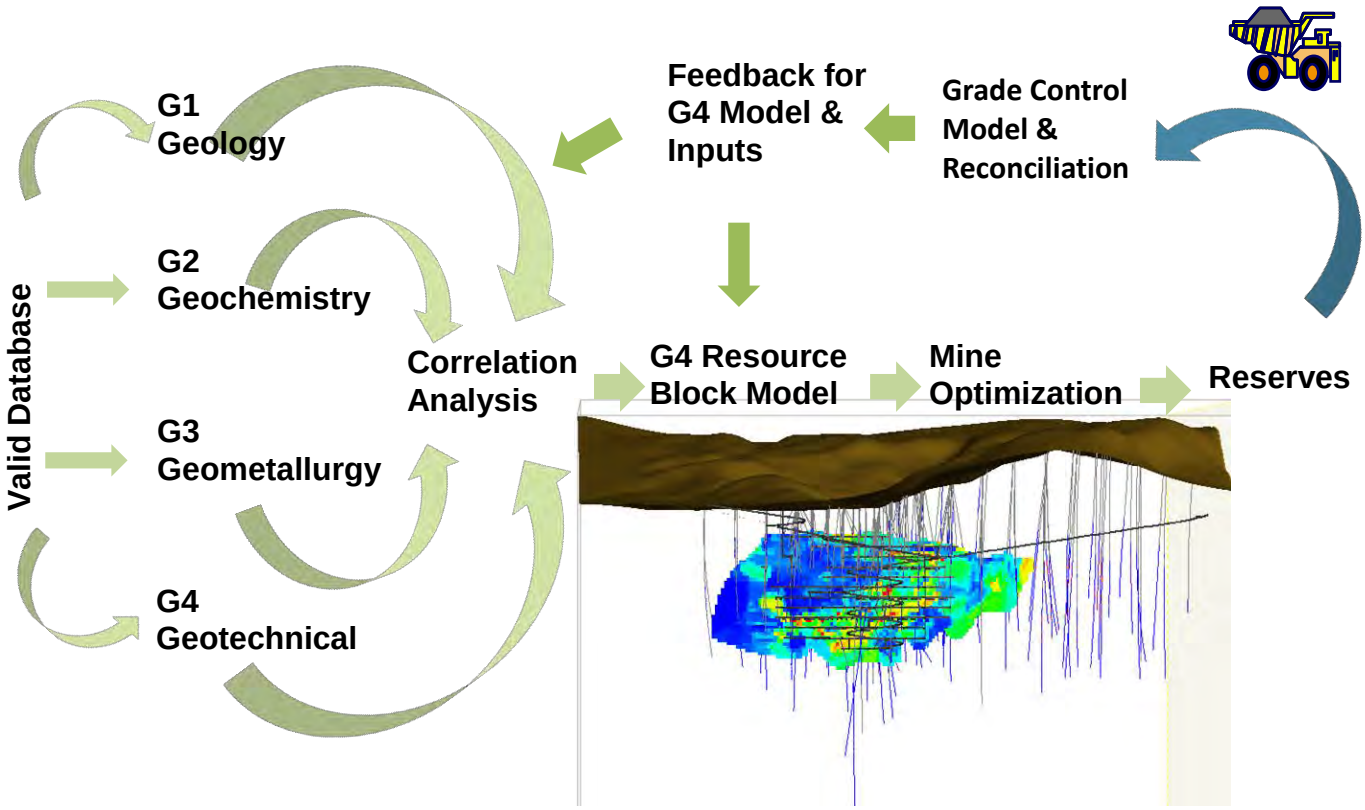

Figure 2 KGC G4 Process for Developing Resource Block Model and Mine Optimization

THE MINE PLANNER'S DILEMMA

INADEQUATE GEOCHEMICAL CHARACTERIZATION

Good management of acid generating materials often begins with initial geochemical characterization efforts. Geochemical characterization is a typical component of baseline studies and factored into mining plans, impact assessment and permitting. Unfortunately too often geochemical characterization begins when an orebody is determined to be economic. At this point in mine feasibility planning, time is money and the pressure to obtain necessary approvals is high. Because sampling, analysis, interpretation and reporting require time, there is a tendency to manage the scope of characterization efforts to stay on schedule. While statistical analysis of test

results is advisable to confirm that a representative data set has been obtained, this may be ignored in deference to pre-established schedules.

Additionally, kinetic testing is required to assess the relative rates of acid generation and metals leaching reactions and to provide information on the evolution of potential acid drainage over time. Because kinetic testing requires time, and time is often in short supply, the mine planner or project team may feel considerable pressure to limit the extent or duration of kinetic testing.

These obstacles can of course be overcome. Sulfur analysis should begin with initial exploration and should be performed on all samples analyzed for target elements. As the geology of a mineral target becomes known, static testing of representative samples from each material type should be performed. Additional static testing, kinetic testing and water quality characterization should follow. With an early start and progressively expanded, it is possible to characterize geologic materials and develop appropriate management strategies for inclusion in mine plans without delay to feasibility and project development schedules.

Acid base accounting (ABA) evaluates the acid generation potential of the various geologic units present at a site. As part of ABA, the bulk quantities of acid generating minerals (e.g., sulfide minerals) and acid neutralizing minerals (e.g., carbonate minerals) are measured to assess whether the materials tested will have sufficient capacity to neutralize the acid potential, or if the materials have the potential to generate acidity. Acid generation potential is commonly interpreted by the ratio of neutralizing potential over acid generating potential (NP/AP) or NPR ratio. Unfortunately, all-too-often, there are geologic units that are quite geochemically variable. In addition, because geochemical weathering rates are dependent upon oxygen, water and temperature, the timeframes for the onset of acid drainage can be quite delayed or difficult to estimate. The mine planner, confronted with these unknowns, is challenged to select the "right" management approach or even, in some cases, to understand if there is a "real" problem.

Of course it can be argued that the mine planner should always exercise the "precautionary principle" when it comes to potential acid rock management, but that is in many cases an overly simplistic, costly, and conservative approach. Support from environmental and geochemical advisors is recommended to ensure that management requirements for various geochemical domains are understood and incorporated into the mine plan.

Because few ore bodies are fully characterized prior to mine development, ultimate geochemistry and mine planning options may not be fully understood. In too many cases, following initial permitting and approvals, ongoing monitoring of geochemical characteristics of wastes is not continued. Further, changes in geochemical domains within the same geologic unit are common, and the need for expanded geochemical characterization, are often not recognized. Failure to recognize these changes can result in the construction of acid generating dumps, tailings facilities, or use of acid generating materials for construction, roads, etc. In the end, mitigation of the consequences of failure to recognize these types of changes can be time consuming, costly, and damaging to the social license of a company.

To reduce the potential that the mine planner is working with inadequate information, geochemical characterization efforts need to continue as the ore body continues to be developed. Plans must include procedures to recognize new geochemical domains and the requirement for more extensive characterization to ensure that these materials are properly recognized and managed.

Integration of characterization in mine planning

Possibly an even more significant obstacle is that geochemistry is commonly not fully integrated into block models. Acid generating potential must be correlated with geology type to create geochemical domains. This information is input to the block model along with metallurgical, geotechnical, and hydrogeological information. At the end of the day, the mine planner is working with a very complex data set. Failure to achieve strong correlations with geology type or to fully understand the potential for acid generation and the management options available can result in the mine planner deciding to ignore the data, as "it is not clear what it means".

The mine planner should be provided support by a geochemist to ensure that initial characterization is well done and correlations with geology are strong. Additional support may also be appropriate to ensure that management strategies for different geochemical domains are well conceived.

As mine plans develop and more information becomes available regarding recovery, grade, geochemistry, etc., mine planners and operators seek management solutions that have minimal impacts on reserve estimate and economic performance. Mine planners are judged on their ability to convert resource to economic reserves and this unfortunately may mean that issues, especially where the impacts are not clear or will only manifest over time, may not be entirely addressed. This focus on positive results can mean that more environmentally acceptable options may not be fully considered as they would mean lower reserve estimates and lower short-term economics. For mines with relatively long lives, e.g. greater than 15 years, the economic tradeoff between avoidance or isolation of potentially acid generating materials and ultimate treatment of acid drainage often favors the selection of water treatment as the preferred alternative.

Corporate policies on full-cost analysis and environmental protection are required in order to limit the potential for this obstacle to result in unacceptable environmental performance. Corporate environmental departments along with independent reviewers of block models and mine plans must be diligent and engaged. More recently, capital approval systems (CAS) which have been adopted by many companies, include more detailed outlines of what is required at each evaluation step, from scoping through feasibility studies, helping ensure that the correct environmental parameters are collected.

Another obstacle, hinted to previously, is that geochemistry and acid rock management are typically not core competence areas for the mine planner. Due to the unique knowledge requirements, planning and management input is typically provided by outside experts who may not fully understand the geotechnical, metallurgical, or economic factors that are critical for planning. The planner's ability to incorporate this information into the mine plan will vary by individual and level of experience. Clearly the ability of geochemical and environmental advisors to understand what is involved in mine planning and to support the mine planning process can be invaluable. Environmental advisors must have a good understanding of the management practices available and the ability to effectively communicate with the mine planning team.

DISCUSSION

Responsible acid rock management involves a host of leading practices of which mine planning, highlighted in this paper, is an important consideration. It is essential that obstacles to responsible acid rock management be identified and overcome. Because many of the obstacles involve the availability of data and its interpretation, it is critical that data base maturity be clearly defined for

all stages of project maturity. Table 1 provides a general summary of critical analyses relative to project maturity/life cycle.

Full implementation 

Use/maintain/update as necessary 

The mine planner cannot be expected to solve the mine waste characterization and management dilemmas described above alone. Geochemical and environmental advisors must provide support and assistance to the mine planning process including the identification of management options, costs and their expected effectiveness. Strategies for more effective planning for acid generating materials should include:

- Statistical analysis and other modelling to integrate basic geochemical information, including a clear understanding of ARD potential, into the overall mine block model. This process may be done in a number of steps of refinement to expedite the overall mine planning process.
- Development of inventories of effective management strategies for various types of ore bodies, acid generating potentials, and climates.
- On-going monitoring of the geochemical behavior of mine materials and the effectiveness of management strategies. Every effort should be made to identify the potential range of uncertainty/variability that may exist. Likewise management strategy performance must be monitored and where necessary updated over the mine life-cycle to maximize the potential for success.

When mine planning is done with a complete set of data, confidence in the results, as required by processes such as NI 43-101, is more likely. When geochemical characterization is not well defined it is suggested that comments be provided to indicate the approach that was used, potential uncertainties and their possible implications. This would provide important information for investors. It is recommended that this be further considered by the ARD community, INAP, and others to support the development of more standardized definition of data and planning requirements for project maturity stages.

CONCLUSION

The mine planner faces a number of obstacles to good management of acid generating materials. Inclusion of 'screening analyses', such as total sulphur and carbon in early analysis of drill holes provides a foundation for subsequent static and kinetic testing. As discussed, this information provides a basis for understanding geochemical weathering, management requirements, and potential environmental impact. Begun early in the process, it is possible to minimize or avoid planning and permitting delays.

Data base and management strategies must advance with project maturity stage. Most mining companies have project stage gates, with well described requirements, that must be met before a project can be advanced. Geochemical characterization and management strategies are important components of the stage gate process and must be defined.

Environmental advisors must provide input on management options, costs and their effectiveness. On-going monitoring of management effectiveness is required to recognize problems early and make adjustments as required.

On-going monitoring data collection and interpretation aims to recognize changes in geochemical domains that may require new management strategies. Collaboration between mine planners and environmental personnel is critical to ensure that management strategies are embedded in mine plans and environmental protection requirements are achieved.

ACKNOWLEDGEMENTS

The authors acknowledge the many individual contributions that have been made to the development of the GARD Guide and acid rock management practices. As this paper points out, the tools for management of acid rock have been developed, it is simply a matter of their utilization.

A Global Mining Industry Perspective on Water Stewardship

Ross Hamilton
International Council on Mining and Metals (ICMM), United Kingdom

ABSTRACT

In recent years water has risen to become one of the most significant issues facing the mining industry. Water is not only a critical resource for mining operations, but also for other industries, communities and the natural environment. Inadequate consideration of water and its other users has resulted in costly project delays, cancellation of licenses, community conflicts and reputational damage. Such experiences have led the industry to acknowledge that its approach has to shift from simply management of operational water supplies to one in which the needs and priorities of other users are considered. In response to this challenge the International Council of Mining and Metals developed a Water Stewardship Framework in 2014, and launched a *Practical Guide to Catchment-based Water Management* for the industry, this year. The new guidance sets out a comprehensive and systematic approach for identifying, evaluating and responding to water-related risks for the mining and metals industry. The document is structured as an interactive and informative prompt to guide companies in the development of their water strategies and plans in accordance with the local context and hydrology in which mining and metals operations take place. Implementation of a catchment-based approach at the operational level is a fundamental step towards mining companies becoming effective water stewards.

Acid Rock Drainage Treatment (TADA) at Codelco Andina

Jorge Lobos
Codelco, Andina Division, Chile

ABSTRACT

The Andina Division of Codelco Chile has a copper operation which combines surface and underground mining. The first requires prestripping which needs to be deposited in waste dumps. These dumps, with a limited authorized capacity, need to be replaced at the end of their lives. For this reason, the Division carried out studies to identify mid and long term alternatives to support current production and future expansions. The Norte Waste Dump (NWD) -located in the upper basin close to the open pit- was chosen as the best alternative to replace the actual dumps once they are depleted.

Precipitation and oxygen in the environment cause chemical reactions over low grade materials with sulfur contents deposited in the dumps, acidifying waters and promoting the growth and development of bacteria. These can accelerate the generation of acidic drainage which contains copper, iron, manganese and sulfates among others.

The purpose of the TADA (acid water treatment) Project is to offer a solution to the acid drainage resulting from the NWD. The plant captures and diverts clean water, avoiding contact with these dumps. It also captures water drained by the NWD and treats it in a High Density Sludge Plant (HDS technology). Treated waters are then returned to natural courses or to the production processes, according to water permissions and environmental regulations.

In order to comply with environmental requirements and meet investment criteria, the TADA Project was constructed stage by stage. The waste dump construction, as well as the treatment plants, was constructed using this mode.

Control of Water Pressure in Mine Slopes

Adrian Brown
Adrian Brown Consultants, Inc., USA

ABSTRACT

Water pressure degrades the performance of slopes, causing reduced slope angles, reduced slope safety, and slope movement leading to catastrophic slope failure. The additional mining costs associated with these slope water pressure effects are significant, and catastrophic failure can be enterprise threatening. Accordingly, for cost-effective large-scale surface mining, elimination of water pressure in slopes is required.

Water pressure exists in slopes for two fundamental reasons. First, water pressure is present throughout slope rockmasses due to normal flow of infiltrating and stored water. Second, water pressure spikes can occur in mining-destressed fractures and faults due to infiltration from rainstorms, flooding, or snowmelt, causing elevated water pressures to propagate deep into the slope rockmass, resulting in water-driven slope movement and, in the extreme, catastrophic failure.

Water pressure in mine slopes is traditionally controlled by dewatering wells, horizontal drains, or drainage galleries. These methods reduce but do not eliminate long-term slope water pressures on failure surfaces. More importantly, they do not significantly reduce sudden pressure spikes in the fracture system. The only reliable method to prevent both of these stability-reducing and failure-inducing conditions is prevention of ingress of water to the mine surface and to the mine crest area, together with conventional pressure mitigation.

This paper reviews the theory of slope stabilization, examines methods of improving the effectiveness of the "standard" pressure control strategies by control of infiltration, evaluates methods of infiltration prevention in large surface mines, determines the effectiveness of infiltration prevention in achieving maximal slope performance, and makes the business case for infiltration control to achieve maximum slope angles, maximum slope safety, and maximum profitability.

Challenges Following the Transitional Phase of Implementing the New Mine Closure Law in Chile

Lilian Valdebenito
SERNAGEOMIN, Chile

ABSTRACT

The Mine Closure Law (N°20.551) and its Regulations (DS 41/2012) took effect in November 2012, and with it the transitional phase began. The law applies to companies that were in operation with a mineral extraction rate or benefit of over 10,000 tons per month. The transitional law was applied for two years and aimed to ensure that all companies had a valued closure plan and would present the State with a Financial Guarantee proposal. The deadline for these companies to submit their closure plan proposals was November 11, 2014.

The question then becomes; what happens now? The mine closure law states that companies must audit their closure plans every five years in order to ensure that the stipulated plans align with the operational reality and comply with the essential requirement of ensuring the chemical and physical stability of mining facilities. The reassessment therefore serves to determine if closure costs and financial guarantees are appropriate. This requirement "forces" companies to internally evaluate if the closures measures that were valued in the transitional phase are really needed to reach the target of physical and chemical stability of the mining facility.

Now is when the real challenge begins for mining operations in relation to the mine closure regulation and how to incorporate these concepts from the earliest stages of projects. By assessing risk and constantly monitoring operations, mine sites can determine which closure measures and activities are really necessary to control these risks.

To achieve this objective, the mining operation needs to make itself present. An appropriate control of mining operations (operating according to design) lowers the risks during closure.

From the physical stability point of view, a permanent geotechnical control of the mining facilities is necessary. This way, one can fix deviations produced during operation, and not when operation will be ending, which certainly will be much complex and expensive. In the same way, to achieve chemical stability, it is necessary to establish a chemical stabilization program for the mining facility to identify the potential sources of mine drainage and to work on them to finally ensure that a non-significant risk could exist once the operations have ceased.

Chemical Transformations of Metals Leaching from Gold Tailings

Bronwyn Camden-Smith, Nicole Pretorius, Anthony Turton, Peter Camden-Smith and Hlanganani Tutu
Molecular Sciences Institute, University of the Witwatersrand, South Africa

ABSTRACT

Chemical reactions that follow the release of metals from gold mine tailings in the Witwatersrand Goldfields were assessed through a combination of analytical techniques and geochemical modeling. A flow path for metal pollutants which consisted of a tailings storage facility (TSF), a rainwater runoff pond, a pollutant control dam and a wetland was considered. Water and solid samples from these features were collected and analyzed. Sequential extractions of solids were conducted to assess the chemical partitioning of metals within them. Metal content was partitioned into water and acid-soluble (readily soluble salt phases), reducible (associated with iron and manganese oxides), oxidizable (bound to organic or sulfide minerals) and residual (silicate minerals) fractions. The change in metal partitioning with increasing distance from the tailings storage facilities was found to be correlated to changes in the chemistry of water which in turn was correlated to the change in the geochemistry of solids along the flow path. Speciation-solubility, inverse and forward modeling using the PHREEQC modeling code were combined with sequential extractions and used to characterize the chemical reactions that transform the metals.

Keywords: Chemical partitioning, sequential extraction, geochemical modeling, inverse modeling

INTRODUCTION

Environmental impacts of the decant of metal-rich, sulfate-rich, low pH water from gold mine tailings around Johannesburg, South Africa have been a cause for concern for some time now (Förstner & Wittmann, 1979; Naicker, Cukrowska & McCarthy, 2003; Tutu, McCarthy & Cukrowska, 2008).

The release of metals from gold mine tailings into the environment is dependent on the mineralogy of the tailings and the association of metals with that mineralogy. Knowledge of bulk mineralogy alone does not provide an accurate indication of the potential release of metal pollutants from the tailings. Metal pollutants could exist in minor minerals that are below standard powder X-ray diffraction (PXRD) detection limits. The chemical behavior of the minerals hosting metal contaminants affects their release and mobility. A metal ion of interest, for instance, can be associated with a single mineral phase or a combination of mineral phases. Such mineral hosts include water-soluble salts, ion-exchange sites on clay minerals, carbonate minerals, adsorption on or inclusion into amorphous or crystalline iron (Fe) oxides, sulfide minerals and silicate minerals (Leinz et al., 2000). Leaching and sequential extraction techniques have been used to characterize the phase association of metals in contaminated sediments and solid waste (Rao et al., 2008). The most commonly used sequential extraction methods have been the Tessier method (Tessier, Campbell & Bisson, 1979) and the Communities Bureau of Reference method (BCR) (Rauret et al., 1999).

In this paper, the use of sequential extractions was combined with speciation-solubility and inverse modeling in order to better understand the partitioning and transport of metals emanating from gold mine tailings at a site in the West Rand of the Witwatersrand Goldfields, South Africa.

METHODOLOGY

Sampling and analysis

The study site comprised a tailings storage facility (TSF) that was undergoing reprocessing; a tailings pond which collected rainwater runoff from the TSF; a pollution control dam that encroached partially onto a reprocessed TSF and collected water from the TSF in the study; and a wetland which is adjacent to the pollution control dam wall.

Water samples were collected during the rainy season (January and March 2014). Water sampling was conducted using acid-washed and deionised water rinsed polypropylethylene bottles. Measurements of temperature, pH, Eh, electrical conductivity (EC) and dissolved oxygen were conducted in the field using calibrated field electrodes. A portion of each sample was filtered in the field using a syringe mounted with 0.45 µm polytetrafluoroethylene (PTFE) filters and acidified prior to metal analysis using inductively coupled plasma-optical emission spectrometry (ICP-OES). A separate portion was filtered in the same manner without acidification and analyzed for anion content using chemically-suppressed ion chromatography (IC). The remaining portion of sample was not filtered and was used for alkalinity determination. Alkalinity was determined using titrations with standard HCl solutions to pH 4.5 using bromocresol green and a calibrated pH electrode to detect the end-point (ASTM International, 2010).

Sediment samples were collected at the same time as water samples in March 2014. Samples with a high water content were centrifuged to extract pore water. Sediment samples were collected at the same points where water samples were collected. In the pollution control dam, there were two distinct layers in the shallow sediments that were sampled as separate samples.

The samples were dried at 35 °C. Samples were ground using a mortar and pestle to particle size <10 μm. Sequential extractions to determine metal partitioning were performed using the Communities Bureau of Reference method (BCR) (Rauret et al., 1999). Leaching solutions were shaken on an elliptical shaker for the duration recommended by the method. The BCR-701 certified reference material was used for assessment of leaching accuracy. The leaching protocol was used to determine the following environmentally important or environmentally extractable metal fractions: 1) water soluble, acid soluble and exchangeable; 2) reducible (metals associated with Fe and manganese (Mn) oxyhydroxides); 3) oxidizable (metals associated with organic matter or sulfide minerals). Acidic microwave digestion of the residues after the third leach step and of the unleached material was conducted using hydrochloric, nitric and hydrofluoric acids to dissolve the silicate matrix. Inductively coupled plasma-optical emission spectrometry was used to determine metal content in the resulting leachates and acidic solutions.

Geochemical modeling

Speciation-solubility, inverse and forward modeling were conducted using the United States Geological Survey (USGS) software PHREEQC combined with the Lawrence Livermore National Laboratory database (llnl.dat) (Parkhurst & Appelo, 1999; Charlton & Parkhurst, 2002). Speciation-solubility models are used to define the distribution of stable species in the system and to determine the saturation states of minerals within the system. In forward modeling, the final composition of a solution after a reaction or equilibration is calculated. Inverse modeling is also known as mass balance modeling and can provide a set of possible reactions that occur between two known solutions along the same flow path (Zhu & Anderson, 2002).

RESULTS AND DISCUSSION

Overview of water analysis

Table 1 summarizes the electrode measurements of the water samples taken during the two sampling sessions. The first sampling took place in the middle of the rainy season, before major thundershowers. The tailings pond samples had lower pH, elevated Eh and EC than samples taken from the same pond two months later towards the end of rainy season. The effect of pH on metal mobility was obvious for the tailings pond samples collected in January that had an average Fe concentration of 54 $mg.L^{-1}$ whereas samples collected in March had an average of 4.2 $mg.L^{-1}$. The same dilution effects are less evident in the pollution control dam samples. The results for percentage electrical charge balance (calculated using PHREEQC) are also presented in Table 1. The charge balance is a common indication of the quality of water analysis (Zhu & Anderson, 2002). Large percentage errors can indicate that a cation or anion was not analyzed for, analyzed incorrectly or that the sample was altered during transport or storage (for example, precipitation of analytes can occur). The charge balances presented in Table 1 are below 20%, with the largest deviations observed in the pollution control dam. The dam has a number of tributaries that could be contributing to various chemical processes occurring in it. Cyanide and organic matter were not

quantified in this study, but their contribution to charge balance may be significant if they are present in high concentrations. Even though the samples were filtered with 0.45 µm filter paper, several colloids are smaller than this and would be analyzed as dissolved species. This would contribute to a positive error. Colloidal aluminum (Al) is known for such behavior and the studied samples contained elevated Al concentrations.

Table 1 Summary of field measurements and PHREEQC-determined charge balance for water samples.

Location	Sample	Month	Temperature (°C)	pH	Eh (mV)	Conductivity (mS/cm)	Dissolved oxygen (mg/L)	Charge Balance (%)
Tailings Pond	TP 1	January	23.8	2.68	625	3.14	6.53	-9.9

Sequential extractions and speciation-solubility modeling

Water and sediment samples from the rainwater runoff pond adjacent to the TSF were analyzed. Speciation-modeling was conducted on water samples in Table 1. Saturation indices (SI) are an indication of a solution's saturation with respect to a mineral (Zhu & Anderson, 2002). A positive SI indicates that the mineral is supersaturated in the system and a negative SI indicates that the mineral is undersaturated. Generally, the water samples showed that most minerals dissolved in them are undersaturated with the exception of gypsum, alunite and jarosite. Gypsum ($CaSO_4.2H_2O$) was close to saturation in TP 1 and TP 2 (SI of -0.03), close to saturation in PCD 1 (SI of 0.02),

supersaturated in PCD 1 and PCD 2 (average SI of 0.10) and supersaturated in W 1 (SI of 0.11). In all other samples, gypsum was undersaturated (SI of < -0.20). Jarosite ($KFe_3(SO_4)_2(OH)_6$) was undersaturated in all of the tailings pond samples and PCDI 2, was close to saturation in PCDI 3 (SI of -0.06) and was supersaturated in all of the pollution control dam samples, PCDI 1 and wetland sample. Alunite ($KAl_3(SO_4)_2(OH)_6$) was undersaturated in all of the samples except for PCDI 1 (SI of 1.5).

The results for BCR extractions of the tailings pond sediments are presented in Figure 1. Over 90% of the total Al, calcium (Ca), potassium (K), magnesium (Mg) and sodium (Na) content is held within silicates that are in the residual phase of the extraction protocol. The residual fraction has been omitted from Figure 1 in order to clarify the partitioning of the environmentally extractable fraction (Figure 1). A significant proportion of Ca and sulfur (S) is held in the water soluble, acid soluble or exchangeable phase. This relates well with the gypsum being near to saturation within the pond (from modeling results). The environmentally extractable Al (from the first three leach steps) is equally distributed in the sediment. Most of the environmentally extractable Fe is present as a reducible phase, that is, ferric oxyhydroxides. The majority of Fe in the tailings pond water samples was speciated as dissolved ferrous iron (Fe(II)). The water samples were found to be close to saturation with atmospheric oxygen. This meant that Fe(II) in solution was oxidized by atmospheric oxygen and converted to Fe(III) which is insoluble and precipitates from solution as ferric hydroxide. The partitioning of trace elements is presented in Figure 1. Cobalt (Co), copper (Cu), Mn and zinc (Zn) were found to be largely held in the water soluble, acid soluble or exchangeable phase. This phase is likely associated with sulfate salts owing to the abundance of sulfates due to AMD. From modeling results, the sulfate salts of these elements were undersaturated in the pond water samples. The saturation indices are calculated for pure end members (Zhu & Anderson, 2002). The minerals present in the system are likely to be solid solutions and will have different thermodynamic properties. Less than 10% of the environmentally extractable fraction of Cd, Co, Mn, U and Zn was associated with reducible Fe oxyhydroxides. There was a strong association of Cr, Cu and Li with the reducible Fe oxyhydroxides (greater than 18%), likely through adsorption on the surface or through incorporation of solid solutions within the lattice. A significant proportion (> 40%) of the trace metals cadmium (Cd), Co, Cu, uranium (U) and Zn extracted from the first three leaches were associated with oxidizable phases. These phases could include organic material, sulfide minerals and possibly strong cyanide complexes.

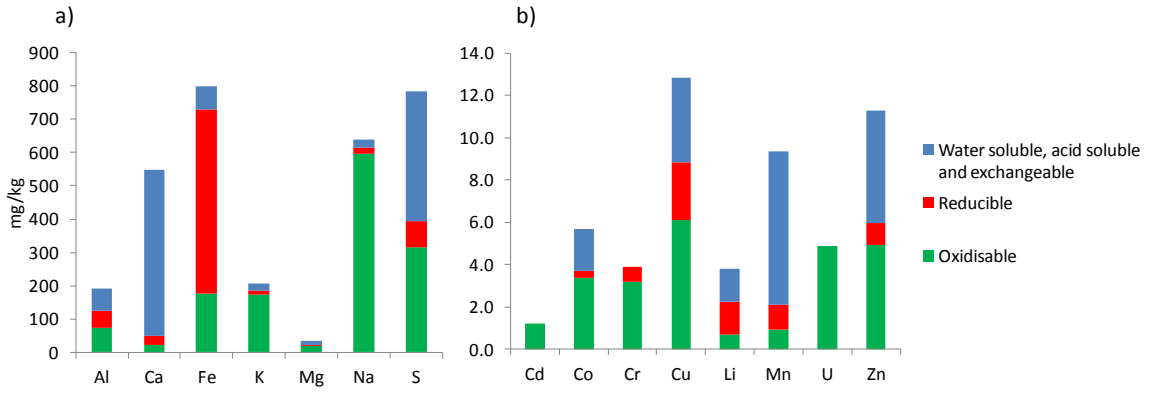

Figure 1 a) Major metal and sulfur partitioning within tailings pond sample. b) Minor metal partitioning within tailings pond sample.

Sequential extractions and inverse modeling

The pollution control dam will be used an example of how the use of sequential extractions can help in mineral selection for inverse modeling.

Modeling results showed that water sample PCD 3 was almost saturated with gypsum (SI of -0.27). Iron was found to be in ferrous (85%) and ferric (15%) form at the measured Eh. The presence of soluble ferric phases led to higher saturation indices of these phases. For instance, $Fe(OH)_3$ had an SI of -2.2; goethite was supersaturated; Na jarosite ($NaFe_3(SO_4)_2(OH)_6$) was saturated (SI of 0.0); and K jarosite ($KFe_3(SO_4)_2(OH)_6$) was supersaturated (SI of 3.4). The results for partitioning of elements in sediments collected at the pollution control dam are presented in Figure 2. The results showed elevated concentrations of Fe in the reducible phase (largely Fe oxyhydroxides), and this corresponded with the characteristic reddish-orange color of the sediments. A large proportion of Cd, Cr, Cu and Mn were associated with the reducible phase in these sediments (Figure 2). In the rainwater runoff pond, Mn and Cu were associated with the water soluble acid soluble or exchangeable phase; Cd, Co and a small proportion of Cu were associated with the oxidizable phase; and Cr was associated with the residual phase (Figure 1). These results suggest that the metals could be readily released from the runoff pond, adsorbing onto Fe oxyhydroxides along the flow path and deposited in the pollution control dam. The contribution of leachates from a municipal waste site is not apparent as sampling at that site could not be conducted.

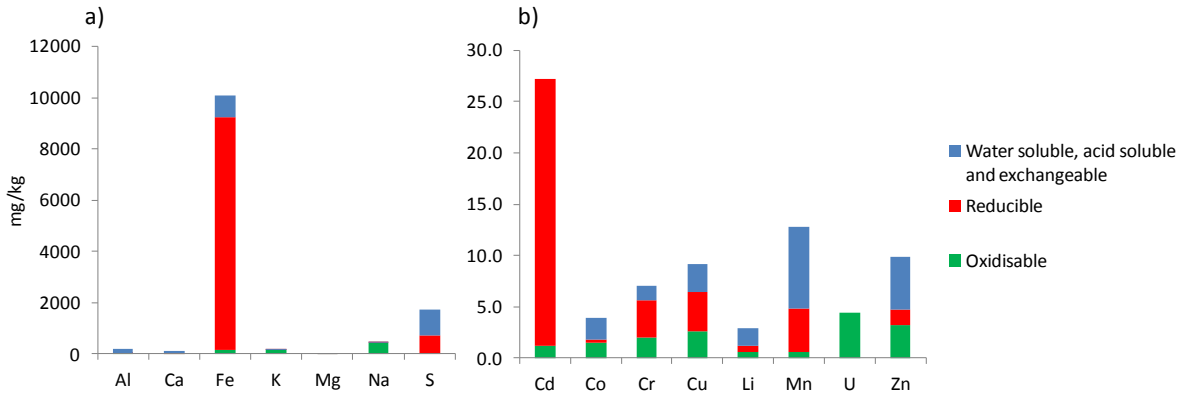

Figure 2 a) Major metal and sulfur partitioning within upper pollution control dam sediments. B) Minor metal partitioning within upper pollution control dam sediments.

To gain further insight into metal partitioning in the sediments, some inverse models were used. One such model generated the pollution control dam sample (PCD 3) from mixing the three incoming water types. The main aim was to identify minerals that would precipitate from this process and correlate these to the phases observed in sequential extractions. The minerals that were chosen as phases of interest were selected from the sequential extraction results of the upper sediments sample presented in Figure 2. The following minerals were selected as phases: $Fe(OH)_3$, gypsum ($CaSO_4.2H_2O$), $Mn(OH)_2$, epsomite ($MgSO_4$), $NiSO_4$, $ZnSO_4$ and bieberite ($CoSO_4.7H_2O$). Chloride and Na were regarded as conservative elements while water vapor was used in the simulation to allow for the impact of evaporation. Several potential models were generated. The

general trend in the models was a large contribution from PCDI 3, a smaller contribution from PCDI 1 and a negligible contribution from PCDI 2. A minimal phase model is presented in Table 2. The solution mixing fractions were: PCDI 1 (0.340), PCDI 2 (0.069) and PCDI 3 (0.840). The mixing of the different solutions generated a solution with a mass of 1.25 kg. An amount of 250 g of water vapor was allowed to exit the system, resulting in 1.00 kg remaining. The negative sign for gypsum in Table 2 indicates that the mineral precipitated out of the solution while a positive sign as in the case of $Fe(OH)_3$ indicates that the mineral dissolved into the solution. Thus, the pollution control dam sample was undersaturated with respect to $Fe(OH)_3$. Given the high concentration of ferric oxyhydroxide in the upper sediments of the dam, it is possible that $Fe(OH)_3$ was in the process of being released from the sediments.

Table 2 Phase mole transfers between a mixture of pollution control dam inlet streams and pollution control dam water.

Phase	Mole transfer
$Fe(OH)_3$	3.04×10^{-4}
Gypsum	-2.35×10^{-3}
$Mn(OH)_2$	-4.01×10^{-4}
Epsomite	-3.43×10^{-3}
NiSO4	-6.56×10^{-5}
ZnSO4	-3.38×10^{-5}
Bieberite	-2.61×10^{-5}
$H_2O(g)$	-138

Since inverse models are based on mass balance principles only and do not take into account mass action principles, forward modeling can be used to test whether the results from an inverse model are thermodynamically possible. The inverse model presented above was tested using non-equilibrium and equilibrium approaches. The non-equilibrium approach forces the precipitation and dissolution of minerals (by disregarding their saturation indices). The equilibrium approach only dissolves minerals that are undersaturated in solution and only precipitates minerals that are supersaturated. A comparison of the final modeled results with the experimental solution is presented in Table 3. In the equilibrium model, no minerals precipitated as they remain undersaturated in solution. Therefore, there are higher elemental concentrations and a correspondingly higher ionic strength than for the other two solutions.

Table 3 Comparison of an experimental solution, non-equilibrium and equilibrium forward-modeled solutions.

Parameter	Experimental solution	Non-equilibrium model	Equilibrium model
pH	2.7	2.78	2.92
pe	11.4	12.5	12.4
Ionic strength	0.065	0.068	0.079
Elemental concentrations (mol.kg^{-1})			
Al	6.68×10^{-3}	5.58×10^{-3}	5.57×10^{-3}
Ca	1.02×10^{-2}	0.90×10^{-2}	1.14×10^{-2}
Cl	1.02×10^{-3}	1.14×10^{-3}	1.14×10^{-3}
Co	6.49×10^{-5}	6.48×10^{-5}	9.09×10^{-5}
Cu	3.38×10^{-5}	2.85×10^{-5}	2.85×10^{-5}
Fe	2.30×10^{-3}	1.95×10^{-3}	1.94×10^{-3}
K	2.49×10^{-4}	3.02×10^{-4}	3.02×10^{-4}
Mg	3.60×10^{-3}	3.47×10^{-3}	6.90×10^{-3}
Mn	3.30×10^{-4}	3.30×10^{-4}	7.31×10^{-4}
Na	1.27×10^{-3}	1.28×10^{-3}	1.28×10^{-3}
Ni	1.27×10^{-4}	1.27×10^{-4}	1.92×10^{-4}
S	2.47×10^{-2}	2.91×10^{-2}	3.50×10^{-2}
U	5.63×10^{-6}	4.61×10^{-6}	4.60×10^{-6}
Zn	1.19×10^{-4}	1.19×10^{-4}	1.53×10^{-4}

CONCLUSION

This study has shown that partitioning of metals within various mineralogical phases in gold mine wastes exerts control over their release and transport to the surroundings. From sequential extraction and geochemical modeling, processes such as dissolution, precipitation, ligand complexation, adsorption and desorption were shown to be important. These processes were apparent when metals in the runoff pond were shown to be essentially in oxidizable phases while a short distance further in the pollution control dam they were found to be held in reducible phases. Combining sequential extractions with geochemical modeling provides insight into the water-solid interactions. Model simulations depicted elemental speciation (through speciation-solubility models) and the likely partitioning within the mineral phases (through inverse models). The simulations were also useful in predicting minerals that would precipitate when various water types are mixed.

ABSTRACT

Attenuation of uranium (U) and rare earth elements (REEs) has been observed in stream and wetland sediments, but the geochemical and mineralogical processes involved in sequestering these elements in natural systems are not fully understood. The decommissioned Bicroft Uranium Mine near Bancroft, ON, operated from 1957 to 1963, and processed approximately 2,284,421 tonnes of low-grade, disseminated U ore hosted by pegmatite dykes in amphibolite gneiss. During operations, the mine used two tailings impoundments and a modified stream and wetland system to reduce the concentrations of U, other metals, and radionuclides in tailings effluent to levels below the Provincial Water Quality Objectives. Since mine closure, the streams and wetland have continued to operate as a passive treatment system for tailings effluent, demonstrating the potential viability and longevity of natural attenuation to sequester U and REEs. In this study, we used tangential flow filtration, ICP-ES/MS, scanning electron microscopy, and synchrotron techniques (bulk- and micro-XANES, -XRF, and -XRD) to characterize processes controlling U and REE mobility and attenuation in tailings, sediment, and colloid samples. Results of this study indicate that Fe- and Mn-(oxyhydr)oxides, including goethite [α-FeO(OH)] and birnessite (δ-MnO_2), are the main mineral hosts for U and REEs in colloids and sediments. In addition, detrital grains of U- and REE-bearing minerals were found >200 m downstream in colloids and sediments, showing the potential for long-range transport of colloids and fine particulates in the stream system. While natural attenuation exhibits great potential to reduce U- and REE- concentrations, seasonal influences on the stability of trace metals in sediments were observed and may demonstrate the limitations of streams and wetlands as a viable method of attenuation. The results of this study are intended to aid development of more effective passive treatment systems and improve environmental monitoring strategies for U and REEs.

Keywords: Uranium, rare earth elements, synchrotron micro-analysis, colloids, passive attenuation

INTRODUCTION

The decommissioned Bicroft Uranium Mine is located 19 km southwest of Bancroft, Ontario, Canada in granitic pegmatites (ca. 1020 to 1050 Ma) of the Grenville Geological Province (Evans 1962; Lentz 1996), (Lat. 44°59'30.39"N, Long. 78°2'16.83"W). Since the closure of the mine in 1963, following seven years of operation, the Bicroft site has acted as a passively attenuating stream and wetland system to achieve below-Provincial Water Quality Objectives (PWQOs) for uranium (U) and other trace metals (MOE 2003). The two decommissioned tailings impoundments at the Bicroft Mine, Auger Lake and South Tailings Basin, drain through an approximately 1 km tributary stream and wetland system, to Deer Creek, before being discharged to Paudash Lake where the waters are required to meet PWQOs (MOE 2003). The environmental conditions and geochemical processes that control the mobility of metals and radionuclides at the Bicroft site are poorly understood. Specifically, the methods by which U and rare earth elements (REEs) are released from the tailings basins and then partially sequestered in the stream and wetland system are unknown.

In effluent released from mine tailings, trace metals and other contaminants are generally partitioned between particulate matter, colloids, and dissolved phases. In most studies of natural water systems colloidal material is considered part of the dissolved fraction (<0.45 μm), and any particles unable to pass through a 0.45 μm filter are considered to be suspended particulate matter. Colloids, in aqueous systems, are any suspended material with a single linear dimension between 0.001 μm and 1 μm. Colloids have large surface-area-to-volume ratios due to their small size, which provides increased sites for reactivity and heightened surface charge allowing for high adsorption capacity (Klaine *et al.* 2008). The large surface area of colloidal particles relative to their mass allows for particles to overcome gravitational forces and to remain in suspension in waters of varying velocities, and travel significant distances (1 km to >500 km), until flocculation of colloidal material results from changes in the solution chemistry and the colloids settle from solution (Kersting *et al.* 1999; Kretzschmar and Schäfer 2005; Wigginton *et al.* 2007).

The natural attenuation of U from mine wastes has been observed in other studies of stream and wetland sediments by Schöner *et al.* (2009) in Germany, Veselic *et al.* (2001) in Slovenia, Groudev *et al.* (1999) in Bulgaria, and Lottermoser and Ashley (2005) in Australia. These studies suggest that U is primarily attenuated in Fe- and Mn-oxyhydroxides and natural organic matter; however, the host mineralogy of U was undetermined. The natural attenuation of REEs has been observed in other studies that focused on the use of REEs as a tracer for geochemical processes by relating the absolute and relative concentrations of REEs to a variety of environments (Goldberg *et al.* 1963; Quinn *et al.* 2006). However, the release of lanthanides from mine waste through weathering processes, and their environmental impacts and toxicity once released into aqueous solution, have not been fully characterized. Previous studies have determined that REEs are mobilized under acidic conditions, and precipitated or otherwise sequestered at high pH conditions (Brookins 1989; Verplanck *et al.* 2004). In addition, REEs are known to readily complex with various ligands in the aqueous environment and are often associated with particulate matter and organics in shallow surface waters (Cantrell and Byrne 1987). Critical gaps remain in our knowledge of the host mineralogy and the processes involved in sequestering U and REEs in complex field systems (Brookins 1989; Schöner *et al.* 2009).

This study focuses on understanding the mineralogical and geochemical controls that influence the mobilization, sequestration, and stability of U and REEs (specifically, cerium (Ce) and lanthanum (La)) in sediments of a stream and wetland system sourced by effluent from a U tailings

impoundment at the Bicroft Mine. The passive treatment system has been in operation for over 50 years and thus provides an ideal natural laboratory to study the processes involved in attenuating these trace elements and the long-term effectiveness of this method of pollution control (Parsons *et al.* 2014). Detailed characterization of tailings, colloids, and stream and wetland sediments through field observations, bulk chemistry, and mineralogical observations from scanning electron microscopy and synchrotron micro-analyses were used to identify the main sources for U and REE within the tailings and their attenuation and stability in downstream environments. The results of this study will help to develop better monitoring strategies for U tailings sites and should reduce the impacts of future U and REE mining operations.

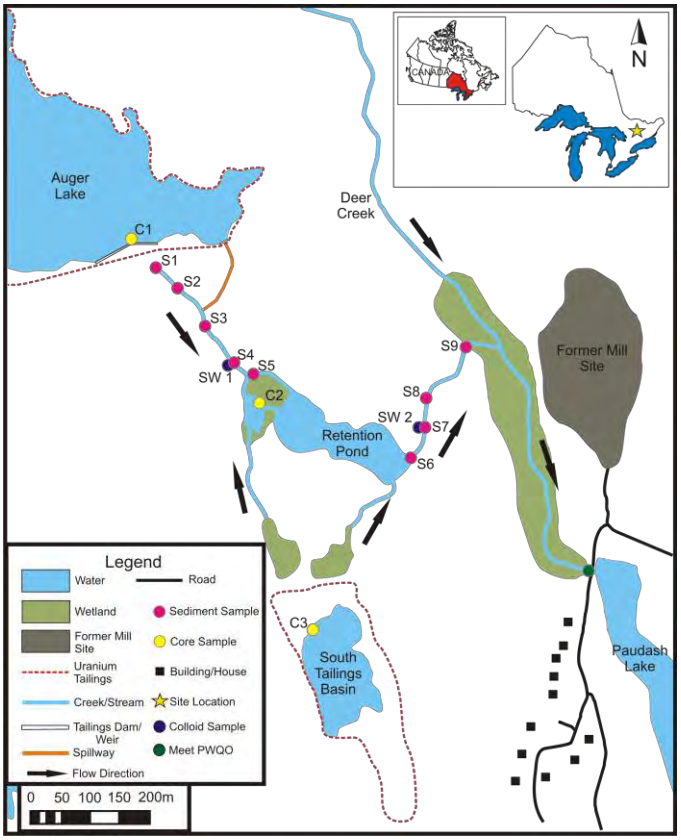

Figure 1 Bicroft Mine site map with field sampling locations of bulk sediment (pink), core (yellow) samples, and surface water (blue) samples. All samples were collected in October 2011, with the exception of a second set of surface water samples in July 2012. PWQOs are to be met at the discharge point of Deer Creek to Paudash Lake (green).

METHODOLOGY

To characterize the chemical and mineralogical controls by which U, La, and Ce are sequestered, 15 bulk samples of hardpan, pebbles, streambed sediments (S1-S9), and tailings were collected in October 2011 from the tributary stream and wetland system, and tailings basins (Figure 1). In addition, two sediment cores were collected in the Auger Lake tailings basin (C1) and Retention Pond (C2) to examine the effect of redox conditions on the mobility and attenuation of U (Figure 1). Surface water sampling was conducted in October 2011 and July 2012 to account for any seasonal changes in water composition. Two water samples were collected in each field season, with a

sample both upstream and downstream of the Retention Pond, identified as SW1 and SW2 respectively, to determine whether this pond was removing colloids from solution. Tangential flow filtration (TFF) was applied to analyze the colloid fraction from the stream waters at the two locations, using a Millipore Prep/Scale Spiral Wound Ultrafiltration Cartridge. Within 48 hours of collection, the water samples were filtered through a 0.557 m^2 (6 ft^2) TFF cartridge with a 10 kdalton (0.005 μm) filter cut off. The <10 kdalton permeate from the TFF system is assumed to represent the dissolved fraction of the sample (Guegon *et al.*, 2002). The retentate, with a size fraction between 0.45 μm and 10 kdaltons, contains the colloid fraction from the water (Guegon *et al.*, 2002). For further information regarding sample collection and preparation please refer to Laidlow (2013).

Bulk chemistry and X-Ray diffraction (XRD)

Ultra-trace analysis for a 43-element suite plus 12 REEs by inductively coupled plasma-mass spectrometry (ICP-MS) (package 1T-MS), following 4-acid digestion, was completed at ACME Analytical Laboratories on all bulk sediments and sub-samples from sediment cores. Additionally, two samples were re-analyzed by inductively coupled plasma-emission spectrometry (ICP-ES) after 4-acid digestion (package 7TD) to determine the percent-level concentrations of manganese (Mn). To identify the major crystalline phases present in the samples, X-ray diffraction (XRD) was completed using the Philips X-Pert diffractometer at Queen's University.

Petrographic analyses and synchrotron micro-analysis

Thin sections were examined optically under the petrographic microscope and characterized using a scanning electron microscope at Queen's University. Two hard X-ray microprobe synchrotron beamlines were used for trace element micro-analysis: X26A at the National Synchrotron Light Source in Upton, New York and Sector 20-ID beamline at the Argonne Photon Source in Argonne, Illinois. Micro X-ray radiation fluorescence (μXRF) mapping and micro X-ray diffraction (μXRD) analyses were conducted at both beamlines, and bulk- and micro-X-ray absorption near edge structure (XANES and μXANES) were conducted at the Sector 20-ID beamline.

RESULTS AND DISCUSSION

Characterization of U and REEs in colloids

During the process of TFF, orange-yellow staining of the ultrafiltration cell was observed for upstream (SW1) water samples. Calculated filter losses are shown in Figure 2. In both the October and July sampling, there were significant losses of iron (Fe) and aluminium (Al), as well as all REEs in the SW1 samples (Figure 2). This demonstrates that these waters were not fully oxidized when sampled and were further oxidized during the filtration process, causing Fe and Al phases to precipitate onto the filter along with their associated REEs.

In Figure 3 it can be seen that U and Mn were present mainly in the dissolved phase, Ce, La, Fe, and Al were present in both the colloidal and dissolved phases, with high proportions of Ce and La in the colloidal phase. This diagram also shows the importance of documenting seasonal variations at sample locations.

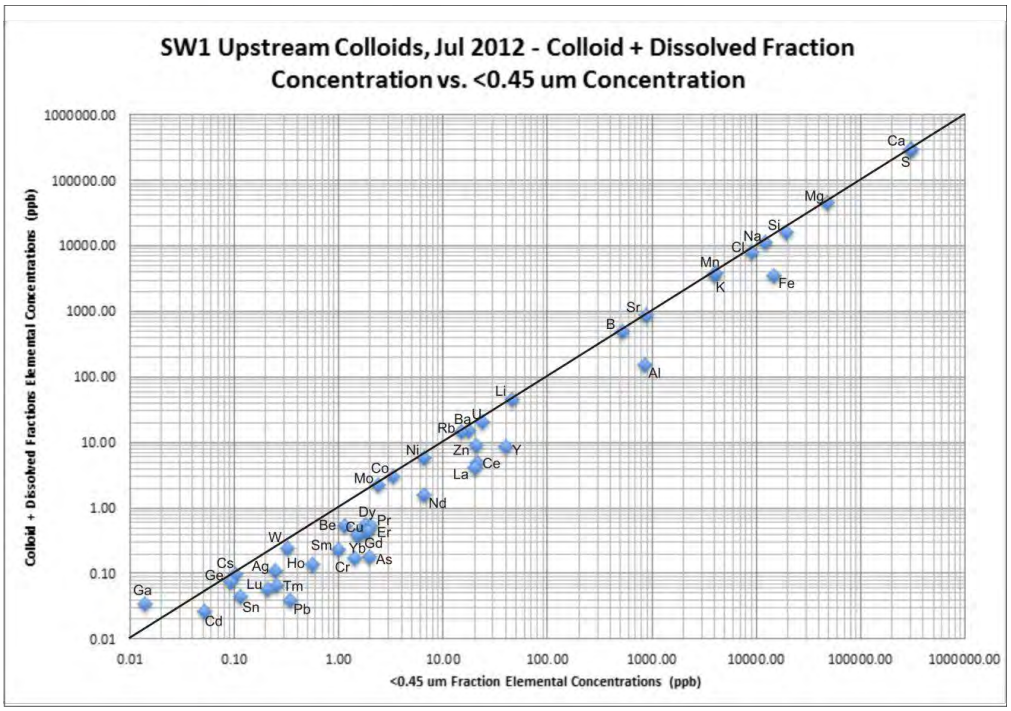

Figure 2 Correlation plot of calculated colloid + dissolved fraction elemental concentrations (ppb) vs. <0.45 µm elemental concentrations (ppb) for SW1 surface water sample from July 2012. Black line represents a 1:1 ratio of concentrations and no element retention on the filter. Elements plotting below the line show greater concentrations in the initial <0.45 µm water sample than in the combined colloid + dissolved aliquots suggesting a loss due to retention on the filter cartridge. Precision is within 5% for most samples, which is represented by the size of each point on the graph.

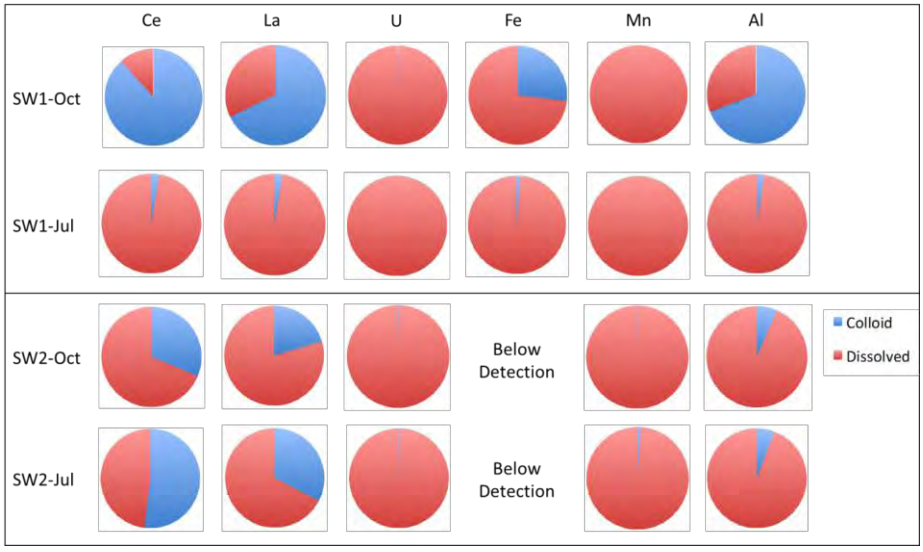

Figure 3 Relative % of Ce, La, U, Fe, Mn, and Al in colloid (blue) and dissolved (red) fractions from TFF.

Lanthanum and Ce were present in both the colloid and dissolved phases, with the greatest relative percent of colloids observed in the SW1-October 2011 sample (Figure 3). Uranium, however, was

predominantly found in the dissolved phase, with less than 1% of its total concentration in the colloid fraction for all samples. This observation is consistent with the results of aqueous speciation modeling by Parsons *et al*. (2014), which demonstrated that >95% of U in the tailings effluent at the Bicroft site occurs as calcium-uranyl-carbonato complexes, which are known to diminish the sorption of U to mineral surfaces and suppress the reduction of U(VI) to the less soluble U(IV).

In the SW1 samples, Al and La showed similar relative percentages in the colloid and dissolved fractions. Concentrations of U and Mn in the dissolved and colloidal fractions showed little variation between the October and July samples. The variance between the SW1 results in October 2011 and July 2012 may be explained in part by dilution of the July 2012 sample by heavy rainfall the day before sampling occurred (Laidlow 2013).

Iron and Mn-oxyhydroxides

Good correlations between Fe and REEs, and Mn and REEs, were observed in the XRF maps (Figure 4), and Fe XANES results suggest a strong association with Fe-oxyhydroxides. At the SW1 (upstream) location, goethite and lepidocrocite dominated the mineralogical composition of the colloids, and at the SW2 (downstream) location, hematite, ferrihydrite and lepidocrocite were the dominant REE-hosting minerals (Figure 5). The observed change in mineralogical composition between SW1 and SW2 may reflect kinetic controls on the formation of Fe-oxyhydroxide minerals in the stream. Hematite is kinetically unlikely to form in solution, but may have formed through dehydration and recrystallization of goethite and ferrihydrite.

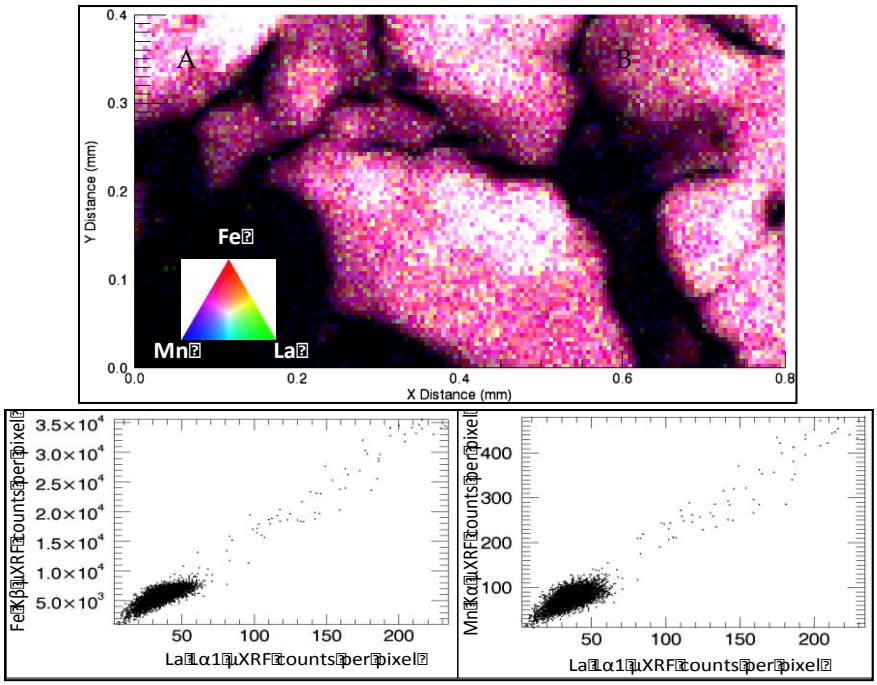

Figure 4 µXRF element map and associated element correlation plots for REEs on colloid sample SW1 – October 2011. Element counts are directly proportional to element concentrations (Jamieson and Gault, 2012).

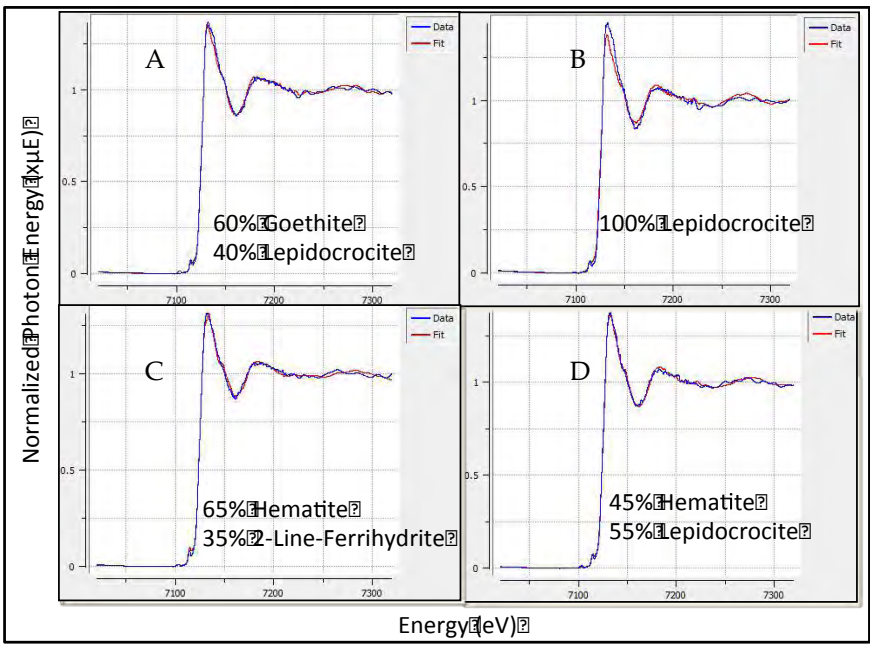

Figure 5 Fitted Fe μXANES collected from SW1 and SW2 colloid samples from October 2011. Background subtracted Fe μXANES collected on 2 targets from SW1 (A and B) and 2 targets on SW2 (C and D) were fitted using the standard reference μXANES patterns for 14 Fe minerals. The blue lines represent the collected, background subtracted scan for the sample and red lines represent the fit of the standard reference scans to the data.

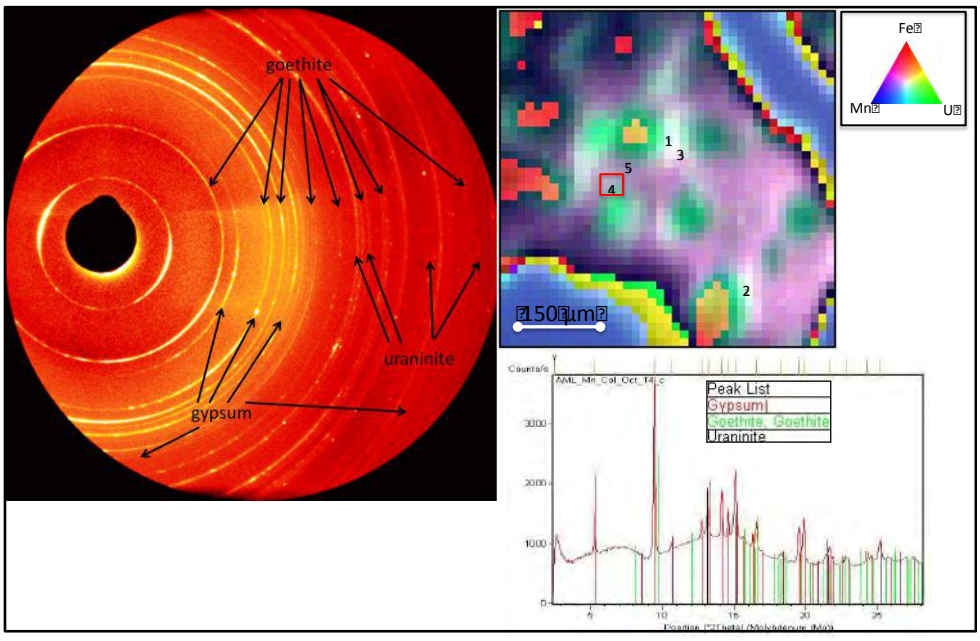

Figure 6 2D μXRD image showing Debye-Scherrer rings for goethite, gypsum and uraninite and corresponding target location on the tricolor μXRF map of the SW2 – October 2011 sample. Mixtures of red, blue and green imply a mixture of Fe, Mn and U.

XRF element mapping, in Figure 6, shows a good correlation between Mn and U only at low concentrations. At higher U concentrations, U shows poor correlations with both Fe and Mn,

suggesting that U is primarily hosted by nanoparticulate ore minerals, rather than secondary Fe- and Mn-oxyhydroxides.

Uraninite

Uraninite (UO_2) was identified in the SW2 colloid sample using μ-XRD (Figure 6). This is most likely a detrital phase, as UO_2 is a primary ore mineral in the Bicroft deposit and is not likely to precipitate from the relatively oxidized tailings effluent. Furthermore, other high-U targets from XRF mapping showed no discernable XRD pattern, but bright spotty images, which are associated with micro-analysis of nano-crystalline particles larger than the spot size of the synchrotron beam. Micro-XANES analyses of colloids with high U and low Fe and Mn concentrations showed that most U was present as U(IV), providing further evidence for detrital U grains in the colloid fraction. This observation is important, as detrital UO_2 transported downstream may oxidize to U(VI) over time, enhancing both the mobility and potential toxicity of this contaminant in the surrounding environment.

Characterization of U and REEs in sediments

Primary grains of UO_2 were identified in the grey, unoxidized section of the tailings core, in sediments downstream in the upper portion of the tributary stream, and in the Retention Pond sediments. The presence of these detrital, nanoparticle-size, grains downstream of the tailings impoundments is important, as they may be a source of further contamination if not maintained in the reduced state. From analysis of the colloids and fine tailings located immediately near the outlet of the tailings dam, it is clear that these UO_2 grains are mobilized from the tailings impoundments and released into the stream and wetland system through effluents.

Generally, most U was present as U(VI) in bulk stream sediments; however both U(IV) and U(VI) were present below the Retention Pond. Variation in the amount of U(IV) and U(VI) present depended on the local mechanism of attenuation. While goethite, maghemite, and lepidocrocite were the predominant Fe-oxyhydroxide minerals observed upstream of the Retention Pond, downstream of the Retention Pond a notable change in the predominant Fe-oxyhydroxide mineralization in stream sediments, to hematite, ferrihydrite and lepidocrocite, was observed. The presence of goethite and lepidocrocite above the Retention Pond is likely related to the relatively rapid precipitation of these phases from tailings pond effluent. Hematite however, is generally formed as a secondary mineral due to the internal rearrangement and dehydration of precipitated goethite, ferrihydrite and lepidocrocite. Uranium adsorbed to these Fe-oxyhydroxides may undergo reduction through dehydration or incorporation into the crystal structure by recrystallization, increasing the relative proportion of U(IV) in these sediments (Marshall *et al.* 2014).

CONCLUSION

The release of U and REEs from U mine wastes into surface waters is of concern for water quality, and the health of humans, organisms, and the surrounding environment. At the Bicroft Mine, an enhanced natural stream and wetland system has passively attenuated these elements of concern from tailings effluents for over 50 years, and sequestered these contaminants into local stream and wetland sediments. If the sediments and adsorbed species in this stream and wetland system

remain undisturbed, U and REEs sequestered in these sediments could be immobilized for many years. The results of this research have led to the following five main conclusions:

- The release of U, Ce, and La into the tributary stream and wetland system is associated with both oxidative and reductive dissolution of tailings within the impoundments, and subsequent release in mine tailings effluent;
- Colloids in the stream and wetland system are dominantly composed of Fe-oxyhydroxides;
- Detrital grains of UO_2 are present in the colloid fraction above the Retention Pond;
- REE-hosts in stream and wetland sediments are primarily composed of Fe- and Mn-oxyhydroxides, while U is present mainly in the dissolved phase;
- After 50 years, the stream and wetland at the Bicroft Mine continue to be an effective passively attenuating remediation system for effluent from low-grade U mine tailings.

ACKNOWLEDGEMENTS

This work was partially funded by Environmental Geoscience Program of the Earth Science Sector at Natural Resources Canada. The authors would like to thank Andrew Gault, Tony Lanzirotti (NSLS), and Robert Gordon (APS) for the many conversations regarding the preparation, use and collection of data from synchrotron facilities. Copper Toxicity and Organic Matter: Resiliency of Watersheds in the Duluth Complex, Minnesota, USA

Nadine Piatak, Robert Seal, Perry Jones and Laurel Woodruff
U.S. Geological Survey, USA

ABSTRACT

We estimated copper (Cu) toxicity in surface water with high dissolved organic matter (DOM) for unmined mineralized watersheds of the Duluth Complex using the Biotic Ligand Model (BLM), which evaluates the effect of DOM, cation competition for biologic binding sites, and metal speciation. A sediment-based BLM was used to estimate stream-sediment toxicity; this approach factors in the cumulative effects of multiple metals, incorporation of metals into less bioavailable sulfides, and complexation of metals with organic carbon.

For surface water, the formation of Cu-DOM complexes significantly reduces the amount of Cu available to aquatic organisms. The protective effects of cations, such as calcium (Ca) and magnesium (Mg), competing with Cu to complex with the biotic ligand is likely not as important as DOM in water with high DOM and low hardness. Standard hardness-based water quality criteria (WQC) are probably inadequate for describing Cu toxicity in such waters and a BLM approach may yield more accurate results. Nevertheless, assumptions about relative proportions of humic acid (HA) and fulvic acid (FA) in DOM significantly influence BLM results; the higher the HA fraction, the higher calculated resiliency of the water to Cu toxicity. Another important factor is seasonal variation in water chemistry, with greater resiliency to Cu toxicity during low flow compared to high flow.

Based on generally low total organic carbon and sulfur content, and equivalent metal ratios from total and weak partial extractions, much of the total metal concentration in clastic streambed-sediments may be in bioavailable forms, sorbed on clays or hydroxide phases. However, organic-rich fine-grained sediment in the numerous wetlands may sequester significant amount of metals, limiting their bioavailability. A high proportion of organic matter in waters and some sediments will play a key role in the resiliency of these watersheds to potential additional metal loads associated with future mining operations.

Keywords: baseline characterization, mineral deposits, water quality criteria, Biotic Ligand Model

INTRODUCTION

The characterization of baseline conditions in unmined mineralized watersheds of the Mesoproterozoic Duluth Complex, northeastern Minnesota (Figure 1), is essential to responsible extract minerals from a region with some of the greatest mineral development potential in the United States. Mining has the potential to release metals into watersheds that already contain ecologically-significant naturally-occurring concentrations of some elements such as Cu and nickel (Ni). The potential for metals to be toxic to aquatic organisms is influenced by the amount of organic carbon in the aquatic environment, the cumulative effects of multiple metals, cation competition for biologic binding sites, and speciation of metals. As a result, we estimated toxicity in mineralized watersheds using approaches that incorporate these water and sediment quality parameters.

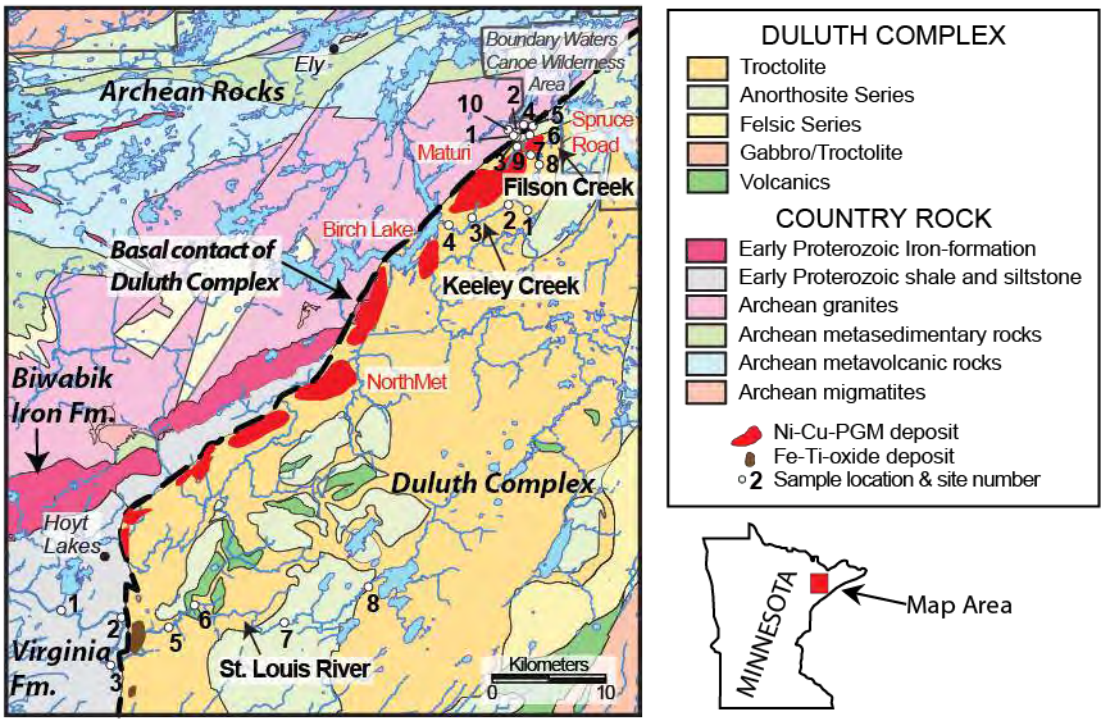

Figure 1 Bedrock geology, mineral deposits, and sample locations in northeastern Minnesota.

Surface-water and streambed-sediment samples shown in Figure 1 were collected from sites along three geologically distinct watersheds: 1. Filson Creek, where Cu-Ni-PGM (Platinum Group Metal) mineralization occurs at the bedrock surface along the basal Duluth Complex; 2. Keeley Creek, where Cu-Ni-PGM mineralization occurs only at great depth; and 3. the headwaters of the St. Louis River in the vicinity of iron (Fe) and titanium (Ti) oxide ultramafic intrusions, which occur in the subcrop beneath glacial cover. The headwaters of the St. Louis River are upstream of drainage from the taconite mining. Samples were collected in watersheds characterized by abundant wetlands, and some lakes and streams. Filson and Keeley creeks have smaller flows compared to the St. Louis River, which is a significantly larger river system. The watersheds are characterized by times of relatively low baseflow during the hot and dry late summer and early fall and again during winter

when creeks and rivers are ice-covered. Medium to high flow rates occur following storms, generally wet periods, and snowmelt, commonly in the spring and early summer.

METHODOLOGY

Surface-water and streambed-sediment samples were collected during September 2012 under baseflow conditions and surface waters were resampled during June 2013 (at medium-high flow), September 2013 (near baseflow), and April 2014 (near peak flow). In Figure 2, the daily mean discharge and instantaneous flow for the separate sampling events are shown for site 6 in the St. Louis River. Sampling locations included 10 sites in Filson Creek, 4 sites in Keeley Creek, and 7 sites in the St. Louis River (Figure 1); however, not every site was sampled during each sampling event.

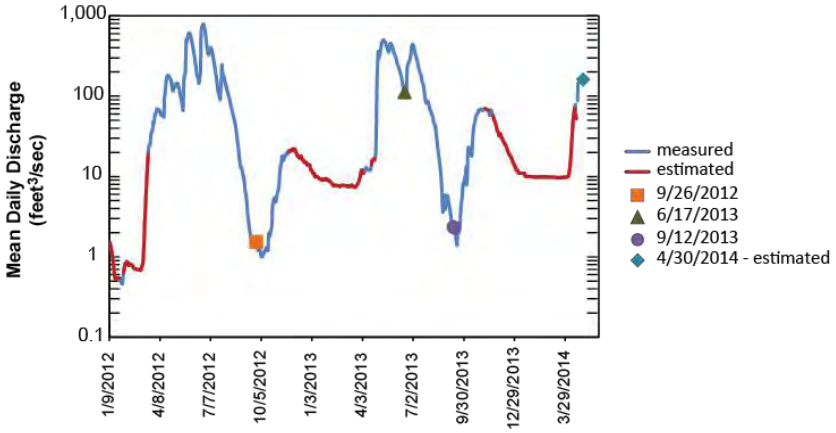

Figure 2 Daily mean discharge for St. Louis River, site 6, from http://waterdata.usgs.gov/nwis. Instantaneous discharge measured during sample collection shown as discreet symbols.

Surface-water samples were collected using United States Geological Survey (USGS) protocols (Wilde & Radtke, 1998; Wilde et al., 1999).Water quality parameters (e.g., pH, water temperature) were determined by discrete measurements at the time of water sample collection. Water samples included a less than 0.45 μm filtered (dissolved) sample and an unfiltered (total) sample. Major ions and trace elements in filtered and unfiltered surface waters acidified with ultrapure nitric acid were analyzed using inductively coupled plasma-atomic emission spectroscopy (ICP-AES) and inductively coupled plasma-mass spectrometry (ICP-MS) (Taggart, 2002). Major anions were analyzed on non-acidified filtered splits using ion chromatography (Taggart, 2002). Samples were analyzed for alkalinity on non-acidified filtered splits by titration; dissolved organic carbon (DOC) was measured by infrared spectrometry on filtered samples preserved with trace element grade hydrochloric acid (Taggart, 2002).

Composite streambed-sediment samples were collected according to USGS protocols (Shelton & Capel, 1994). Sediments were composites of approximately 30 surface subsamples collected in a grid pattern. The composite was homogenized and then sieved to a diameter of less than 2 mm. Samples were analyzed for total concentrations of major and trace elements using a combination of ICP-MS and ICP-AES following acid digestion using a mixture of HCl-HNO_3-$HClO_4$-HF. Total organic carbon is calculated as the difference between total carbon and carbonate carbon, which were determined using an elemental analyzer and coulometric titration, respectively. In order to

determine elements not tightly bound to silicates, partial extractions were conducted using HCl-H_2O_2 and a Diisobutyl Ketone (DIBK) solution; extracted metal concentrations were determined by ICP-AES. (For details regarding previously mentioned analytical methods for sediments see: http://minerals.cr.usgs.gov/projects/analytical_chem/references.html). Samples were also analyzed for acid volatile sulfide - simultaneously extracted metals (AVS-SEM) using a procedure modified after United States Environmental Protection Agency (USEPA, 1991). The AVS is operationally defined here as the sulfide fraction released by extraction with 1.2 N HCl at approximately 80º C; the metal fraction released during the AVS extraction is the SEM.

RESULTS AND DISCUSSION

Water and sediment chemistry

The geochemistry of the surface waters and stream sediments reflects underlying rock types, glacially transported unconsolidated materials, mineralization style within each watershed, and geochemical processes occurring in the streams. The water chemistry is also influenced by the ambient and flow conditions and therefore changes daily and seasonally. In general, the surface water is oxic, near neutral to slightly acidic (pH 5.0 to 7.6), has low total dissolved solids (38 to 110 mg/L), and is characterized by low hardness (10 to 53 mg/L $CaCO_3$), moderate carbonate species concentrations (4 to 44 mg/L $CaCO_3$ as bicarbonate), low sulfate (< 0.8 to 3.1 mg/L), and high DOC concentrations (18 to 47 mg/L) (Figure 3). The dominant dissolved trace elements are Fe (400 to 4,000 µg/L), Al (59 to 320 µg/L), Cu (< 0.8 to 9.6 µg/L), and Ni (0.6 to 7 µg/L).

For each specific sampling event, the average pH values are slightly lower and Cu and Ni concentrations are higher in water samples collected from the Filson Creek watershed, where the basal contact of the Duluth Complex is exposed. In contrast, the concentrations of major cations such as Ca and Mg, and, thus, hardness, as well as alkalinity are commonly highest in the St. Louis River for each sampling event compared to the other watersheds. Dissolved organic carbon is found in similar ranges of concentrations for all three watersheds during all sampling events, with a few exceptions; sulfate is generally low (Figure 3).

In addition to variation among watersheds, the chemistry of the streams changes with flow. Water samples collected during medium-high and peak flows (June 2013 and April 2014) are slightly more acidic, less alkaline, and generally more dilute with lower concentrations of some major and trace elements including Ca, Fe, Mg, and Na compared to water samples collected during low flow (Figure 3). Lower dissolved concentrations of elements are consistent with dilution after rainstorms or periods of snowmelt. However, despite generally more dilute conditions, the amount of dissolved elements (load) transported by the stream is greater under high flow conditions relative to low flow conditions as illustrated in Figure 4. In fact, the instantaneous loads for nearly all elements are greater during medium-high flow than under low flow and not correlated with element concentrations (Figures 3 and 4). During the drier and/or winter low flow conditions, major and trace elements and sulfate may accumulate in the wetland areas and in groundwater. These constituents may then be flushed from the reservoirs downstream during spring and summer high flow events. Similarly, DOC loads in the streams increase significantly during higher flow conditions, which also may be result of stream recharge through wetland areas that are organic-rich and oxygen-poor, as suggested by Berndt & Bavin (2012) for increased DOC concentrations following a major storm event in the St. Louis River watershed in August 2010.

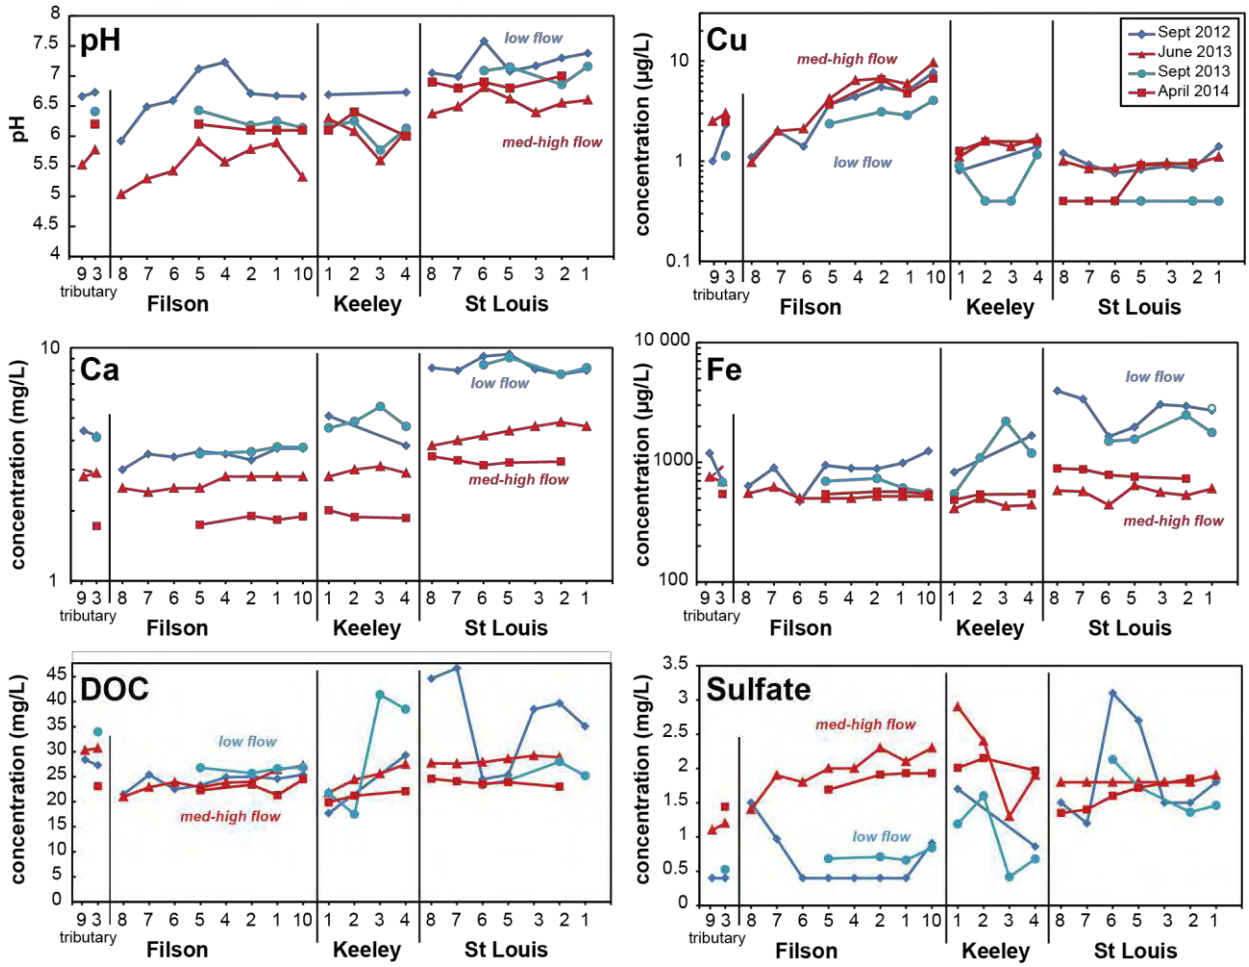

Figure 3 The pH and dissolved (< 45 µm) concentrations of Cu, Ca, Fe, DOC, and sulfate for each watershed plotted upstream to downstream (right to left for each watershed). Site numbers are given on the x-axis.

Stream sediments contain significant Al (7 to 11 weight percent, wt. %), Ca (1.5 to 6 wt. %), Fe (1 to 7 wt. %), and Na (2 to 4 wt. %). Sulfur is very low (< 0.05 wt. %). Organic carbon reaches 4.7 wt. % in one sample but is ≤ 1.5 wt. % in all the other samples. Trace metals are dominated by Cr (14 to 346 mg/kg), Cu (10 to 179 mg/kg), Ni (13 to 127 mg/kg), and Zn (23 to 95 mg/kg). On average, Cu and Ni are highest in Filson Creek stream sediments where Cu-Ni-PGM mineralization occurs at the surface (Figure 5). Samples collected from the St. Louis River watershed, where Fe-Ti oxide-bearing ultramafic rocks and a Paleoproterozoic shale/greywacke unit (Virginia Formation) occur, contain the highest average concentrations of many other trace elements including As, Cr, Fe, Pb, and Zn.

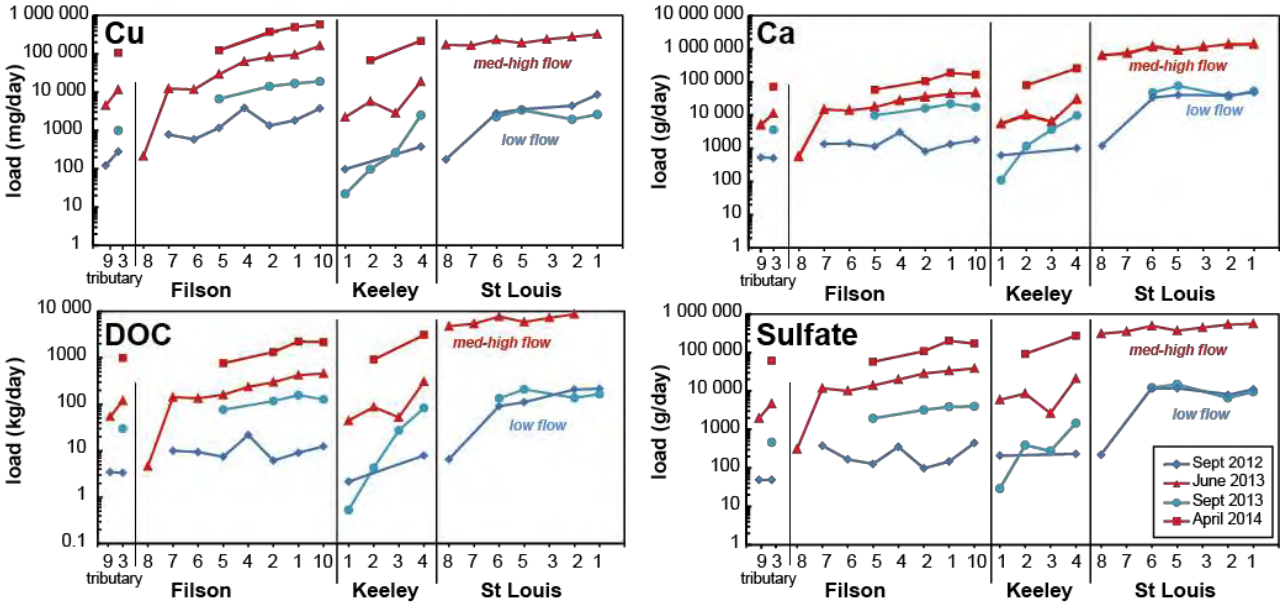

Figure 4 Instantaneous dissolved loads for Cu, Ca, DOC, and sulfate for each watershed plotted upstream to downstream. Flow data are not available for Keeley 1 or sites in the St. Louis River for April 2014.

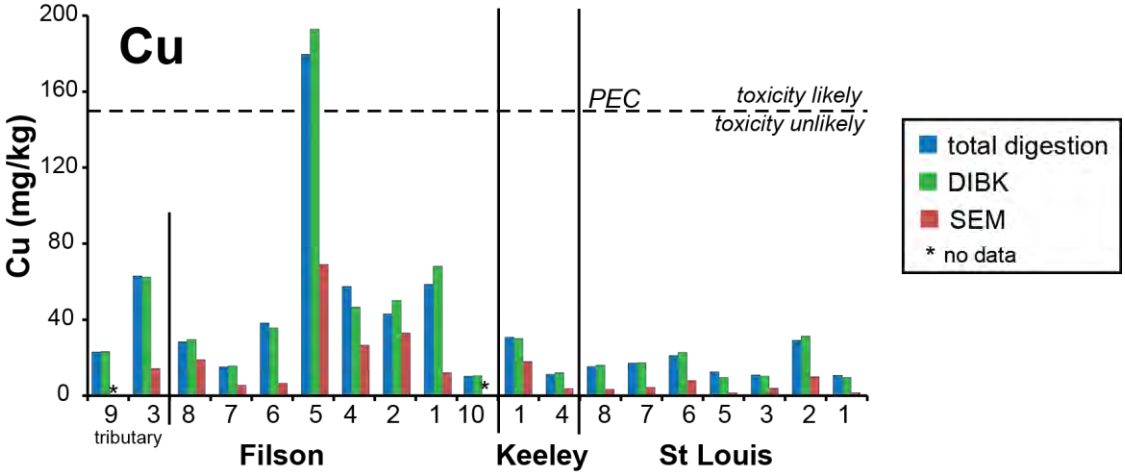

Figure 5 Concentrations of Cu in stream sediments for various digestion procedures for each watershed plotted upstream to downstream. Probable Effect Concentration (PEC) from MacDonald, Ingersoll, & Berger (2000).

Toxicity

In water, the toxicity of most metals is assessed on the basis of hardness-based criteria that adjust for the protective effects of Ca and Mg ions, which compete with metal ions for binding sites on organisms (USEPA, 2014). For sediment, consensus-based total-metal guidelines (i.e., Probable

Effect Concentration, PEC) are routinely used and rely on laboratory toxicity tests that document increased toxicity caused by increased metal concentrations (MacDonald, Ingersoll, & Berger, 2000). However, new guidelines that rely on the BLM utilize a more sophisticated approach incorporating a greater array of water and sediment quality parameters including the cumulative effects of multiple metals in sediment, metal speciation in water, and organic carbon complexes in both water and sediment (Di Toro et al., 2005; USEPA, 2007). The surface-water and sediment metal concentrations can be compared to aquatic guidelines using the hazard quotient (HQ), which is the ratio of the concentration of a metal in the sample to the guideline value. Values above 1 imply toxic conditions, whereas those below do not.

Copper is the main element of concern in these baseline-condition waters with regard to aquatic toxicity. Using hardness-based criteria, chronic toxicity HQs for Cu in water are greater than 1 for many sites during both medium to high and low flow conditions in the Filson Creek watershed and a few sites in Keeley Creek during medium-high flow (Figure 6A). However, as shown in Figure 6A, nearly all chronic toxicity HQs for Cu in water calculated based on the BLM model are less than 1 (assuming a high HA fraction, i.e., 60 %), suggesting a lack of toxicity in most samples. The radically different results from the hardness-based and BLM-based approaches suggest that the former approach routinely used by regulators may be inadequate to describe metal toxicity in these DOM-rich watersheds because it is based on a more limited set of parameters (i.e., only hardness).

In addition, the complexation of Cu with DOM likely significantly affects the bioaccessiblity of dissolved Cu in these watersheds, helping to mitigate its toxicity. However, the relative proportions of HA and FA in DOM greatly influence Cu complexation. The results from the BLM using various ratios of HA and FA at low and medium-high flow conditions for a site in Filson Creek are shown in Figure 6B; also, the range of HA (i.e., 10-60 %) that the BLM model is calibrated for is also shown. The concentration of Cu in the stream exceeds the chronic WQC for a medium-high flow sampling (June 2013) when WQC are calculated assuming a 10 % HA fraction. This is a conservative assumption for the percentage of HA that is recommended by HydroQual (2007) when HA and FA fractions are not known. If this reactive HA component makes up a higher proportion of the DOM, as is suspected for these waters (research currently ongoing), the WQC may increase above the Cu concentrations in the stream (Figure 6B). As illustrated by this example, it may therefore be important to quantify these acid fractions in order to accurately assess toxicity when using BLM, particularly for sites with HQ values close to 1. It is also apparent from Figure 6B that the Cu concentrations in the stream do not vary significantly with flow; however, other chemical changes in the stream result in significantly different WQC under different flow conditions.

The main elements of concern regarding benthic organism toxicity from streambed sediments include Cu as well as Ni and Cr. Partial digestions using a DIBK extraction suggest metals such as Cd, Cu, Pb, and Zn are likely partitioned into the more soluble and bioaccessible phases and not tightly bound to less reactive silicates (Figure 5). Although not analyzed in the DIKB extractions, only a small fraction of Ni and Cr was extracted during the AVS-SEM procedure suggesting that these elements, in addition to Cu, are not bound to less bioaccessible sulfides (Figure 5). Overall, both extractions suggest potentially toxic metals in sediments may be hosted in more bioaccessible forms such as sorbed onto clays and hydroxide phases that are available for benthic organism uptake.

Similar to the inconsistent predictions for water toxicity based on the BLM and hardness-based approaches, the sediment BLM approach suggests a different level of toxicity from sediments than would be predicted from consensus-based guidelines.

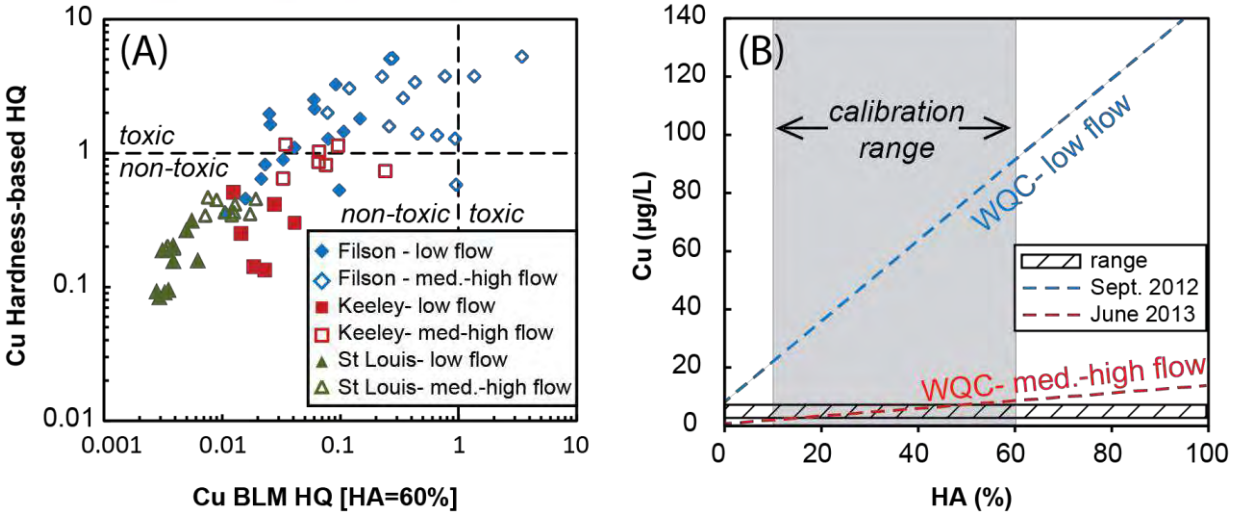

Figure 6 (A) Hardness-based and BLM-based HQs of chronic Cu toxicity. (B) Range in Cu concentrations and BLM- based chronic WQC for various proportions of HA for low and medium-high flows for Filson Creek site 2.

Several HQs for Ni and one HQ for Cu are greater than 1 when calculated using the consensus-based guidelines (i.e., PEC), which suggests toxic conditions (Figure 7A). In comparison, no toxicity (< 130 micromoles per gram of organic carbon, µmol/gOC) to uncertain toxicity (130 to 3,000 µmol/gOC) is predicted based on Equilibrium Partitioning Sediment Benchmarks (ESB) (USEPA, 2005) (Figure 7B). This approach includes: 1. determining extractable (a proxy for bioaccessible) metal concentrations (i.e., combined simultaneously extracted metals, ΣSEM = $SEM_{Cd}+SEM_{Cu}+SEM_{Ni}+SEM_{Pb}+SEM_{Zn}$); 2. adjusting them for potential incorporation into less bioaccessible sulfides (i.e., acid volatile sulfide, AVS); and 3. Adjusting for complexation with organic carbon (i.e., fraction of organic carbon, f_{oc}). The high organic carbon in some of the sediments could sequester significant amounts of trace elements; however, the low AVS suggest trace elements bound to sulfides are not significant components in these sediments.

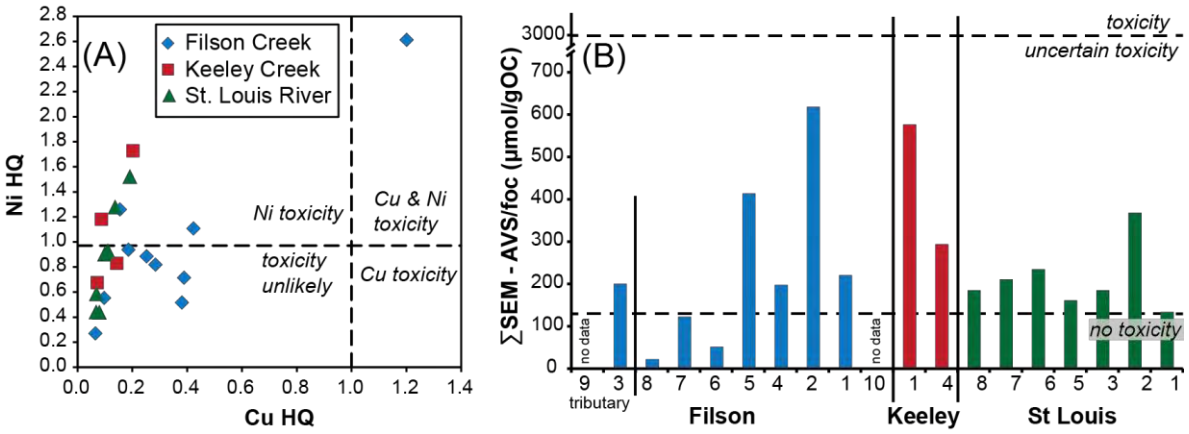

Figure 7 (A) Consensus-based HQ for Ni and Cu in sediment. (B) ESB for sediment samples by watershed and plotted upstream of downstream.

CONCLUSION

The chemistry of surface water and stream sediment in three watersheds from the Duluth Complex is variable due to different mineralization styles. The water chemistry also changes seasonally for most major and trace elements. However, the concentration of Cu, the main element of concern in these watersheds with regard to aquatic toxicity, and DOC only vary within a narrow range for each watershed among the various seasons and flow conditions sampled. The complexation of Cu with DOM significantly limits the bioaccessibility of dissolved Cu, and the generally consistent concentrations of DOM ensure the continued resiliency of water in Duluth watersheds to toxicity year round. As for the sediments, Cu and trace elements may occur in the more bioaccessible forms; however, organic carbon in some of the sediments may help to sequester significant amounts of trace elements. The high organic matter in waters and some sediments certainly plays a key role in protecting aquatic organisms from naturally-occurring concentrations of Cu and other elements in these mineralized watersheds. Nonetheless, the productivity and subsequent organic content of the stream waters and sediments could change if their chemistry is impacted by drainage from future mining (i.e., increase in metals and acidity). Changes in the amount of organic matter and its composition (i.e., changes in the fraction of humic and fulvic acids) could also influence the capacity of organic matter to bind metals and thus limit toxicity to aquatic organisms.

Prediction of Acid Neutralizing Potential of Wetlands Affected By Gold Mining in a Semi-Arid Area

Julien Lusilao-Makiese, Ewa Cukrowska, Hlanganani Tutu, Luke Chimuka and Isabel Weiersbye
University of the Witwatersrand, South Africa

ABSTRACT

South Africa's mining activities play an important role in ensuring the country's position in the global market. Unfortunately, the country's mining history also has resulted in dramatic environmental consequences especially, in the case of acid rock drainage (ARD) production from gold mines of the Witwatersrand. The legacy of mining continues to affect water resources even long after mining operations have ceased.

The issue of ARD at both historic and active mines has led to the worldwide need to implement prediction methods and for the assessment of the acid generation potential during the exploratory phase of mine development.

In this study, static acid base accounting (ABA) tests were conducted on and around an active gold mine tailings dam to predict the risk of acid generation at the site. Sediment samples were collected from wetlands (natural and constructed) and tailings materials were obtained from a Tailings storage facility that has been built about a century ago. The Sobek method was used for the ABA test. Total metals and speciation (BCR extraction) analyses were also carried out on the collected samples.

Results of ABA tests showed variable Net Neutralization Potentials (NNPs) for surface samples (generally negative for tailings and positive for sediments), although the obtained NNPs fell within the range of uncertainty (i.e. -20 < NNP < 20), which demonstrated the need for kinetic tests. Natural wetland samples appeared to have a greater acid forming potential compared to the constructed ones. Moreover, the experiment also showed that acidic conditions would dominate after complete oxidation of the samples. Metals studies revealed not only high total metals values in the samples but also, for several metals, a strong correlation between fraction of "reducible" species (metals bound to sulfides or organic matters) and sulfur. Once exposed to oxygen, these non-soluble metals-sulfides can generate ARD and become available in acidic waters.

Keywords: Acid-Base Accounting, Net Neutralization Potential, Acid Mine Drainage

INTRODUCTION

Acid rock drainage (ARD) is produced by the oxidation of sulfide minerals, frequently pyrite (FeS_2). This is a natural chemical reaction that proceeds when minerals are exposed to air and water. ARD is found around the world as a result of both naturally occurring processes and activities associated with land disturbances, such as mining where acid-forming minerals are exposed at the surface of the earth. Mine tailings and waste rock have much greater surface area than in-place geologic material due to their smaller grain size and are, therefore, more prone to generating ARD. Metals that were once part of the host rock are solubilized and exacerbate the deleterious effects of low pH on terrestrial and aquatic receptors (Jennings *et al.*, 2008). Water contaminated by ARD often contains elevated concentrations of metals, which are toxic to aquatic organisms, leaving receiving streams devoid of most living creatures (Kimmel, 1983).

As elsewhere in the world, the activities of the mining sector in South Africa have resulted in serious environmental consequences, notably with respect to poor environmental and water management and, in the case of the gold mines of the Witwatersrand, production of ARD. Reappraisal of the risks attributable to ARD formation has become increasingly necessary in view of the looming crisis in the mining basins of the Witwatersrand region (Inter-ministerial committee, 2010). ARD and the mitigation thereof are critically important to South Africa. Mine waste particularly tailings, are a large contributing factor to ARD generation. Characterization of the acid generating properties of mine waste is fraught with uncertainty and deficiencies that create difficulties in evaluating and selecting suitable interventions for mitigating associated ARD risks in line with cleaner production and sustainable development principles (Kotelo, 2013).

Accurate prediction of acidic drainage from proposed mines is recognized as a critical requirement of mine permitting and long-term operation (Skousen and Ziemkiewicz, 1996). Mine drainage chemistry can be quantitatively predicted by investigating the geochemistry of rocks to be disturbed by mining (Pope *et al.*, 2010).

Prediction of acid generating potential from geologic formation, referred to as acid-base accounting (ABA), is essentially the ability to identify and quantify both acid-forming and neutralizing minerals in the geologic materials to be unearthed during mining operations (Skousen *et al.*, 2002; Smart *et al.*, 2002). A standardized EPA protocol known as the Sobek method (Sobek *et al.*, 1978) was developed to characterize mine soil and overburden. Although, this method is still used mainly due to its simplicity and low cost analytical procedures (USEPA, 1994), various modifications of the original procedure have been developed that "correct" some of the observed drawbacks from the original method (Chotpantarat, 2011).

In this study, the modified Sobek method (Skousen *et al.*, 1997) was adopted to predict the acid neutralizing potential of wetlands sediments and tailings materials collected from an active gold mine site in South Africa. This method involves the addition of hydrogen peroxide (H_2O_2), which oxidizes the ferrous iron in the dissolved siderite, yielding lower alkalinity predictions.

METHODOLOGY

Sampling

Forty-five sediments profile samples were collected at a gold mine site near Carletonville (North-West Province, South Africa). The samples were obtained from both natural (31 samples) and constructed wetlands (5 samples) near a tailings storage facility (TSF) which was built more than seven decades ago, and tailings materials (9 samples). The constructed wetlands (CWs) in the area are reed beds that are part of a succession from young trees colonizing water ponds and are less than five years old. Sediments in the CWs were "tailings like", especially at the surface, and were characterized by a low percentage carbon (between 0.2 and 1.3 %). Due to the wet conditions of the ponds on the day of sampling, only one CW profile (down to 50 cm depth) was collected from a relatively dryer pond. Natural wetlands (NWs) were characterized by a natural plants colonization and the sediment had a percentage carbon that varied between 0.3 to 2.1% with the highest values mostly measured at top layers. NW profiles were collected down to 100 cm depth whereas tailings materials were obtained from the TSF in horizontal profiles of 40 and 50 cm length. All profiles were later on divided, where possible, into layers of 10 cm each.

Analytical methods

Once in the laboratory, samples were homogenized and a representative aliquot of each sample was dried then pulverized with a pestle and mortar to approximately < 2 mm.

The samples were digested in a microwave assisted extraction system at 800 W for 30 min using a mixture of HCl, HNO_3, HF and H_3BO_3. The samples were then diluted with deionized water and stored in a fridge until analysis. A sequential extraction was performed according to the procedure recommended by the Standards, Measurements and Testing Programme of the European Union (SM& T, formerly BCR), for the determination of some elements of interest in the collected samples. The chosen extraction scheme is an operationally defined and standardized procedure (Tokalioglu *et al.*, 2003; Davidson *et al.*, 1999) in which the reagent used at each stage is intended to release metals associated with particular soil phases such as acid soluble, reducible, oxidizable, and residual. Reported results were related to the extraction step numbers as shown in Table 1. Thus, Fe1, Fe2, and Fe3 refer to the concentration of iron (Fe) in fraction 1, 2, and 3, respectively. Metal determination in the extracts was carried out by ICP-OES.

Table 1 The BCR three-stage sequential extraction scheme.

Extraction step	Reagents/ concentration/ pH	Solid phase
1	CH_3COOH (0.11 M) pH 2.85	Exchangeable, water & acid soluble (e.g. carbonates)
2	$NH_2OH.HCl$ (0.1 M) pH 2	Reducible (e.g. Fe/Mn oxides)
3	H_2O_2 (8.8 M) following by CH_3COONH_4 (1.0 M) pH 2	Oxidizable (e.g. organic substance and sulfides)

Total sulfur (S) used for ABA was determined using a LECO S632 analyzer, and Statistica software (Statistica® 7, USA) was used to check for correlation between the different studied parameters.

Static tests

Static ABA was performed on each pulverized sample. The following are the procedures used for the static ABA studies:

Initial pH

A sample mass of 5 g was weighed and added 50 ml of deionized water and was left for 24 hrs., after which the initial pH was measured (Usher *et al*, 2003).

Final pH

A volume of 80 ml of H_2O_2 (30% w/v) was added to a mass of 2 g of pulverized sample. The reaction was left to oxidize for 24 hrs, after which the final pH was measured (Usher *et al*, 2003).

The acid production potential

The acid production potential (AP) was determined from the total S content as follows:

AP (kg $CaCO_3$/t equivalent**)** = 31.25 x %S

Neutralization Potential (NP)

The peroxide siderite correction for Sobek method, as developed by Skousen *et al.* (1997), was used for determination of neutralization potential (NP). An initial fizz test was performed to select the volume and normality of HCl that was added to the sample prior titration. After the HCl addition, the sample was boiled until the reaction was complete. The resulting solution was back titrated to pH 7 with NaOH to determine the amount of acid consumed in the reaction between HCl and the sample. Blank titrations were also carried out to determine the blank constant critical for the calculation of the amount of acid consumed. NP was then calculated as follows:

NP (kg $CaCO_3$ equivalent / ton of material) = (ml of acid consumed) x (25.0) x (Normality of added HCl).

The net neutralizing potential (NNP) was determined by subtracting the AP from the NP and is a measure of the difference between the neutralizing and acid forming potentials.

RESULTS AND DISCUSSION

Elemental analysis

The results of selected elements concentrations in surface sediments and tailings materials are shown in Table 2. High metal concentrations relative to background levels were measured in the study samples with values sometimes reaching the percentage level, as was the case for aluminum (Al), Fe, and manganese (Mn), to mention a few. The measured concentrations are a clear indication of a pollution occurring at the site, probably from surrounding TSFs. Analysis of wetlands surface waters (Table 3) also revealed elevated concentrations in both CWs and NWs for elements such as Ca, Fe, Mg, Mn and S.

Table 2 Selected element concentrations (mg kg^{-1}) in surface sediments and tailings

Sample	Al	As	Co	Cu	Fe	Hg	Mn	Pb	S	Zn

Acidity in ARD is comprised of mineral acidity (Fe, Al, Mn, and other metals depending on the specific metal-sulfide minerals present) and hydrogen ion acidity (Skousen *et al.*, 2000). The extremely high concentrations of Fe (and S) could be due to the abundance of pyrite (FeS_2) in the overburden material. It was observed that Fe had a positive linear correlation with S (Figure 1). BCR sequential extraction procedure (SEP) also showed, in some cases, positive correlations between Fe3 (i.e. oxidizable) and S (Figure 1).

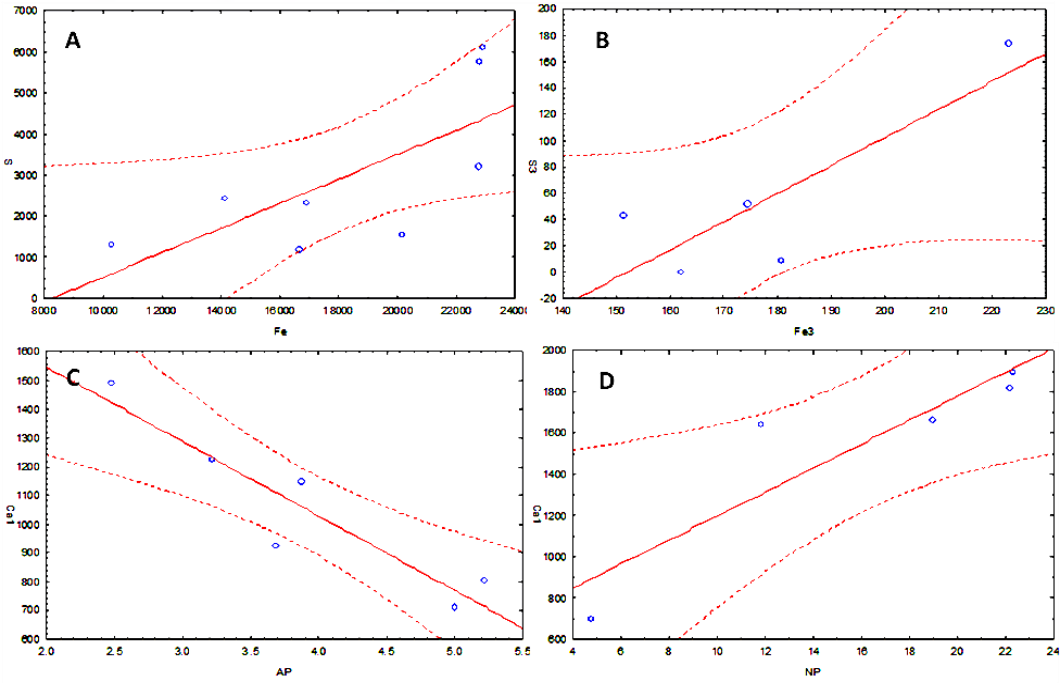

Figure 1 Correlation plots between total Fe and S (A), oxidizable Fe and S (B); Exchangeable Ca and AP (C), and Exchangeable Ca and NP (D), in natural wetlands sediments. Concentrations are in mg kg^{-1}.

The observed correlations could indicate the presence of pyrite in the overburden material, although other forms of Fe-S (e.g. pyrrhotite or $FeSO_4$) could also be present in the samples, as a good correlation was also found between total Fe and S. Good correlations were also observed between S and oxidisable cobalt (Co), copper (Cu), Mn and zinc (Zn) (Figure 2). It is known that these metals can complex with sulfides to form chalcopyrite ($CuFeS_2$), covellite (CuS), and sphalerite (ZnS). Pyrite commonly occurs with these other metal sulfides, and therefore ARD is likely to occur where Cu, Pb, and Zn are mined. The determination of the samples' mineralogy is, therefore, critical to reaching better conclusions about specific deposits.

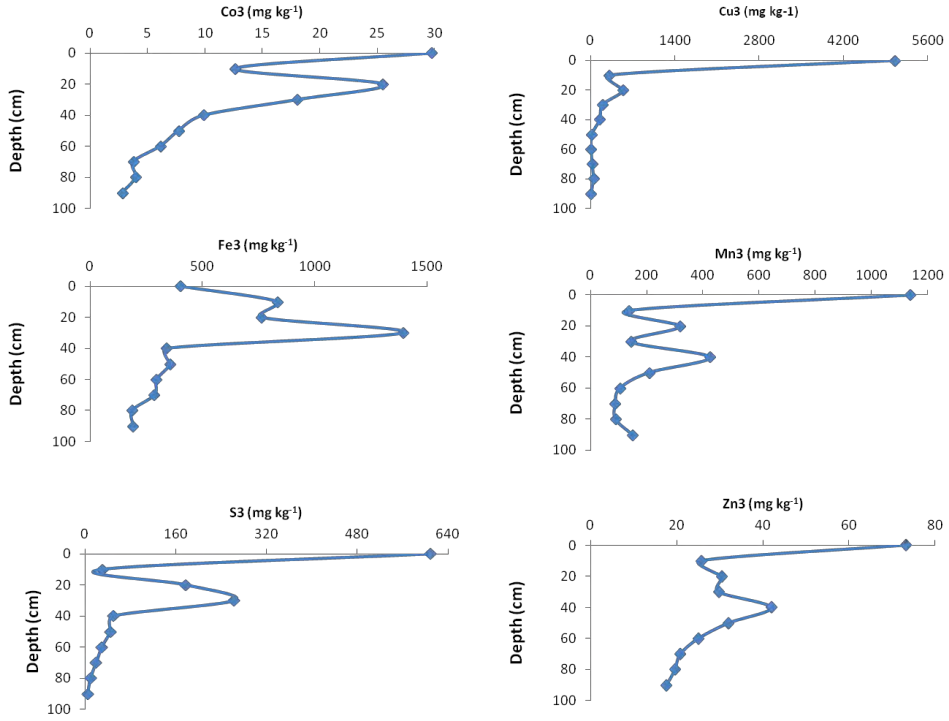

Figure 2 Trends of oxidizable forms of selected elements in a natural wetland sediment profile

Static tests

A plot of average pHs of the samples (Figure 3) shows that the initial average pH values ranged of 5.1 to 6.9.

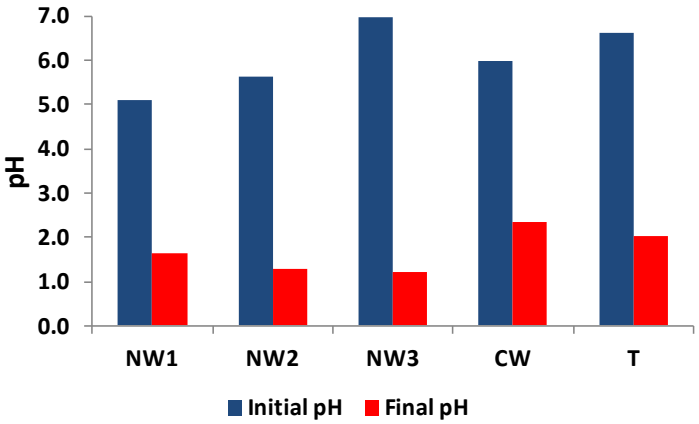

Figure 3 Average pH values of the samples before and after oxidization

The initial pH indicates the immediate acidic or basic characteristic of the sample and it could also indicate if acid generation has already been generated (Usher *et al.*, 2003). Note that, with the exception of NW3 which showed initial pH values close to neutrality, the majority of NW and CW samples had acidic pH, especially in bulk sediments were pH values as low as 3.8 were measured. This could be an indication that acid generation is already occurring at the site as a result of the oxidation of the above mentioned pyrite in the area. Acidic pH values were also measured in wetlands waters (Table 3). The final pH values suggest that after complete oxidation, the pH of each of the study samples would be less than 2.5

ABA tests revealed (Table 4) that the NNP (and NPR) values for the majority of the samples fell within the range of uncertainty (i.e. -1.3 ≥ NNP ≤ 9.1, or 0.9 ≥ NPR ≤ 2.8), except for the sample profile collected from one of the natural wetlands (i.e. NW1), which had an average NNP of 85.2 and falls within the non-acid forming range. This location exhibited higher NP values (up to about 190 Kg $CaCO_3$/t) at deeper layers (30 to 70 cm depth).

Table 4 ABA results of study samples

		AP (Kg $CaCO_3$/t)			NP (Kg $CaCO_3$/t)			NNP (Kg $CaCO_3$/t)		
Sample	n	Min	Mean	Max	Min	Mean	Max	Min	Mean	Max
NW1	11	3.3	6.2	9.5	4.7	91.5	187.6	-0.5	85.2	181.6
NW2	10	3.7	8.7	19.1	2.1	7.44	14.3	-13.9	-1.3	5.6
NW3	10	4.6	26.2	63.8	8.54	25.3	50.7	-51.8	-0.9	22.7
CW	5	1.3	5.0	7.7	-4.7	14.1	22.3	-6.0	9.1	16.9
Tailings	9	5.6	7.2	8.8	5.4	8.7	11.6	-0.2	1.5	2.8

These results may suggest an important source of acid-consuming constituents at this location. Since carbonates are known to be one of the main sources of alkalinity production (Sobek *et al.*, 2000), correlations have been plotted between the BCR SEP exchangeable fractions of selected elements and NP or AP, as that BCR fraction is known to contain carbonate-bound metals. Among all the study elements, a positive correlation was found between Ca1 (i.e. exchangeable Ca) and NP whereas a strongly negative correlation was observed for the same Ca fraction and AP (Figure 1), indicating that $CaCO_3$ could be the main acid-neutralizing agent in the study samples. Additionally, it has to be noted that the sample profile NW1 had the highest concentrations of exchangeable Ca.

With the exception of the above-mentioned sediment profile NW1, all the sediments also showed a strongly positive correlation (r^2 up to 0.899) between the pH after oxidization (final pH) and NNP. This implies that samples with the lower final pH (NW2 and NW3) might have been depleted of the total available carbonates leaving a lesser source of alkalinity to buffer the acid. Another reason may be that there were more acid-producing constituents than acid-consuming constituents in the sample as these two sample profiles had negative average NNP (i.e. Average AP > Average NP). Sample profile NW3 showed the lowest mean final pH, the lowest NNP, as well as the highest AP (Figure 2). The high AP values obtained in this profile may suggest an important presence of acid-producing constituents, such as metal sulfides. Furthermore, at the point where the lowest NNP was recorded, the concentration of total S was as high as 2% and NP was at one of its lowest recorded values in this profile (i.e. 12 kg $CaCO_3$/t). The more negative NNP could also imply,

therefore, that the sediment did not have enough $CaCO_3$ to neutralize the acidity in the soil hence there was a potential of ARD in the area.

It is important to recall that the method used in this study is based, in part, on calculation of potential acidity from total S measurements. However, potential acidity is known to be overestimated where organic S, sulfate S, and some sulfide compounds make up a substantial portion of the total S content (Schumann *et al.*, 2012). Thus, a method speciating S, such as the chromium reducible S (CRS) method, would be useful to refine the obtained results.

In general, NNP values were lower at depth in the sediments profiles (Figure 4). This could be attributed to anoxic conditions encountered at deeper layers in wetland sediments, which favor the reduction of sulfate, as well as \ formation of non-soluble metal-sulfides. Thus, in case of land disturbance (or water infiltration), there is a possibility for these sulfide-rich layers to become exposed to oxygen and undergo different reactions that lead to ARD generation and subsequent solubilization of toxic metals.

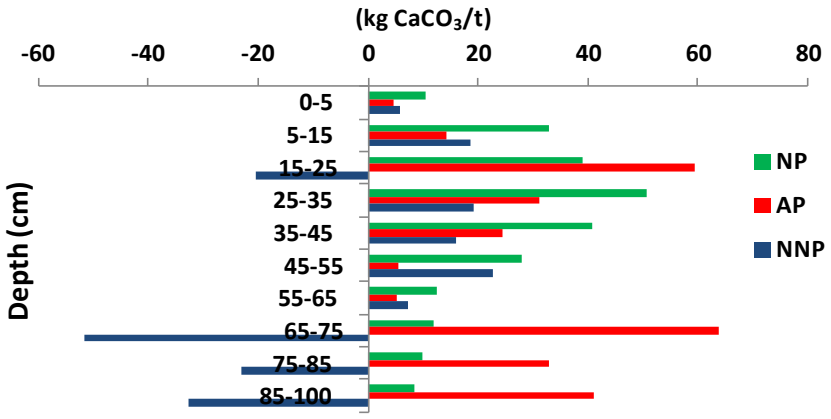

Figure 4 ABA results of the sediment profile NW3

CONCLUSION

Static ABA tests were performed in different samples collected from a gold mine site. Results showed that NNP (and NPR) values were mostly in the range of uncertain acid production, which suggests the need for kinetic tests, although pH tests revealed a risk of acid production if samples were exposed to more oxidizing conditions. Elemental analysis showed contamination already occurring at the site, and the pollution source is believed to be the presence of massive TSFs at the site. Generally, sample from the natural wetlands (and tailings) exhibited higher acid-forming potential than the constructed wetlands. BCR extraction helped to identify FeS_2 and $CaCO_3$ as the likely sources of acid- and alkalinity-production, respectively, in the samples. Mineralogical data would be necessary to verify the specific minerals contributing to ABA analysis and reported results.

Assessment of As and Hg in Mine Tailings and Indigenous Grass: A Case Study of Non-Functional New Union Gold Mine, South Africa

Tsedzuluso Mundalamo, Jabulani Gumbo, Confidence Muzerengi and Francis Dacosta
School of Environmental Sciences, University of Venda, South Africa

ABSTRACT

The present study was carried out to assess the uptake of toxic metals, arsenic (As) and mercury (Hg), by *Cynodon dactylon* grass species at New Union gold mine tailings, Limpopo Province, South Africa. The samples were collected from New Union Gold Mine tailings and from Ka-Madonsi Village (control), and concentrations of As and Hg in soil and plant material were determined by ICP-MS. The average dry weight concentrations of As and Hg in mine tailing dam A were 2.53 and 1.18 μg/g, respectively, and 2.24 and 0.91 μg/g, respectively, in mine tailings B. The average dry weight of As and Hg in the control soil samples were 0.30 and 0.05 μg/g, respectively. The *C. dactylon,* on average dry weight, absorbed 5.45 μg/g of As, and 1.72 μg/g of Hg from mine tailings A, and 4.29 μg/g of As; and 1.55 μg/g of Hg from mine tailings B. The control grass, on average dry weight, absorbed 0.53 μg/g and 0.01 μg/g of As and Hg, respectively. In most cases, significant differences were observed between bioaccumulation of Hg and As in plant tissue from mine sites and control sites. The study showed that the bioconcentration factor was less than 1 for the acidic mine tailings, with exception of the root and rhizome system which was greater than 1. This contrasted sharply with the control site where the pH was alkaline, and As and Hg levels were low. The pH values were significantly different ($p < 0.05$) between the soils originating from mine tailings and the control site. The electrical conductivity (EC) of soil at mine tailings A and B were 1847.35 and 1777.5 μS/cm, respectively. The EC for the control site was significantly different ($p < 0.05$) at 543.3 μS/cm. *C. dactylon* was found to be capable of bioaccumulation of As and Hg, effective at soil stabilization, and grew well under the acidic conditions. The control grass was healthy and thrived under the alkaline conditions.

INTRODUCTION

Mining operations contribute wealth to an economy in a variety of ways, but mine wastes can negatively impact the environment. Abandoned mine tailings sites are a source of environmental problems throughout the world and the number of these sites is on the increase (Lodenius and Malm, 1998; Bell *et al*., 2001; Ogola *et al*., 2002; Naicker *et al*., 2003; Mendez *et al*., 2007; Schuwirth *et al*., 2007; Mulugisi *et al*., 2009). This study focuses on the abandoned mine tailings at New Union Gold Mine, Malamulele, Limpopo province, South Africa, an arid region with limited rainfall. During the processing of the gold ore at New Union Gold mine, the gold was recovered after addition of amalgam (mercury) (Janisch, 1986). The mine operated from 1935 to 1998 in Giyani greenstone belt under various mining companies such as New Union Mining, Northfields Gold Pty Ltd, New Union Gold, Noorde, Offspring and Barberton until the exhaustion of the underground gold ore (Potgieter and De Villiers, 1986; Du Plessis, 2011). According to Potgieter and De Villiers (1986) the gold ore was associated with sulfur-rich arsenopyrite in garnetiferous, biotite-rich bands. Thus, the mine processing wastes were probably rich in arsenic (As) and mercury (Hg), and were discarded to the mine tailings dams. These mine tailings dams are thinly covered by vegetation on slopes and on the surface such that water and wind erosion are likely to occur (Figure 1).

Figure 1 Thinly covered vegetation at New Union Gold Mine tailings showing water erosion

The study of Rösner and Schalkwyk (2000) in the mine tailings of Witwatersrand goldfields, South Africa showed that water erosion contributed to loading of heavy metals in nearby and deteriorated water quality in nearby rivers. The studies of Mulugisi *et al.* (2009) and Magonono *et al.* (2010) at New Union Gold Mine demonstrated the presence of heavy metals such as manganese, zinc, copper, lead, As, cadmium, and cobalt in the mine tailings. The study of Winde *et al.* (2004) showed that the contamination of the streams adjacent to the Witwatersrand goldfields mine tailings posed

a health risk for the people in the nearby informal settlements who drink the river water without appropriate treatment.

It is known that some plant and, more specifically grass, species are able to remove heavy metals from contaminated soil and water (Comino *et al*., 2008). Plant species that accumulate large amounts of heavy metals from soils are referred as hyper-accumulator species (Madejón *et al*., 2002; Li *et al*., 2007). The use of plants to remove heavy metals from contaminated soils is an environmentally friendly and cost-effective method, termed phytoremediation (Cunningham *et al*., 1995; McLaughlin *et al*., 2000; Mulugisi *et al*., 2009). At New Union Gold Mine tailings an indigenous grass, *Cynodon dactylon*, has been growing in different patches on the mine tailings. According to Soleimani *et al.* (2009), *C. dactylon* can hyper-accumulate nickel and lead and was one of the candidate methods for cleaning up heavy metal contamination of soil and sediments in Shadegan wetland, Iran. *C. dactylon* has an extensive roots system which is suitable for soil stabilization (Smith *et al*., 1998; Rizzi *et al*., 2004), and the studies of Smith *et al.* (1998) and Madejón *et al*. (2002) also showed that *C. dactylon* has a widespread creeping ability, which is useful for the stabilization of mine tailings. A similar, but separate study of Nelushi *et al.* (2013) of *C. dactylon* under field conditions at New Union Gold Mine showed that the grass was able to bioaccumulate significant amounts of chromium and uranium. The study on the bioaccumulation potential of As and Hg uptake by *C. dactylon* under field conditions are rather limited. The main aim of this study was to assess the uptake of As and Hg in different parts of *C. dactylon* plants (roots, rhizomes, stems, and leaves) from the New Union Gold Mine tailings under field conditions. A second objective was to determine pH and electric conductivity (EC) of the mine tailings, and how these contribute to availability of the toxic metals, As and Hg.

METHODOLOGY

Sample collection and preparation

The samples were collected from tailings dams at the New Union Gold Mine and control samples from Ka-Madonsi village, South Africa, on June 2010. The study area is well described in Mulugisi *et al*. (2009). The samples, C. *dactylon* and soils were obtained from the same spot from the mine tailings and the control site. The samples were collected at the following geographical coordinates: 23º01'05"S and 30º43'50"E; 23º00'59"S and 30º43'53"E; 23º01'06"S and 30º43'47"E; and 23º01'04"S and 30º43'45E"; for sample tailings A1, A2, B1 and B2, respectively. The samples were then sealed in sample bags and transported in coolers to the laboratory at the University of Venda for further analysis.

The grass samples were washed with distilled water, oven dried at 55 °C (Vacutec oven, Labcon, South Africa) to constant weight for a week and subsequently cut into plant sections (roots, rhizome, stems, or leaves). After drying soil samples for a week, the individual samples were ground with a Retsch RS 200 grinding mill (Retch, United Kingdom) to 80% fine or < 75µm, and were then weighed to 5.00g, using an AS 220/C/2 analytical balance (Radwag, United Kingdom). All grass and soil samples were acid-digested following the procedure of the APHA (2006), and were sent, in duplicate, to the ARC Institute of Soil, Water & Climate, Pretoria, South Africa for metal analysis.

Determination of pH and EC

The soil samples were weighed to 50 g, (BP 1200 balance) and mixed thoroughly with 50 ml of distilled water (Sampanpanish *et al.,* 2006) prior to conducting pH and EC measurements, for which a Crison Basic Model meter was used. The pH and EC measurements were determined in duplicate.

Determination of metals, arsenic and total mercury

The acid digested samples were analyzed, in duplicate, for As and Hg using cold vapour/hydride generation ICP-MS (Chen *et al*., 2008), using a Thermofischer ICP MS Model X Series II.

Data analysis

The concentrations of As and Hg were reported on a dry weight basis (d.w.). Statistical analyses were carried out using single factor ANOVA, with a significance level of $p < 0.05$. The bioconcentration factor (BCF) was calculated as per procedure of Al-Qahtani (2012). The BCF ratio, which was calculated as metal concentration in plant divided by metal concentration in soil, represents the ability of the plant to bioaccumulate the metal in question.

RESULTS AND DISCUSSION

The pH and EC of soil samples mine tailings and control sites

The research findings, presented in Table 1, indicate that the mine tailing dams were highly acidic and the control site was neutral.

Table 1 Average pH and EC of soil samples from at New Union Gold Mine tailings and the control site

Sample ID	pH	EC (µS/cm)
Mine tailing (A1)	3.55±0.04	1712.70±37.4
Mine tailing (A2)	3.49±0.01	1982.00±9.3
Mine tailing (B1)	3.62±0.01	1568.00±8.2
Mine tailing (B2)	3.66±0.05	1983.00±14.8
Control site	7.59±0.17	548.33±0.7

The pH results for replicate mine tailings samples were not significantly different ($p>0.05$) from each other, but were significantly different ($p<0.05$) from the control site. The acidity of the mine tailings was probably due to oxidation of pyrite and other sulfide minerals of geological origin (Potgieter and De Villiers, 1986; Mulugisi *et al.,* 2009; Magonono *et al.,* 2010). According to Al-Qahtani (2012) and Nelushi *et al.* (2013), soil pH, EC, organic content, and metal speciation may influence the plant-bioavailability of metals. The EC values of soil samples from mine tailings were higher than those from the control site (Table 1). The EC values of the mine tailings A and B were not significantly different ($p>0.05$, and their relatively high EC values probably result from oxidation of pyrite and sulfide minerals exposed to oxygen and water (James, 1997). Electrical conductivity of the soil is an indirect measure of the Total Dissolved Solid (TDS) present in the soil,

which has negative impacts on plant growth due to increased osmotic pressure of the soil solution, thereby inhibiting water and nutrient uptake by plants (James, 1997). Thus the acidic conditions are conducive to metal availability in the mine tailings soil coupled with easier metal uptake by the plants. Additionally, once the metals are in solution, they contribute to EC, as supported in this study. In contrast, the neutral conditions at the control site do not promote dissolution of metals, thus contributing to low electrical conductivity.

Concentrations of toxic metals in mine tailings and control sites

The research findings showed that As and Hg were significantly elevated in the New Union Gold Mine tailings in comparison with the control site (Figure 3). The range in concentrations of As and Hg in the mine tailings were 1.48 to 3.58 ug/g and 0.59 to 1.27 ug/g d.w., respectively. The levels of As and Hg in the mine tailings were higher than the control site, which may be attributed to the gold ore-amalgam processing and presence of sulfur-rich arsenopyrite in garnetiferous, biotite-rich bands.

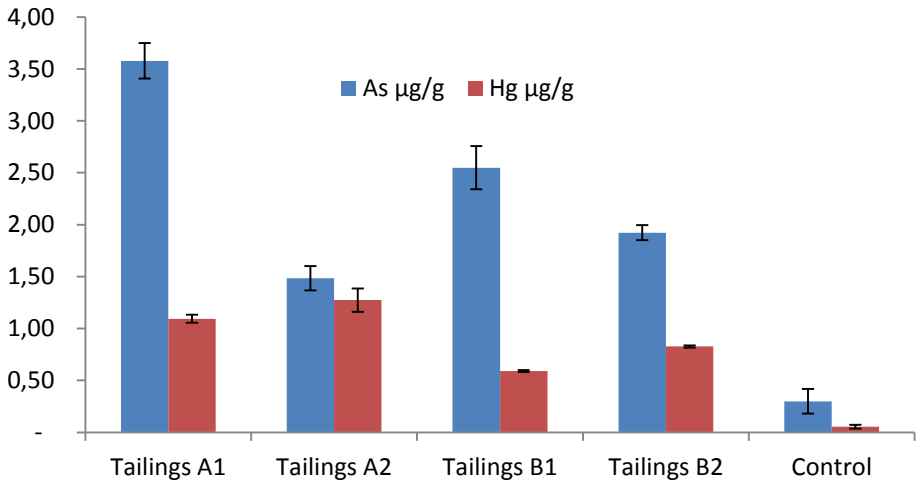

Figure 3 Average dry weight concentrations, based on duplicate analyses, of As and Hg in mine tailings at New Union Gold Mine and at the control site, whiskers reflect standard error

For both As and Hg, the mine tailings A and B were not significantly different ($p > 0.05$) from each other, but were significantly different from the control for Hg, ($p < 0.05$), with an insignificant difference for As ($p > 0.05$). This supports that the source of Hg likely originates from the New Union Gold Mine, where Hg was used to extract gold during operations (Janisch, 1896). Additionally, as previously described, the presence of As in the mine tailings is probably geological, coming from sulfur-rich arsenopyrite (Potgieter and De Villiers, 1986).

These findings are in agreement with numerous studies from a variety of mine sites, such as Amono-Neizer *et al*. (1996) which reported 12.92 µg/g and 0.93 µg/g of As and Hg, respectively, in soils around the gold mining town of Obuasi in Ghana. Furthermore, the As concentrations are similar to the study of Madojen *et al*. (2002) at the Aznallcollar mine spill (SW Spain), who found levels of of 9.59 µg/g in soils, and the study of Visoottiviseth *et al.* (2002), which reported As concentrations in soil of 14 µg/g. The research findings are also in agreement with the study of

Fernandez-Martizer (2009) which recorded Hg concentrations ranging from 0.59 µg/g to 1.59 µg/g in soils.

Toxic metal concentration in different parts of *Cynodon dactylon*

The concentrations of As and Hg were also determined in the different plant parts (roots, rhizome, stem and leaves) of *C. dactylon* harvested from the study sites (Figure 4). The *C. dactylon* growing on the mine tailings accumulated more As and Hg in the leaves and stems than the *C. dactylon* growing on the control site (Figures 4a and b), with a significant difference of $p < 0.05$. There were significant differences in the accumulation of As and Hg in plant parts from the various mine tailings sites. *C. dactylon* collected from the mine tailing sites was shown to accumulate higher levels of As and Hg in leaves than in stems. The metals under study, As and Hg, have no known biological function in plants (Comino *et al.*, 2009) and are reportedly toxic to plants including the *C. dactylon*; being detrimental to plant health and wellbeing. According to Comino *et al*. (2009), the As-uptake by plants was inhibited by the presence of antimony and phosphate, but was promoted by the presence of molybdate.

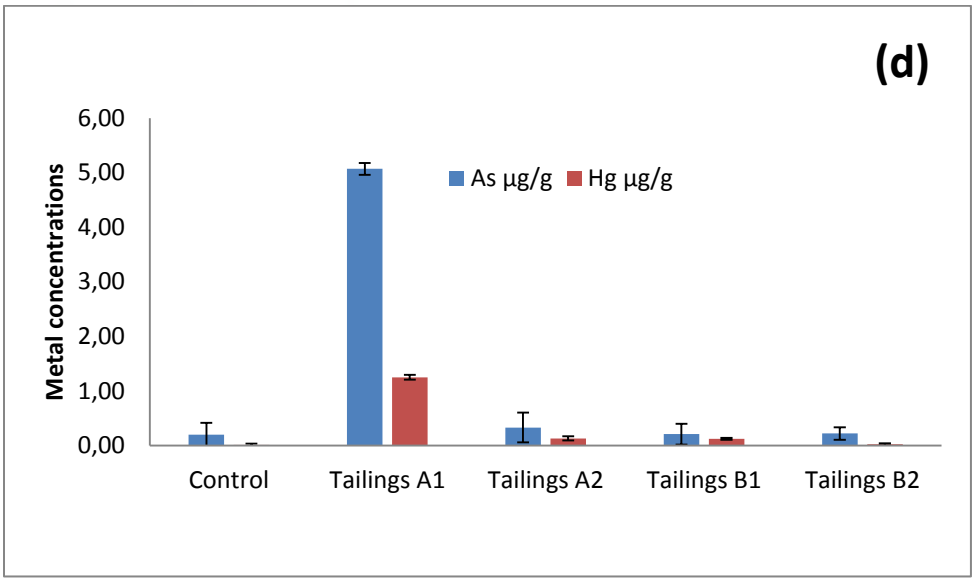

Figure 4 Average dry weight concentrations, based on duplicate analyses, of As and Hg in (a) leaves, (b) stems, (c) roots and (d) rhizomes of *C. dactylon* mine tailings at New Union Gold Mine and at the control site, whiskers reflect standard error

Similar to observations from the leaves and stems, *C. dactylon* growing on the mine tailings accumulated more As and Hg in the roots and rhizome than the *C. dactylon* that was growing on the control site (Figures 4c and d), with significant differences from the control ($p < 0.05$). This was expected since the roots grow deeper into mine tailings than the rhizome. Significant differences ($p<0.05$) in the accumulation of As and Hg were observed among the mine tailings sites. The *C. dactylon* was shown to bioaccumulate more As than Hg in roots than rhizome. This was expected since soil samples from mine tailings had higher concentrations of As than Hg (Figure 3), and thus the *C. dactylon* had access to more As than Hg. It is also possible that As and Hg compete with each other for uptake, as was shown by the study of Comino *et al*. (2009) in tomato plants. In the same study Comino *et al*. (2009) also showed that the uptake of Hg by tomato plant was inhibited by selenate, which has chemical similarities to certain forms of As. It may, therefore, be possible that As was inhibiting Hg uptake with a similar mechanism, thereby leading to higher As uptake by *C. dactylon*.

Generally, the most toxic metals such as As and Hg are highly bioavailable to grass under acidic conditions, conditions in which metals are more soluble (Okunola *et al.*, 2007). The research findings are in agreement with Smith *et al*. (1998), who reported that *C. dactylon* may tolerate pollution of trace elements (e.g. up to 30,000 µg/g of As in soil). The research findings are also in agreement with the study of Madejón *et al.* (2002), who reported that *C. dactylon* had a high bioconcentration of As (up to 75 µg/g) in a contaminated site in Spain.

Bioconcentration factors of *Cynodon dactylon*

The availability of metals for uptake by plants is determined by factors such as soil pH, EC, natural organic matter in soil; and metal speciation (Al-Qahtani, 2012). The bioconcentration factor (BCF) was calculated as metal concentration in plant divided by the metal concentration in soil, which

thus represented the ability of the plant to bioaccumulate the metal in question. Using this calculation, a BCF < 1 indicates lower bioavailability of a metal, while a BCF >1 indicates a higher bioavailable metal. The research findings showed that the BCF ratios were variable between the *C. dactylon* growing on mine tailings and that growing at the control site (Table 2). This BCF variability may be attributed to metal mobility and bioavailability as a result of acidic versus alkaline conditions. The study of Comino *et al*. (2009) showed that the uptake of As and Hg at the same time and space may interfere with each other, a finding that may support our results. Al-Qahtani (2012) stated that neutral to alkaline conditions restrained metal mobility and therefore the metal bioavailability in plant uptake and translocation into plant tissues. This is consistent with our study, where the alkaline conditions inhibited metal mobility and probably contributed to low BCF ratios for the control site. Our study showed that in the acidic mine tailings, the BCF was less than 1 with exception of the root and rhizome system which was greater than 1 for mine tailings such as A2 and B2 (Table 2). The location of accumulation of As in plant tissue was variable, but generally absorbed more in roots and the rhizome. Conversely, although the location of accumulation of Hg was also variable, it was generally absorbed more in leaves and the roots.

Table 2 Bioconcentration factors (BCF) of *C. dactylon* for As and Hg

	Tailings A1		**Tailings A2**		**Tailings B1**		**Tailings B2**		**Control**	
pH	3.55		3.49		3.62		3.66		7.59	
	As	**Hg**	**As**	**Hg**	**As**	**Hg**	**As**	**Hg**	**As**	**Hg**
Leaves	0.2	0.6	0.5	0.1	0.4	0.8	0.5	0.3	0.0	0.0
Stem	0.2	0.3	0.5	0.1	0.7	0.4	0.5	0.2	0.6	0.0
Rhizome	1.4	1.1	0.2	0.1	0.1	0.2	0.1	0.0	0.7	0.2
Roots	0.1	0.2	1.6	0.4	0.5	0.7	1.1	0.6	0.5	0.0

CONCLUSION

The ability of *C. dactylon* to uptake metals under acidic conditions and stabilize slopes as a result of creeping ability, makes it a suitable vegetation cover for the exposed mine tailings from a remedial perspective. However, this study showed that soil and *C. dactylon* samples at New Union Gold Mine tailings contain high levels of As and Hg in comparison to the control site. The acidic mine tailings likely solubilize the metals As and Hg, thus making these elements available for uptake by the C. *dactylon*. In contrast with control sample, the alkaline conditions were not conducive to metal solubility thus limiting uptake by *C. dactylon*. At the mine tailings sites in this study, the presence of As and Hg in the leaves and stem of this grass is worrisome, because grasses are frequently grazed upon by livestock and wild animals, which may lead to biomagnification in the food chain. The presence of animals at the mine tailings was shown by animal droppings. At the New Union Gold mine, there is presently no one to look after the property and the mine tailings are not fenced; the animals can thus freely graze on *C. dactylon* that was growing on the mine tailings.

Acid Rock Drainage in Antarctica: An Important Source for Trace Elements in the Southern Ocean

ABSTRACT

Here we describe biogeochemical processes that lead to the generation of acid rock drainage (ARD) on the Antarctic landmass and show that ARD is an important source of trace elements for the Antarctic Ocean. During three expeditions, 2009 – 2011, we examined three sites on the South Shetland Islands in Antarctica. Two of them displayed intensive sulfide mineralization (up to 10 wt.% of pyrite) and generated acidic (pH 3.2 – 4.5), iron and trace element-rich drainage waters. The formation of ARD in the Antarctic was catalyzed by microorganisms found in acid mine drainage in cold climates, including *Acidithiobacillus ferrivorans* and "*Thiobacillus plumbophilus*".

At Cardozo Cove, lowest pH (3.2) with highest element concentrations were detected and infiltrated mainly as groundwater into the sea, and as superficial runoff (as Fe^{3+}), latter with the formation of schwertmannite in the sea ice (with up to 100 mg/L Fe (as Fe^{2+}), 95.2 mg/L Al, 19.7 mg/L Mn, 3.4 mg/L Zn, 1.46 mg/L Cu, 1.06 mg/L Ni and Rare Earth Elements (REE) up to 16.2 µg/L). At Marian Cove, the pH values were slightly higher and the element loads were generally lower than at Cardozo Cove (in the range of 10 – 25 %). In contrast, the liberation of trace elements from the non-mineralized control site (Punta Hannah) was in the range of 3 to 4 orders of magnitude less than from the two mineralized sites. Thus, our results show that ARD has to be seen important sources of trace elements to the sea. The increased iron and trace element input correlates with increased phytoplankton production close to the source. This might even be enhanced in the future by a global warming scenario, and could be a process counterbalancing global warming if the biomass is buried effectively in the sediments.

In Situ Attenuation of Selenium in Coal Mine Flooded Pits

Alan Martin, Robert Goldblatt and Justin Stockwell
Lorax Environmental Services Ltd., Canada

ABSTRACT

Suboxia is a prerequisite for the bioremediation of selenium (Se), whereby Se is removed from solution as reduced species (*e.g.*, elemental Se). In this regard, flooded open pits offer suitable repositories for the bioremediation of Se given the tendency of these systems to develop suboxic conditions through either passive or active means. Specifically, the geometry of flooded pits and their water column density characteristics often make them conducive to permanent stratification (meromixis) and the development of bottom water suboxia. In order to assess the potential for Se bioremediation in a coal mine flooded pit in northern Canada, a combination of high resolution physical profiling (temperature, dissolved oxygen and conductivity) and water quality sampling was conducted. Vertical profiling revealed a stratified water column with respect to both temperature and salinity, with the pycnocline occurring at a depth of 5 m. Dissolved oxygen was absent below a depth of 20 m, suggesting that the water column stratification is permanent. Profiles of other redox-sensitive species (dissolved manganese and nitrate) further support the presence of bottom water anoxia below 20 m. The data for nitrate, for example, show evidence of denitrification immediately below the oxic-suboxic boundary. Dissolved Se shows evidence of attenuation in response to the vertical redox gradient in the water column, with surface values (12 to 20 µg/L) decreasing to <3 µg/L in the suboxic zone. Overall, the data reveal evidence of both denitrification and Se reduction, with Se being removed from solution presumably as either selenite (Se^{+4}) (via adsorption to settling particles) or as precipitation of elemental Se (Se^{0}) or selenide (Se^{2-}). The implications of the data with respect to mine water management and Se bioremediation are discussed.

Keywords: coal, mining, bioremediation, passive treatment

INTRODUCTION

For coal mine districts throughout North America, selenium (Se) is a water quality parameter of concern with respect to environmental compliance and the protection of aquatic resources. The common occurrence of elevated Se concentrations in coal source rocks (*e.g.*, wasterock, pit walls, tailings, coal reject, *etc.*), and leaching through natural weathering, can increase levels of Se in mining-influenced drainages to well over background levels. Due to potential environmental consequences aquatic taxa exposure to Se in mine-affected settings, considerable effort has been placed on the development and evaluation of active and passive treatment systems for Se removal (CH2MHILL, 2010, 2013). In particular, the potential for the passive removal of Se through various forms of bioremediation has received considerable attention due to the favourable cost implications and the ineffectiveness of traditional chemical precipitation methods for reducing Se to environmentally-acceptable limits (Frankenberger *et al.*, 2004).

Engineered passive and active treatment systems designed to remove Se from solution generally rely upon the development of suboxia. Under suboxic conditions, the potential for Se attenuation is enhanced by a suite of microbially-mediated processes that favour the reduction of selenate (Se^{+6}) and removal of dissolved Se from solution via adsorption and precipitation reactions. Such suboxic mechanisms include: 1) reduction of selenate (Se^{6+}) to selenite (Se^{4+}) followed by adsorption of selenite to particles; 2) precipitation of elemental Se (Se^{0}); 3) precipitation of Se as inorganic/organic selenides (Se^{2-}); and 4) co-precipitation of Se with reduced sulfur (Masscheleyn and Patrick, 1993). Suboxia is also required to reduce nitrate (through denitrification), the presence of which can inhibit Se reduction and hence its potential for attenuation (Oremland *et al.*, 1991).

Mine settings offer significant opportunities for the bioremediation of Se through the natural and/or engineered development of suboxia within mine facilities. Specifically, large-scale zones of suboxia may occur in pit lakes (Castro and Moore, 2000), within the pore spaces of saturated wasterock (Bianchin *et al.*, 2013), and in some cases, within unsaturated zones of large wasterock dumps (Kuo and Ritchie, 1999). Further, such suboxic zones have the potential to be incorporated into water management strategies designed to reduce Se loadings from mine operations.

In this paper, the potential utility of flooded open pits as bioremediation cells for Se is discussed through examination of water quality data from a mine in northern Canada. Mine pit lakes often differ from natural lakes in that they are typically deeper, more saline, and less susceptible to wind mixing (due to small fetch and topographic sheltering from pit walls). These features can lead to the development of permanent stratification (meromixis), resulting in the development of suboxic bottom waters. Specific objectives this study are as follows: 1) describe the physical and chemical limnological setting of the flooded pit; 2) delineate the biogeochemical processes governing the behaviour of Se and other mine-related parameters; and 3) discuss potential applications of flooded pits for Se bioremediation through passive and engineered methods.

ENVIRONMENTAL SETTING AND METHODOLOGY

The study site is situated at a closed coal mine in northern Canada at an elevation of ~1,500 m. The open pit was developed between ~1987 and ~1995 and partially backfilled with spoils from ~1995 to ~1998. Passive flooding of the pit began in 1998, reaching a static water level in 2002. The maximum water depth in the pit is 72 m, encompassing a total water volume of 2.35 million m^3. Due to the generally low total sulfur content (generally <1%) and high abundance of carbonate minerals in

host rocks, waste materials in the region are not acid generating. Environmental concerns relating to Se are typically associated with neutral to basic-pH leaching from subaerial (unsaturated) wasterock.

On July 31, 2013, the flooded pit was sampled through a combination of *in situ* profiling and water sample collection. *In situ* vertical profiling (20 cm vertical resolution) of conductivity, temperature, pH, dissolved oxygen (DO) and fluorescence was conducted over the deepest portion of the pit using a Sea-Bird Electronics™ conductivity-temperature-depth (CTD) profiler (SBE 19plus SEACAT Profiler, Bellevue, Washington). The CTD was configured with a WETLABS ECO Fluorometer™ to measure vertical variations in chlorophyll concentration in the water column (proxy for photosynthetic algal biomass). Water quality samples were collected at depths of 1, 2, 4, 6, 8, 10, 12, 15, 20, 30, 40, 50 and 60 m, and analyzed for physical parameters, anions, nutrients and total/dissolved trace elements. Trace element concentrations were determined via inductively-coupled plasma mass spectrometry (ICP-MS), while anions were analyzed via ion chromatography (Dionex).

RESULTS AND DISCUSSION

Water column physical structure

High resolution profiles of temperature and conductivity show the presence of a stratified water column in the flooded pit, with a pronounced thermocline observed between 3 and 6 m (Figure 1). The thermocline overlaps with a sharp gradient in salinity as revealed by the profile of specific conductivity. The combined effect of the temperature and salinity gradients result in a pronounced density gradient (pycnocline) that is spatially consistent with the temperature and conductivity gradients observed in the uppermost 6 m of the water column (Figure 1).

Salinity gradients in the flooded pit are dominantly governed by vertical variations in the concentrations of sulfate, calcium and alkalinity, all of which represent products of mine waste weathering (wasterock and pit walls) (Figure 2). Sulfate is liberated through the oxidation of reduced sulfur minerals (*e.g.* pyrite) while calcium and alkalinity represent the products of carbonate mineral dissolution which are abundant in the host Cretaceous sedimentary rocks. Sulfate concentrations in the water column (750 to 1,000 mg/L) are strongly elevated above background values, and illustrate the pronounced mine-related signature in pit waters. The range in sulfate concentration is comparable in magnitude to values observed in wasterock seepages in the region.

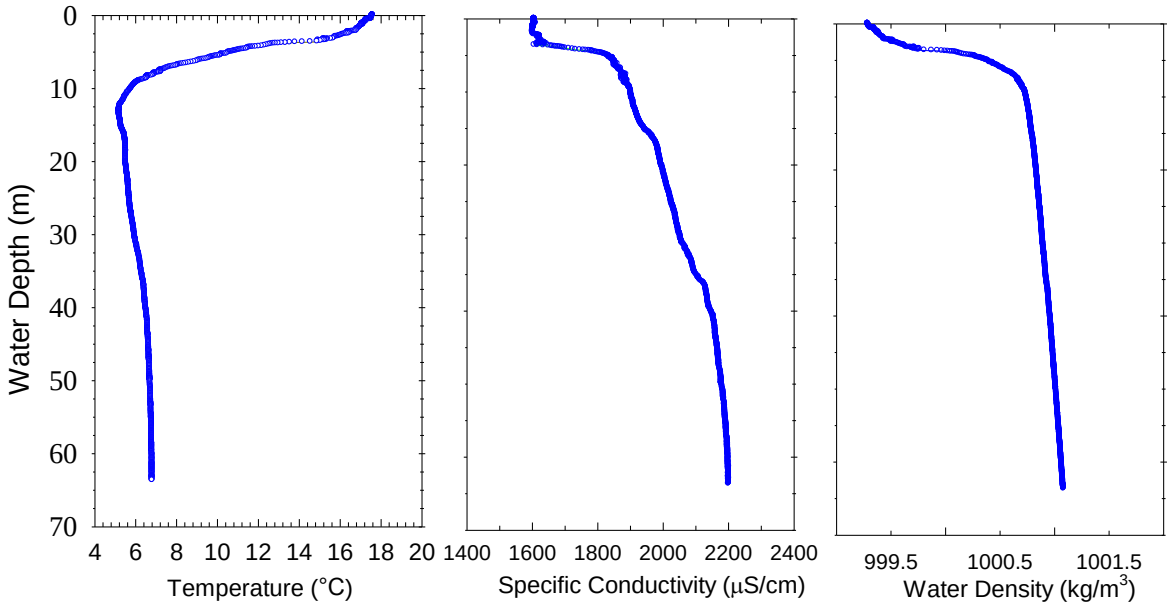

Figure 1 High vertical resolution (20 cm spacing) profiles of *in situ* temperature, specific conductivity and calculated water density in the flooded pit.

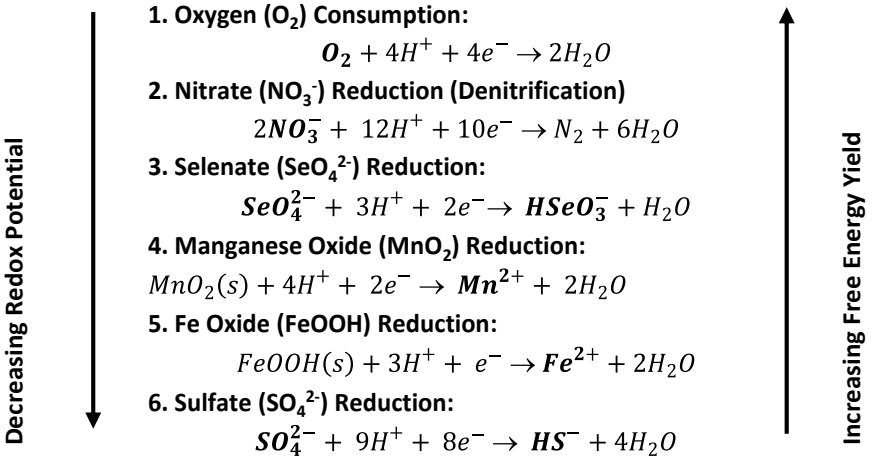
Redox conditions

Redox conditions have been shown to be the dominant variable governing Se speciation, precipitation/dissolution, sorption/desorption, methylation and volatilization in water and sediments (Masscheleyn and Patrick, 1993; Zhang and Moore, 1996). Accordingly, an understanding of redox conditions is essential to support interpretations of Se behavior. In natural systems, redox reactions are driven by the oxidation of organic matter, which can be defined by a series of microbially-mediated reactions (Table 1). In the presence of dissolved oxygen, aerobic bacteria will utilize O_2 as a terminal electron acceptor since this redox reaction affords the greatest energy yield. However, in systems where the rate of O_2 consumption exceeds the rate of re-supply, O_2 will become depleted and other secondary oxidants will be utilized by facultative anaerobic bacteria. These, in order of their free energy yield, are nitrate, manganese oxides, iron oxides, and sulfate (Table 1). In this sequence of redox reactions, selenate reduction occurs at a similar redox potential to that of nitrate.

Table 1 Oxidation/reduction reactions associated with the re-mineralization (oxidation) of organic matter. Parameters measured to elucidate redox conditions are highlighted in bold.



Water column redox conditions in the flooded pit were assessed through examination of various redox-sensitive indicators including dissolved oxygen (DO), nitrate, ammonia, dissolved Fe and dissolved Mn (Figure 2). Overall, the presence of lake stratification has a pronounced effect on water column redox conditions. DO levels show a progressive decline below the thermocline, from a maximum of 12 mg/L (at 5 m) to undetectable concentrations below a depth of 22 m. The absence of DO below 22 m provides strong evidence to indicate that the flooded pit is permanently stratified. If a mixing event had occurred in the previous months, some residual DO would be expected to persist in lake bottom waters.

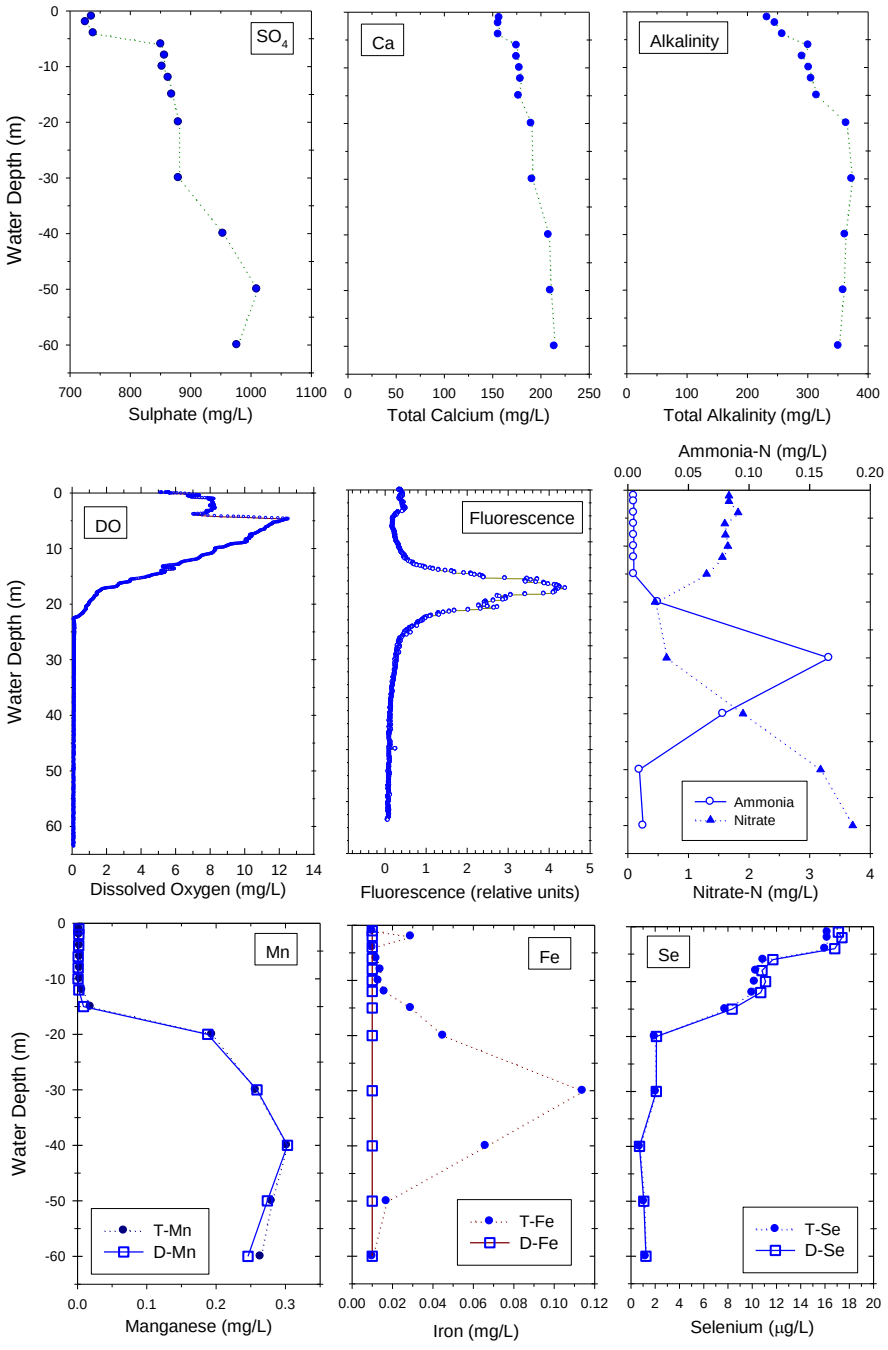


Figure 2 Vertical profiles of sulfate, total calcium, total alkalinity, dissolved oxygen, fluorscence, nitrate-N, ammonia-N, manganese, iron and selenium in the flooded pit. Data for fluorescence and dissolved oxgyen were collected via high vertical resolution *in situ* profiling.

Nitrate shows a pronounced mine-related signature in surface waters (1.6 mg/L), and reflects the input of residual nitrogen-based blasting residues. Below the oxic-suboxic boundary at 22 m, nitrate-N values decline to a minimum value of 0.5 mg/L at a depth of 20 m. The horizon of low

nitrate concentration is interpreted to result from denitrification (microbially-mediated nitrate reduction) in the suboxic zone below 20 m. Below the nitrate minimum, nitrate-N values progressively increase to a bottom water maximum of 3.7 mg/L, presumably reflecting the original mine-related signature established post-filling. Overall, the data suggest that the nitrate profile is in non-steady-state, whereby denitrification is progressively depleting the nitrate inventory in the suboxic zone below 20 m.

The occurrence of nitrate reduction near the oxic-suboxic boundary may in part be related to the peak in photosynthetic biomass (*e.g.*, algae) observed between 16 and 23 m, which will supply a source of organic detritus (and oxygen demand) to this portion of the water column. The magnitude of the fluorescence peak is indicative of oligotrophic conditions, which is common to pit lake environments. The influence of the autotrophic peak is also illustrated by the ammonia data, which show a concentration maximum in the upper portion of the suboxic zone (Figure 2). This ammonia peak is inferred to represent a product of organic matter remineralization. The presence of ammonia also provides additional evidence in support of suboxic conditions below water depths of 20 m, given the chemical instability of this species in the presence of DO.

Below the oxic-suboxic boundary at 22 m, dissolved Mn concentrations increase to a maximum of 0.3 mg/L. This is consistent with the reductive dissolution of Mn-oxides in the suboxic water column, which will liberate dissolved Mn^{2+} into solution. In contrast to Mn, dissolved Fe does not show any evidence of bottom water enrichment. Low levels of particulate Fe (as inferred from the total Fe profile) are evident; however, the data do not indicate the occurrence of Fe-oxide reductive dissolution. Collectively, the data for redox proxies are indicative of mildly suboxic conditions below 20 m, as inferred by the absence of DO, evidence of denitrification, presence of ammonia, and elevated levles of dissolved Mn. Indicators of more strongly reducing conditions, as would be revealed by Fe oxide reductive dissolution and/or sulfate reduction, are not observed.

Selenium

Profiles for dissolved and total Se are congruent, indicating that Se is present almost exclusively as dissolved species (Figure 2). Se shows evidence of attenuation in response to the vertical redox gradient in the water column, with surface values (12 to 20 μg/L) decreasing to <3 μg/L in the suboxic zone (Figure 2). The low Se values below the oxic-suboxic boundary, and the strong parallels between Se and DO, suggest that the behaviour and attenuation of Se is tied to vertical variations in redox conditions. Specifically, the data strongly suggest that the decrease in Se concentrations below 20 m reflects the removal of dissolved Se from solution as reduced Se phases, presumably as either selenite (Se^{+4}) (via adsorption to settling of particles) or as precipitation of elemental Se (Se^{0}) or selenide (Se^{2-}). The redox-controlled attenuation of Se is supported by the data for other redox proxies, which show evidence of both denitrification and Mn-oxide reductive dissolution. Specifically, the selenate/selenite redox couple occurs between nitrate reduction and Mn-oxide reduction (Table 1) Importantly, these data demonstrate that Se removal is achievable under mildly suboxic conditions in the presence of nitrate, which could be expected to hinder Se reduction.

The mechanism of Se attenuation described here is consistent with other forms of passive and engineered Se removal systems that rely on suboxic conditions, including passive wetland treatment (Martin *et al.*, 2011), passive removal in saturated wasterock (Bianchin *et al.*, 2013),

constructed permeable reactive barriers (Morrison *et al.*, 2001), and active biological treatment systems (CH2M HILL, 2010, 2013).

A conceptual model for Se bioremediation is shown in Figure 3. The required elements to support selenate reduction and removal from solution include: 1) a stratified water column, which allows the development of bottom water suboxia; and 2) a source of oxygen demand, which in this case is provided by *in situ* photosynthetic activity. The input of terrestrial organics via surface runoff likely also provides a source of organic carbon (and oxygen demand) to the system.

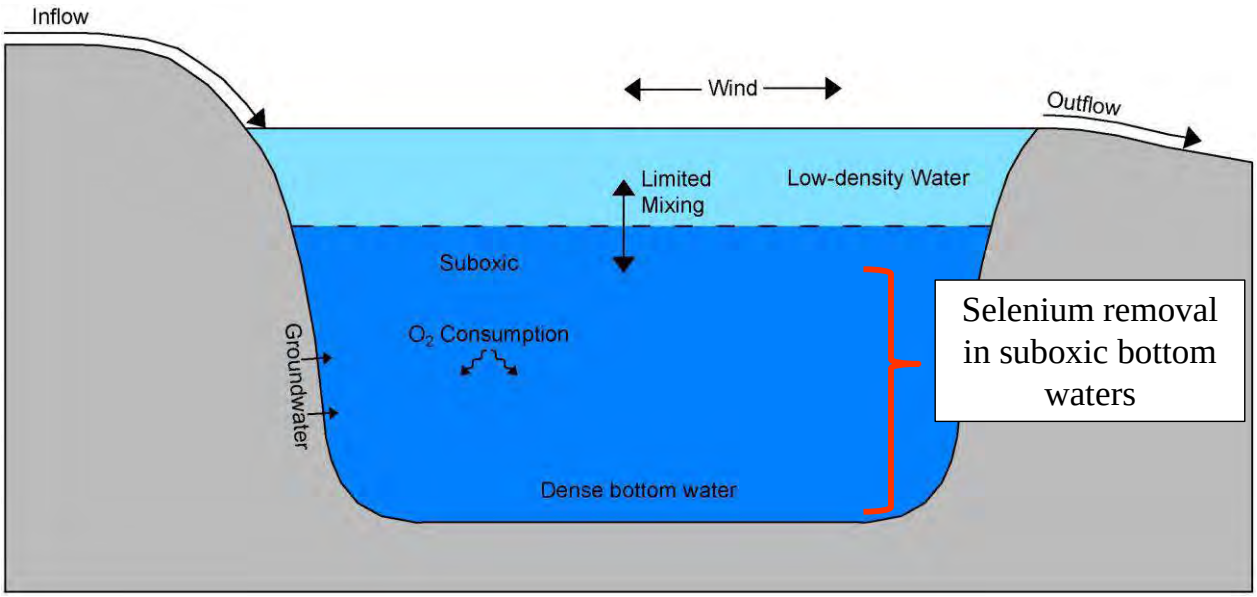

Figure 3. Conceptual model for selenium removal in a stratified flooded pit.

CONCLUSIONS AND IMPLICATIONS FOR MINE WATER MANAGEMENT

Overall, the data provided here illustrate the potential utility of flooded pits as *in situ* bioremediation cells for the removal of Se. The scale of Se removal can be illustrated by the volume of water in this system showing Se concentrations <5 µg/L, which equates to approximatly 1 million m^3 (below a depth of 20 m). There is also the potential to enhance rates of Se removal via the addition of organic amendments. Lake fertilization, for example, can provide an effective means to increase rates of *in situ* algal production and associated carbon generation (Dessouki *et al.*, 2005; Martin *et al.*, 2009). Such methods rely upon the well-established links between phosphorus limitation and algal growth (Schindler *et al.*, 1980). This form of amendment is very cost effective, given that only small additions of phosphorus can promote extensive carbon production. Alternatively, successful Se removal has been achieved via the direct addition of organic amendments to flooded pits (as liquid or solid forms) (Park *et al*., 2006).

Flooded pits that exhibit stratified and suboxic water columns also offer the potential to passively treat other site contact flows. This is illustrated in Figure 4 which shows a conceptual model depicting the injection of contact waters (*e.g.*, wasterock seepage) into the suboxic (bottom) zone of a flooded pit. Following mixing and Se attenuation in pit bottom waters, waters are then withdrawn from the pit for final discharge, which may require aerobic polishing prior to release to

receiving streams. The input of contact waters to the pit bottom will introduce DO, which has the potential to push the system to a less favourable redox regime (more oxic). In this regard, the addition of fertilizer and/or innoculum (*e.g.*, Se and nitrate reducing microbes) could be used to sustain suboxia and the desired redox state conducive to Se removal (also illustrated in Figure 4). This form of semi-passive treatment has been implemented at the Island Copper Mine, which uses a combination of ARD injection to bottom waters and surface water fertilization to promote more reducing conditions in the lower water column (Polling *et al.*, 2003).

With regards to mine water management, the data presented here also highlight the merits of maximizing saturated storage volumes in the design of mine waste facilities, which can passively, or through augmentation, form large-scale zones of suboxia. This requires consideration during mine planning (pit morphometry), potential use of in-pit berms to maximize in-pit water levels, mine waste management and water management.

ABSTRACT

Predicting the source and fate of selenium (Se) from mine waste requires a multi-disciplinary understanding of the biogeochemical and hydrogeological processes that can occur, as differences in rock processing, waste storage configuration and resulting hydraulic properties can lead to orders of magnitude differences in the rate of Se release.

Non-acid generating coal reject piles stored on-site at the Willow Creek Mine, north-eastern British Columbia, Canada, were identified as a Se-leaching risk during environmental assessment studies. A condition of the mine permit included moving the piles to an alternative storage location to mitigate the risk of impacts to the nearby Pine River. Rates of Se leaching assumed for environmental studies were based on laboratory and small-scale site geochemical studies, performed under aerobic conditions that were ideal for Se release. However, to date, none of the available monitoring data have shown elevated Se concentrations in groundwater surrounding the piles.

To better understand why the coal reject piles did not appear to be leaching Se at predicted rates, a multi-disciplinary characterization study of the piles was performed that included borehole instrumentation of the piles to monitor gas composition and temperature, as well as collecting solid samples for microbial characterization coupled with geochemical and physical testing results from operational sampling.

Results from the study indicated the piles were sub-oxic and support a microbial community capable of reducing selenate, nitrate and ferric iron. Despite the piles being in an unsaturated state, the small particle size of the coal rejects and high residual moisture content has likely led to the observed sub-oxic conditions that provide a mechanism for Se sequestration within the piles resulting in low to non-detectable release rates to the surrounding environment. Findings from this study suggest there is currently no need to move the piles, and raises the question of whether re-handling would perturb established Se sequestration mechanisms.

Keywords: Selenium sequestration, biogeochemistry, coal rejects, field instrumentation

INTRODUCTION

The Willow Creek Mine (WCM) is located approximately 45 kilometres west of Chetwynd, British Columbia. Metallurgical grade coal seams are recovered by open pit methods and processed on site. The most recent operational phase for the mine was between 2010 and 2014, with operations placed on care-and-maintenance in the middle of 2014 due to low coal prices.

The economic coal seams are mined from the Lower Cretaceous Gething Formation. Surrounding the coal seams are sandstones, shales, siltstones, and mudstones, which are typical of the coal-bearing strata in the Rocky Mountains of western Canada Also typical of these rock types, and notably for the coal mines in eastern BC, is the enrichment of selenium (Se) when compared to typical global values for sandstones (Price 1997) On average Se concentrations range from 2-4 mg/kg Se, but have been reported as high as 15 mg/kg (Western Coal 2010; Kennedy et al, 2012).

Unsaturated coal reject (CR) piles stored on an alluvial fan (Figure 1) at the WCM were identified as a Se leaching risk during Mines Act Permit C-153 amendment (MAPA) studies to re-open the mine in 2010 (Western Coal 2010). A condition of the Mines Act Permit included moving the piles to an alternative storage location to mitigate the potential for impacts to the nearby Pine River. Rates of Se leaching assumed for environmental studies were based on laboratory and small-scale site geochemical studies, performed under aerobic conditions that were ideal for Se release. However, none of the available monitoring data before or the year after the MAPA studies were completed showed elevated Se concentrations in groundwater surrounding the piles. As a result, in 2011 a multi-disciplinary study was initiated by SRK Consulting (Canada) Inc and Walter Energy Inc. to assess the Se leaching potential from the CR piles currently stored near the plant site and better understand the implications of moving the piles to another location as currently stipulated in the Mines Act Permit.

Conceptual model and program design

A conceptual model was used as the basis for designing the study to determine if the pile is a long term risk for Se loading to the receiving environment. The model was divided into hydrogeology and biogeochemical components. A schematic of the overall conceptual model is provided in Figure 2.

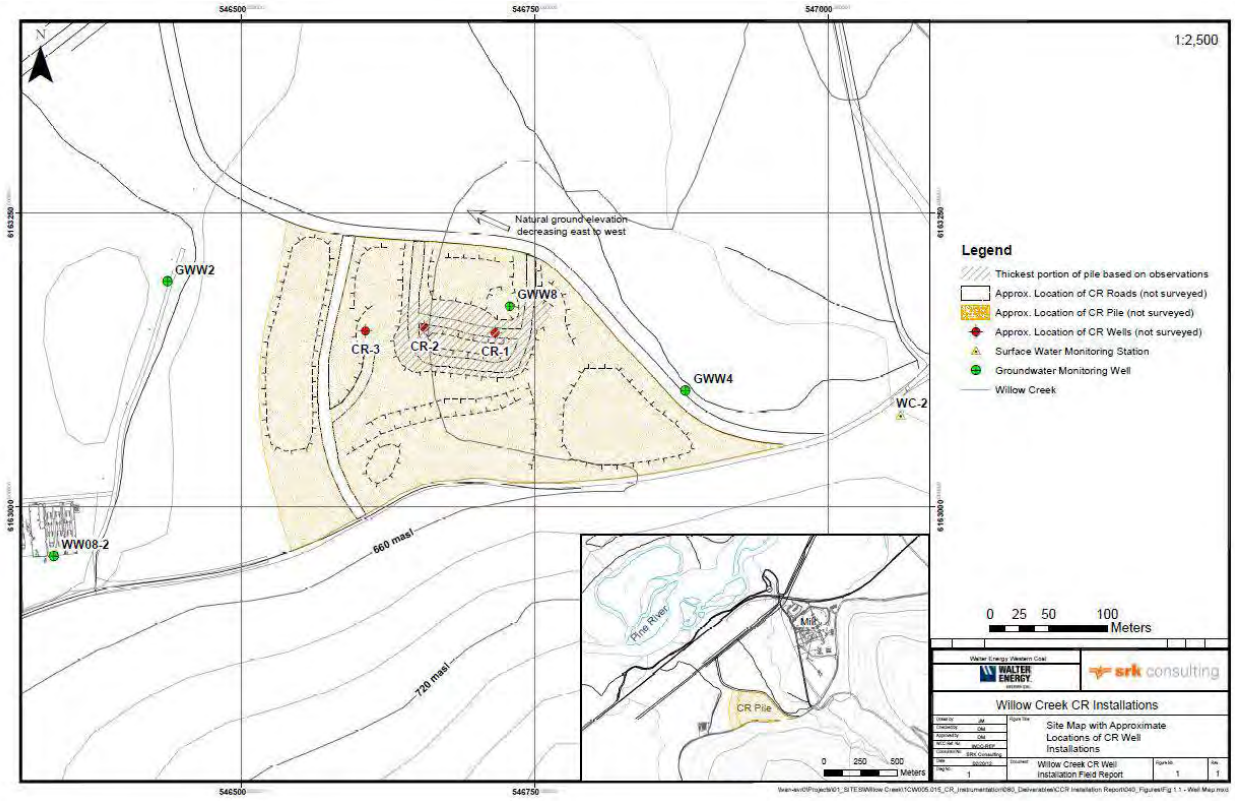

Figure 1 Location of coal reject pile on alluvial fan study site at Willow Creek Mine

Hydrogeology conceptual model

The groundwater flow system in the CR has two main components: (1) existing flow within the alluvial fan groundwater system and (2) seepage from the CR pile (Figure 2).

Groundwater is expected to move in the alluvial fan system from relatively high elevations near the apex of the fan, towards lower elevations and the Pine River. Recharge to the groundwater system comes from infiltration of direct precipitation, leakage from Willow Creek, and runoff from the mountains. Groundwater discharges to the Pine River. Seepage from the CR pile originates from precipitation infiltrating the pile and drain down of pore water within the pile when it was deposited. Precipitation on the CR pile either evaporates (or sublimates), runs off the pile, or infiltrates. The relatively fine-grained nature of the pile and presence of standing ponds indicate that infiltration is not likely to be excessive. Drain-down from within the pile itself is not likely significant.

Infiltration that does reach the base of the pile can infiltrate into the underlying substrate of the alluvial fan or run out along the ground surface and daylight as seeps at the toe of the pile. Water that does infiltrate into the alluvial fan percolates to the water table, then moves in the same direction as overall groundwater flow. There is the potential for silty interbeds to locally perch water, but all water will eventually reach the fan groundwater system.

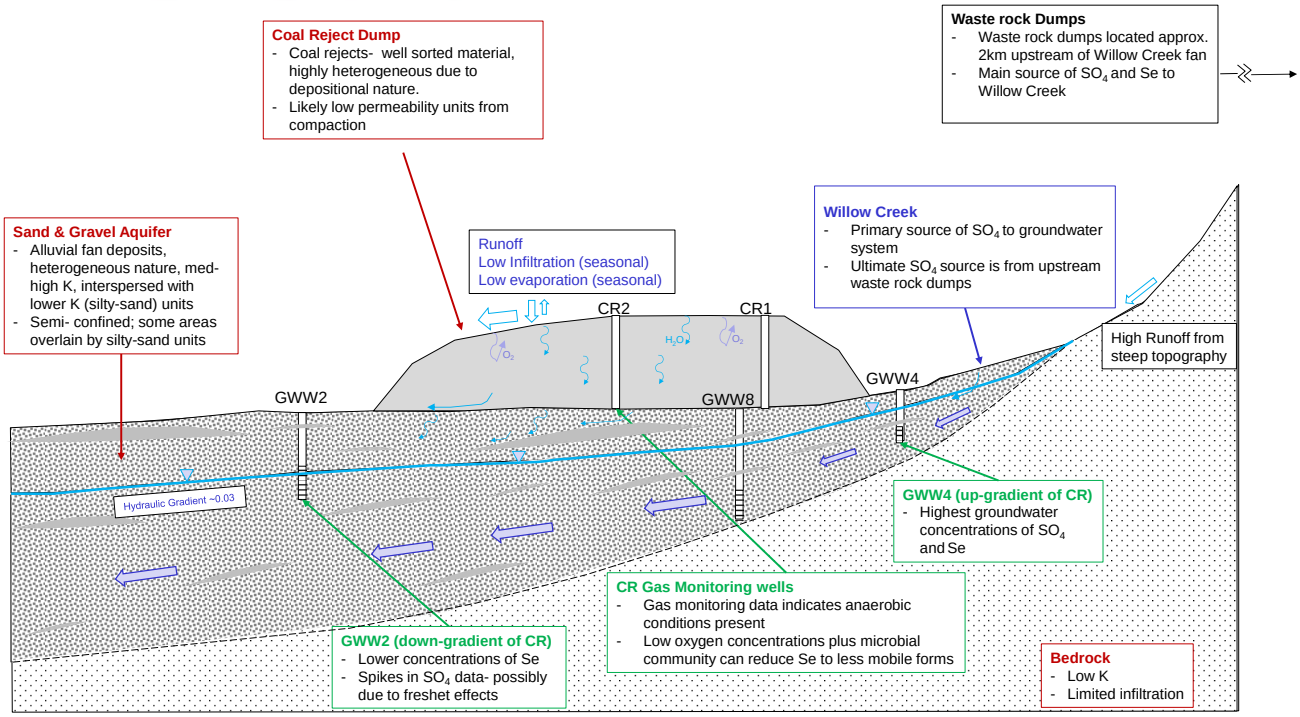

Figure 2 Conceptual model schematic for the WCM CR piles

Biogeochemical Conceptual Model

Selenium release from coal waste materials in British Columbia is generally understood to occur due to oxidative dissolution of pyrite, meaning that Se release is dependent on conditions favourable for the oxidation of sulfide minerals (Kennedy et al. 2012). Oxygen is the most likely oxidant and therefore if low level oxygen conditions are present in the CR piles, this should slow down the oxidation of sulfides and therefore Se release.

The following processes could be occurring in the CR pile:

- A thin layer on the exposed surfaces of the CR pile oxidizes producing soluble sulfate and Se, and dissolved organic carbon. Due to their concurrent release, Se and sulfate concentrations are expected to be correlated.
- Infiltrating precipitation dissolves Se, sulfate, and organic carbon.
- At depth, suboxic conditions develop and a microbial population that favours reduction becomes dominant, leading to conversion of Se to reduced states (selenite, potentially elemental Se and selenide).
- Sulfate may not undergo reduction unless anoxic conditions develop. As a result, the correlation between sulfate and Se diverge if Se is removed from solution.
- Selenium is sequestered in the pile by either selenite adsorption to reactive surfaces or by forming elemental Se and selenides (a solid phase precipitate).

Ultimately all of the above processes could result in leachate leaving the CR pile and travelling into groundwater with low Se, and relatively unchanged sulfate.

METHODOLOGY

In order to further understand the processes occurring in the CR piles, a multi-disciplinary characterization study of the piles was performed that included borehole instrumentation of the piles to monitor gas composition and temperature, as well as collecting solid samples for microbial characterization coupled with geochemical and physical testing results from operational sampling. The details of each component are provided below.

CR pile instrumentation and monitoring

Three monitoring boreholes were installed in 2012 using air rotary drilling into the CR piles. Each hole had thermistor strings installed and Solinst continuous multilevel tubing (CMT) with multi-level gas monitoring systems. Locations of these wells (CR-1, CR-2 and CR-3) are shown on Figure 1.

Monitoring of the gas wells included carbon dioxide and oxygen concentrations using an RKI Eagle multi-parameter gas sampling probe. Temperature was monitored by a multimeter capable of measuring the resistance in the thermistor strings.

Solids chemistry and reactivity assessment

Geochemical characterization of the CRs was based on previous studies from the MAPA study (Western Coal 2010) and supplemented by additional grab samples in 2010 and 2011 by WCM staff. The MAPA study included analysis of 44 operational samples from 2005 and 2006 and another 69 samples from operations after the mine re-started.

Analytical testing of all samples included acid-base accounting (Sobek et al. 1978) and element composition by aqua-regia digestion and ICP-MS. Neutralization potential (NP) is site specific at the WCM as defined in permit C-153 where NP for CR is calculated as Sobek NP (in kg $CaCaO_3$/t) multiplied by 0.8 plus 0.71. Acid potential (AP) for all rock types is calculated from sulfur concentrations determined by ICP-MS following aqua-regia digestion. Mineralogy of CR was characterized by semi-quantitative XRD and optical petrography descriptions.

Weathering kinetics were assessed using a humidity cell test (referred to as the "CCR H Cell" in the MAPA study), a 200 to 300 kg field barrel test and meteoric water mobility procedure (MWMP, NDEP 1990) tests on weathered samples collected in 2005 and 2006.

Microbial characterization

Grab samples were recovered aseptically from each borehole and shipped to the Microbial Geochemistry Laboratory at the University of Toronto, Ontario, for microbial analysis. A cultivation presence/absence approach was selected due to difficulties recovering DNA from the surface of the coal, which was found to be somewhat hydrophobic.

Media for anaerobic cultivation were prepared by mixing an artificial groundwater solution with solutions to support one of: nitrate; selenate; iron; or sulfate reduction. Lactate, acetate and pyruvate were used as the carbon sources. All solutions were sterilized (i.e. autoclaved) prior to inoculating with CR sediment. Sand and silt sized particles of CR were transferred into cultivation vials in an anaerobic chamber and stored at room temperature for 5 weeks. Successful cultivation

was indicated by biofilm accumulation on the vial walls for the nitrate and iron reducing media and by the presence of pink precipitates in the Se media.

Groundwater and surface water chemistry

In 2005, eight groundwater monitoring wells were installed in the Willow Creek Fan and the Pine River floodplain. The purpose of these wells was to assess groundwater quality and to develop a hydrogeological conceptual model for the fan in preparation for construction of the CR pile (Western Coal 2010). Five of the eight monitoring wells are located in the fan itself, although only GWW2, GWW4, and GWW8 are used in this study (Figure 1). Groundwater sampling data were available from late 2005 to 2013, with analyses including pH, sulfate, alkalinity, chloride, fluoride, nitrogen species, phosphorus species, dissolved organic carbon, and a 32 element scan by ICP MS for dissolved ions.

The spatial context of the fan monitoring locations (Figure 1) and context for interpreting water quality data are as follows:

- WC-2 represents upstream surface water that carries sulfate and Se from the up-land waste rock dumps at WCM.
- Groundwater generally follows topography, flowing from higher elevation portions of the fan towards the Pine River (i.e. GWW4 towards GWW2, passing GWW8), a distance of approximately 600 m horizontally from the toe of the CR pile.
- GWW4 is located upgradient of the CR pile and will not be impacted by the pile. The monitoring screen in GWW4 is within sandy gravel materials at a depth of 10 to 13 m below ground surface. The water table is about 7 m below ground surface at this location.
- GWW8 is screened below the CR pile footprint and has the potential to be impacted by the CR pile. The monitoring screen in GWW8 is within silty sand and gravel materials at a depth of 19 to 28 m below ground surface. The water table is about 9 m below ground surface at this location.
- GWW2 is located about 90 m down gradient of the CR piles and has the potential to be impacted by the CR piles. The monitoring screen in GWW2 is within sand and gravel materials at a depth of 10 to 16 m below ground surface. The water table is about 9 m below ground surface.

RESULTS AND DISCUSSION

Gas composition and temperature of the coal reject pile

Gas composition changes quickly over the first two metres below the surface with oxygen dropping below 4% and concentrations near detection at 8 metes below the surface. Carbon dioxide concentration shows an opposite trend in that it immediately increases below the surface to 3% and is relatively stable thereafter to the base of the pile.

Temperatures also appear to be higher inside the pile than regional ambient conditions during parts of the year, notably winter. Temperature monitoring of ambient conditions of the CR piles was not performed, although the average temperature during winter (November to March) in Chetwynd, British Columbia, ranges between -10°C and -5°C.

Geochemical characteristics

The CRs were characterized by relatively low sulfide sulfur (average of 0.16% interpreted from ICP aqua regia results) and levels of Se (average of 2.6 mg/kg) typical of coal waste material in eastern British Columbia. A statistical summary of the 69 grab samples that were analysed since the MAPA is provided in Table 1. When compared to the 2005 and 2006 operational samples (Western Coal 2010), sulfide sulfur and NP were somewhat lower in the grab samples. However, the overall difference between the acid-base account (NP divided by AP) of the two samples sets was small with averages for both around 3.0. Selenium concentrations were very similar between the two sample sets, with the average Se concentration in the 2005 and 2006 samples approximately 3 mg/kg.

The main sulfide mineral identified was pyrite, with possible pyrrhotite and trace levels of sphalerite and chalcopyrite also noted. X-ray diffraction determined that calcite, dolomite/ankerite and siderite were the main carbonates present.

The previous assessment of the CR piles by SRK (2007) and Western Coal (2010) indicated that the ARD potential was low. Grab sample results provided by WCM since the 2007 assessment support the original finding when an NP/AP criterion of 2 is used to delineate between PAG and non-PAG. While some of the samples have produced some acidity (as interpreted from a negative NP), water quality results from around the pile (Western Coal 2010) support that the piles overall are not a source of acidity despite being allowed to weather for several years.

Table 1 Summary of geochemical characteristics for operational coal reject samples

Statistic	Sulfide %S	AP kg $CaCO_3$/t	NP(Sobek) kg $CaCO_3$/t	NP/AP	Se mg/kg
Minimum	0.030	0.94	-3.3	-1.0	0.05
5th Percentile	0.040	1.3	3.4	0.64	0.94
25th Percentile	0.08	2.5	7.1	1.5	1.5
Mean	0.16	4.9	16	3.2	2.6
75th Percentile	0.21	6.6	18	5.0	3.2
95th Percentile	0.35	11	39	14	6.1
Maximum	0.61	19	108	43	8.9

Concentrations of Se and sulfide sulfur were compared in this study to confirm previous findings from other coal mines in British Columbia that Se was likely associated with sulfide (Kennedy et al. 2012). Selenium substitutes for sulfur and is often present as an accessory element in pyrite. The correlation coefficient for total sulfur (which will include any organic sulfur and sulfate sulfur) and Se was poor (r = 0.26, 99% confidence = 0.31), but improved when sulfide sulfur and Se were correlated (r = 0.45). Figure 3 compares of sulfide sulfur and Se in the CR samples.

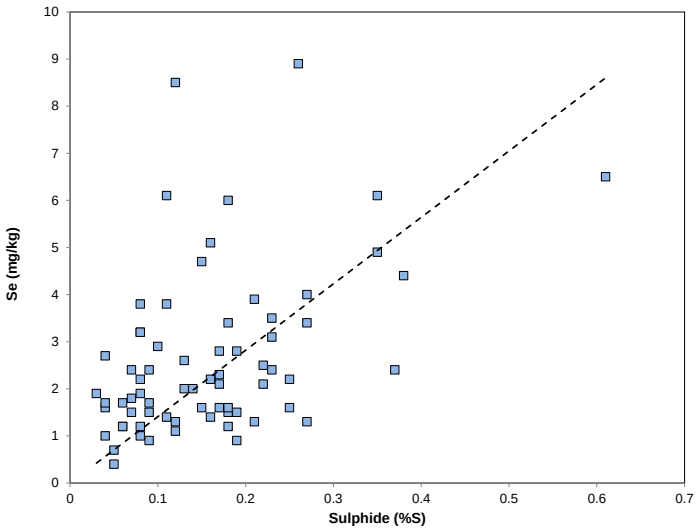

Figure 3 Comparison of Se and sulfide sulfur in WCM CR samples

Based on the results presented in Figure 3 and experience at other coal sites in British Columbia (e.g. Kennedy et al, 2012), Se leaching is expected to result from sulfide oxidation and generally at elevated levels compared to background levels (e.g., greater than 0.1 mg/L).

The field barrel test produced leachate pHs between 7.7 and 8.1, sulfate concentrations ranging from 283 to 2300 mg/L, and Se concentrations between 0.18 to 0.49 mg/L. Results from the MWMP tests confirmed these findings, as did the humidity cell tests, albeit at lower concentrations owing to the higher dilution in the humidity cell test (Western Coal 2010).

Microbial characterization

Results of microbial cultivation analysis demonstrated the viability of nitrate-, selenate- and iron-reducing communities of bacteria. Sulfate-reducing bacteria do not appear to be viable based on the cultivation tests.

The microbial communities identified are consistent with the low oxygen conditions present in at least portions of the CR piles. Bacteria respiring on selenate for electron transfer results in the formation of the more reduced forms of Se, such as selenite and elemental Se (Oremland 1994). These more reduced forms are readily removed from the soluble phase in groundwater by either adsorption or precipitation (selenite will adsorb, elemental Se will precipitate) (Neal & Sposito, 1989; Ralston, Unrine & Wallschläger, 2008). Nitrate and selenate are reduced at very similar oxidation potentials, while iron reduction requires more reducing conditions. Finding all three communities is a good indication that conditions are ideal to support suboxic to anoxic microbial communities and also that other requirements for survival are available, such as dissolved organic carbon and trace nutrients.

Based on the microbial characterization results, it is likely that a microbial community capable of converting selenate to more insoluble forms (e.g. selenite and elemental Se) will persist in the CR piles so long as suboxic conditions are maintained. It is likely a microbial communtiy is able to inhibit elevated concentrations of Se entering the receiving environment that was predicted by MAPA studies based on reactivity of the CRs under aerobic laboratory and field testing conditions.

Groundwater and surface water chemistry

Concentrations of sulfate and Se in groundwater and surface water are compared to infer the potential reactions occurring within the CR piles. This is because field and laboratory leach tests from previous studies indicated that pyrite in the CR oxidizes to release sulfate and if no other processes were occurring within the CR piles, a plume of sulfate and Se would be expected in the groundwater below and down gradient of the CR pile.

At the upstream surface water monitoring station WC-2 (Figure 4), sulfate concentrations are highest compared to all other monitoring stations, with seasonal spikes typically around 100 mg/L over the last four years. Sulfate concentrations in the groundwater wells typically decreases in a downstream direction. Monitoring well GWW2 shows moderate (~60 mg/L) seasonal spikes in sulfate concentrations, potentially indicating that this location is impacted more by surface water than GWW8 during certain times of the year. There are gaps in the record for GWW4, so it is not possible to confirm if seasonal spikes also occur at this location, but it is considered likely based on historic comparison of GWW4 and WC-2. Monitoring well GWW8 has shown a slow increase in sulfate concentration over time, roughly intermediate between GWW4 and GWW2 on an average annual basis.

Selenium concentrations were highest at WC 2 and GWW4 (Figure 4) at around 0.005 and 0.003 mg/L. Concentrations downstream the CR piles (i.e., GWW8) are near analytical detection limits (0.0005 mg/L) (Figure 5) and an order of magnitude lower than WC2 and GWW4 (i.e. than upstream of the pile). The step change in Se concentrations in 2010 is likely a function of changing detection limits in the analytical laboratory, although this has not been confirmed.

Sulfate and Se concentrations at WC-2 were well correlated ($r = 0.85$, 99% confidence = 0.2) whereas at GWW8 they were not ($r = -0.3$) (Figure 5). The divergence at GWW8 is likely evidence of conditions in the sub-surface supporting reduction of selenate to selenite and possible elemental Se. While redox was not measured in the wells, using the concentration of redox sensitive elements and compounds under alkaline conditions (pH of about 8), the redox level of the groundwater is estimated to be approximately 400 mV, which is near the redox potential required to reduce selenate to selenite (Ralston, Unrine & Wallschläger, 2008). This is interpreted from the concentrations of nitrate and nitrite at GWW8 (0.1 and 0.01 mg/L, respectively) and also from dissolved iron concentrations. Iron occasionally spikes in GWW8 (up to 0.11 mgFe/L), which could simply be a result of poor filtering (i.e. partiulcate iron oxide contamination), or indicate times when redox conditions are closer to 0 mV and favour the formation of elemental Se. Under alkaline pH conditions, iron is only soluble when it is present in the reduced form as ferrous iron.

CONCLUSION

A multi-disciplinary characterization approach was used to assess the Se leaching potential from the CR piles at the WCM. Based on the results of this study, the piles appear to be sub-oxic and support a microbial community capable of reducing selenate. Despite the piles being in an unsaturated state, the conditions within the CR piles provide a suitable environment for selenate reduction and therefore Se sequestration to occur resulting in low to non-detectable release rates to the surrounding environment. Findings from this study suggest there is currently no need to move the piles, and raises the question of whether re-handling would perturb established Se sequestration mechanisms.

ACKNOWLEDGEMENTS

ABSTRACT

Changing regulations and water scarcity combined with increased fiscal pressure in the mining industry have increased the calls for new, lower cost methods for sulfate removal from mining effluents. In the last decade, membrane-based processes have been implemented on a large scale for advanced sulfate removal and have achieved a level of commercial acceptance in the mining industry. But membrane systems are complex and costly. On the other hand, many applications of sulfate removal in mining do not require a high removal efficiency, so simpler systems that are less costly may be more appropriate. Passive treatment offers the potential for reduced cost on sites where sufficient land area is available to construct treatment cells. Passive treatment has been demonstrated at a large number of sites, but has well-known drawbacks that encourage innovation. This paper will describe a recent project in passive biological sulfate removal for a mining effluent, and reports on the emerging concept of hybrid biological treatment. Hybrid treatment is intended to reduce the land area needed for passive treatment and thereby to make passive systems applicable for larger flow rates.

Keywords: Passive Treatment; Advanced Sulfate Removal; Hybrid Treatment

INTRODUCTION

Increasing pressure on water resources, changing regulations, and increasing awareness of the impacts of mining on water quality have led to increasing need for sulfate removal from mining effluents. Lime treatment has traditionally been used to reduce metals and acidity, but is able to remove sulfate only to the limit of gypsum solubility. The term "advanced sulfate removal" has been adopted by many to refer to sulfate removal below the level of gypsum solubility. Depending on the jurisdiction, and on the assimilative capacity of the receiving environment, some operations may be required to achieve an "end of pipe" sulfate limit of 300-500 mg/L, while others may be under even more strict limits.

In the last decade, a number of operators have successfully demonstrated advanced sulfate removal using membrane processes, at large flow rates, to achieve sulfate levels in product water of 100 mg/L or below (Hutton 2009). Examples include the eMalahleni water treatment plant (started 2005) and the Optimum Coal mine water treatment plant (2009) in South Africa, a facility at Kennecott Mine for treatment of impacted groundwater (2006) and the Northern West Virginia Water Treatment Plant (2013) in the USA. The product water from the eMalahleni and Kennecott plants is sent directly to local municipalities to provide drinking water.

On the other hand, alternatives to these large scale "active treatment" processes are sought which are less costly for applications where strict discharge limits are not required, for example, in cases where only 30-50% removal is desired. The cost of treatment to moderate sulfate levels should be significantly lower than the cost to meet strict levels. One option is to bypass part of the flow, allowing for a smaller capacity membrane plant, so the mixture of treated water and bypass water meets the objectives. Another option is to select membrane types which are semi-permeable to the target ions, thereby increasing the sulfate level in the effluent, and hopefully, decreasing costs. All the active treatment options, however, require a fully-staffed mechanical treatment plant with appropriate skills and training and attention to process control, to prevent costly problems such as scaling.

"Passive treatment" can offer sulfate removal with a greatly reduced level of complexity, greatly reduced staffing levels and skills, and as a result, potentially offers cost savings. Passive treatment research and development has been carried out over a period of decades. A large number of facilities have been constructed, but a relatively small subset of these projects involves designs specifically targeting sulfate removal. Passive treatment for advanced sulfate removal has met with mixed success, however the limitations of the process are beginning to be well understood and companies can now evaluate the passive treatment option with greater confidence. In general, passive treatment requires a much larger land area than active treatment, and as a result the process has not been frequently applied to large flow rates.

"Hybrid treatment", also known as semi-passive treatment, is an emerging concept that combines aspects of active treatment and aspects of passive treatment. In hybrid treatment, a biological sulfate reduction process takes place in a lined earthen vessel containing inert media and bacteria,

fed with a soluble electron donor and nutrients. The use of a soluble electron donor reduces the size of the vessel, and improves control, compared to passive treatment. The result is a process having low complexity, relatively low cost, and less operator input, but without necessarily requiring a large land area. The hybrid process has been successfully demonstrated on a small scale for selenium removal, however early attempts in sulfate removal have encountered problems.

BIOLOGICAL SULFATE REMOVAL

Biological treatment removal utilizes an organic carbon source, or hydrogen, as an electron donor to and sulfate as a terminal electron acceptor, thereby achieving reduction to sulfide through cellular metabolism. In a broader context, a variety of organisms use a variety of terminal electron acceptors in cellular metabolism, depending on the environment. A conceptual model of electron transfer in cellular metabolism is provided in Figure 1.

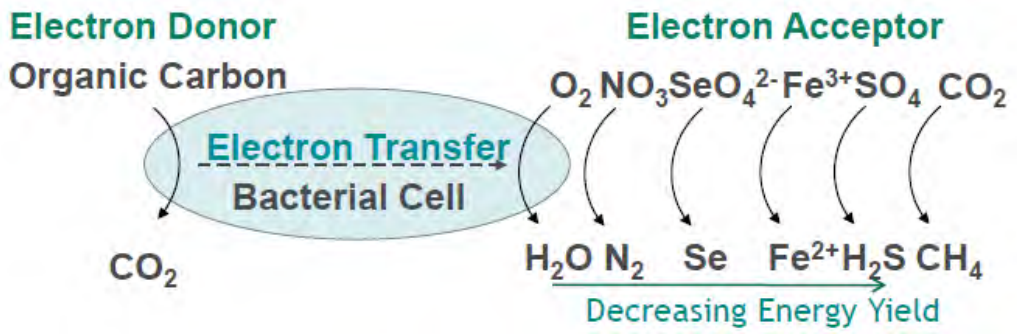

Figure 1 Electron donors and acceptors

There is a decreasing energy yield for successive electron acceptors illustrated by the figure, and, for example, oxygen and nitrate must be depleted prior to sulfate being reduced. The oxidation of organic carbon and the reduction of sulfate produces carbon dioxide (present at neutral pH as bicarbonate), water, and sulfide (present at neutral pH as a mixture of dissolved hydrogen sulfide and bisulfide).

A range of organic carbon sources have been employed for sulfate reduction, including but not limited to: methanol, ethanol, sugarcane waste, agricultural waste, sawmill waste, abattoir waste, sewage sludge, compost biosolids, cleared vegetation, and garden waste (Kumar 2011, Liamlean 2007). Selection of the lowest cost electron donor depends on the availability of materials close to the mine, and on the pre-processing costs that are required to deliver the material to the system.

Sulfide Sequestration

For biological treatment to be successful, it is essential that, once sulfate reduction is achieved, the resulting sulfide be removed from the system. The reasons are, firstly, sulfide is toxic and generally must be removed from effluents to low levels prior to release to natural water bodies. Secondly,

sulfide can off-gas from a treatment system as hydrogen sulfide, which is a health and safety or aesthetic concern and can add complexity to operation and maintenance. Thirdly, if not removed from the bioreactor effluent, sulfide can be oxidized back to sulfate through exposure to oxygen, in a process called reversion, which defeats the purpose of the process.

Some of the failures or difficulties of biological sulfate removal in the past have been associated with sulfide sequestration rather than sulfate reduction. Sulfide sequestration can be achieved in a variety of ways. In water sources that contain significant quantities of metals, the sulfide will act as a ligand and many base metals will precipitate. Alternatively, some of the sulfide may be removed using air-stripping, however this option produces a sulfide off-gas, and, practically, cannot achieve low levels of dissolved sulfide in the effluent. Air stripping may be combined with oxidation of sulfide to elemental sulfur, which is a solid and can be normally be separated from the liquids. The sulfur oxidation process can be biologically catalysed and is pH dependent. However, the process of oxidizing sulfide to sulfur can be difficult to control in passive systems, increasing the chance of reversion to sulfate, and creating polysulfides.

If the metals in the feed are not sufficient to sequester all of the sulfide, then a supplemental source of metals may be provided, and this usually consists of an abundant, low-cost iron carbonate, oxide or hydroxide material. Iron sulfate or chloride salts are not appropriate, since the resulting release of the sulfate or chloride ion to the effluent is counter to the overall objectives. Other base metal hydroxides can sequester sulfide, and their use depends on local availability. Also, the material should not contribute undesirable impurities, such as lead or arsenic, to the effluent. A reduced or partially reduced iron source is preferred, such as ferrous hydroxide, or magnetite to prevent redox reactions that contribute to reversion. Ferrous hydroxide sequesters sulfide as follows in equation 1.

1) $Fe(OH)_2 + H_2S = FeS(s) + 2H_2O$

In the case of an oxidized iron source, such as ferric hydroxide or ferrihyrite, the ferric ion will be preferentially be reduced to ferrous ion, resulting in the oxidation of sulfide and the production of elemental sulfur, as described in equation 2. Depending on the pH, some of the elemental sulfur will be soluble as polysulfide, as shown in equation 3. The polysulfide, if present, is undesirable since it is likely to report to the effluent and eventually revert to sulfate. Therefore, the success of sequestration processes using oxidized iron involves the control of the formation of polysulfide, and the separation of the elemental sulfur.

2) $2Fe^{3+} + S^{-2} = 2Fe^{2+} + S^{o}(s)$

3) $S^{2-} + n\ S^{o} = S^{o}_{n}S^{2-}$

If ferric hydroxide ($Fe(OH)_3$) is used as the iron source, then one third of the sulfide mass could follow this pathway, while two thirds would deport at FeS. Magnetite, ($Fe^{2+}Fe^{3+}{}_2O_4$) has been successfully used as a sequestering agent, and is discussed in the passive treatment case study below. Magnetite is an insoluble, black mineral that is widely available. It may be finely ground and added to the mixture of media as part of a sulfide sequestration system. The makeup of the media, the predicted longevity, and testing of such, are the subjects of recent and ongoing work (Blumenstein 2012, Van Niekerk 2015). A final stage of aeration is typically required to polish the

effluent to remove excess nutrients from the biological treatment system, and to oxidize a trace amount of residual sulfide downstream of the sulfide sequestration system. The final aeration also serves to increase the dissolved oxygen concentration of the effluent prior to discharge.

PASSIVE TREATMENT EXPERIENCE

Passive treatment systems commonly consist of biochemical reactors (BCRs), sulfide sequestration, and final polishing/aeration. A BCR is typically a gravity-flow bioreactor with a limestone-buffered organic treatment medium that is intended to require minimal operation and maintenance (Gusek, 2002). Passive BCRs consist of a series of geomembrane-lined cells or ponds filled with organic media, located outdoors. The organic media in the BCRs typically consists of woodchips and/or hay and limestone. A considerable amount of innovation has been seen in the development of the media for the BCR, to facilitate biological processes and to promote hydraulic conductivity. This organic matter provides a surface for the growth of microbial colonies and is gradually degraded to generate the organic carbon required for sulfate reduction. The typical construction of a BCR is shown in Figure 2.

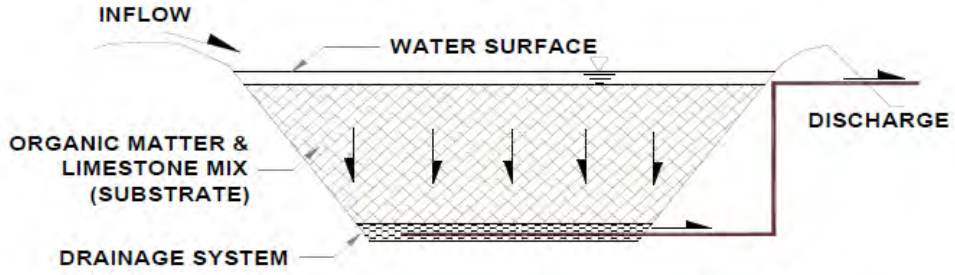

Figure 2 Profile of a BCR

A range of treatment mechanisms may be working in a BCR, depending on the particular feed conditions and the design as summarized below (Reisman 2009):

- biological reduction of sulfate to sulfide and subsequent precipitation of metal sulfides,
- alkalinity increase due to biological sulfate reduction and dissolution of limestone contained within the substrate,
- precipitation of metal hydroxides, and
- sorption of trace metals (e.g., Cd, Cu, Pb, Zn) to metal hydroxides and the organic medium.

The rate of degradation of organic material varies with media age and temperature and is likely the limiting factor in sulfate reduction in a BCR. Sulfide sequestration is achieved using an anaerobic sulfide polishing cell (SPC) that contains iron media. Effluent from the BCRs that contains high levels of sulfide flows through the SPC where sulfide is precipitated as an iron sulfide solid. Flow through a passive system is achieved through gravity flow and chemical addition is generally not required. Maintenance is performed at periodic intervals, for example, with SPCs media renovation every 3-5 years and BCRs media replacement every 10-20 years.

Advantages and disadvantages of passive biological sulfate removal

Passive treatment is well-researched and the benefits and limitations of the process are well understood:

- Passive treatment is not well suited to meeting strict effluent limits, due to a lack of process feedback signals and lack of process control mechanisms.
- Passive sulfate removal is founded on a biological process which is sensitive to low temperatures, and therefore may be sensitive to cold climates. However, as a mitigating measure, the BCR may be covered by an insulating layer of water, soils or even foam, to prevent freezing. Nevertheless, BCRs generally need to be sized for ambient feed water temperatures; lower temperatures require larger reactors.
- The breakdown of organic matter to produce volatile fatty acids (VFA) is believed to be the rate limiting step, and it is not directly linked to the subsequent consumption of VFAs for sulfate reduction. Under normal operation, most passive systems suffer from some degree of nutrient leakage. Nutrient leakage can result in failure to meet water quality objectives in terms of nitrogen, phosphorous or biological oxygen demand. An aerobic polishing cell, trickling filter, and/or lagoon may be installed downstream to help address the problem.
- Passive systems require large land areas, particularly for large flow rates. The availability of land near mining operations may be the limiting factor for passive systems.
- Passive systems benefit from a low degree of complexity. Often, little or no concrete, mechanical, electrical and structural work is required, drastically reducing capital costs compared to conventional active treatment systems, and simplifying maintenance operations.
- Passive systems cannot treat for chloride and generally do not result in a reduction in total dissolved solids (TDS) where chloride, magnesium, or other common anions are present.
- Passive systems benefit from low power consumption and are suitable for remote sites without access to line power. Depending on the site, water generally flows by gravity through the treatment system.
- Passive systems benefit from lower labour inputs, due to inherent differences including lower complexity, compared to active systems.
- Passive system can take advantage of low grade, lower cost carbon sources, which make the operating cost competitive compared to active biological sulfate removal systems.

Passive sulfate removal treatment case study

Golder Associates has been actively developing passive systems for various applications over the past 10 years both in the Americas and in Africa. In spite of a large number of published case studies involving passive treatment, there are few that have been designed specifically for sulfate removal. One such case is an operating coal mine located in a rainy and temperate part of Canada, shown in Figure 3. The feed sulfate level, typically 400-700 mg/L and the target for treatment is 300 mg/L, so the treatment effciency need not be high. This is considered an excellent application for passive treatment.

The feed is predominantly calcium sulfate, with a limited amount of metals available to sequester sulfide. The system contains a biochemical reactor (BCR) for sulfate reduction, an anaerobic sulfide

polishing cell (SPC), and aerobic lagoon and a settling pond. The SPC consists of a mixture of woodchips and a locally available magnetite. The pilot demonstration work commenced in 2009 (Blumenstein 2012) and a demonstration system at a quarter of the full scale (planned to be approximately 65 m3/hr) was constructed summer of 2012. The land area required from the demonstration scale was 0.8 ha. The feed and effluent sulfate data is shown in Figure 4, below. Data collection and compilation are ongoing.

The preliminary results from the case study are promising, and the system will continue to be adjusted through operations. The anaerobic sulfide polishing cell was commissioned in early 2013. The effluent from the SPC consistently is below 1 mg/L sulfide, and this residual is oxidized in the aerobic cells.

HYBRID TREATMENT

The hybrid biological reactor concept has been developed to address some of the limitations of passive treatment systems, and to make passive treatment more applicable to large flow rates. Hybrid reactors operate on the principles of biological sulfate reduction, except the reactors are constructed using inert media in lined, covered, earthen basins, and are fed a soluble nutrient source by means of a metering pump. Although the biological sulfate reduction process can be engineered in an "active" mechanical treatment plant, but this process has all the disadvantages of cost and complexity of the membrane plants mentioned above. As a result, there are very few commercial examples of the active biological sulfate reduction process. Hybrid reactors, in contrast, are designed to contain few moving parts, draw very little electrical power, and to require a minimum of operator intervention. Hybrid systems are intended for cases where only partial sulfate reduction is required and where strict process control is not necessary, including cases with a relatively constant flow rate. The hybrid system takes advantage of the benefits of both active and passive systems, with lower costs than active systems and using less land area than conventional passive systems. While hybrid biological sulfate systems are in the early stage of development, they are anticipated to offer the following benefits:

- A variety of soluble electron donors can be utilized, including low cost or dilute options that are not recommended for conventional active treatment systems, such as compost leachate, silage or waste biological sludge.
- Hybrid systems eliminate most of the concrete, steel, mechanical equipment, electrical equipment, and much of the ancillary infrastructure, along with the engineering and construction costs associated therewith.
- Hybrids decouple sulfate reduction from the rate-limiting carbon metabolism of a BCR, reducing the size of the sulfate reducing bioreactor.
- Hybrids, like passive reactors, may be buried to protect from freezing in cold climates.
- Bioreactors may be constructed using a variety of on-site materials, such as coal beneficiation rejects, taconite wastes, or gravels.
- Hybrids are unique compared to passive systems in that they may be back-flushed, reducing problems with hydraulic conductivity, greatly extending their life span and allowing for higher loading. Early problems with passive treatment have commonly been associated with the mundane problem of flow distribution and distribution piping.
- Hybrids are intended to eliminate heating of water needed for typical active biological processes, by increasing the size of the bioreactor bed but at a reasonable cost.
- Hybrids require a small amount of electrical power, but unlike active biological or membrane systems, do not necessarily require access to line power.
- Hybrids, like passive systems, eliminate continuous operator attention and reduce labour costs compared to active systems.
- Hybrids improve control of nutrient leakage.
- The largest operating cost of a hybrid system is the electron donor. For a case study employing ethanol, the cost is estimated to be less than \$0.10 per m^3 of feed to reduce

sulfate from 600 mg/L to 300 mg/L, assuming the current market price for ethanol of $830/t. Lower cost alternatives, using waste products, are also possible.

Golder Associates has successfully applied the hybrid concept to selenium reducing bioreactors at a demonstration site. Biological selenium removal operates on similar principles as sulfate removal. The hybrid concept was applied at the Leviathan Mine, and this case study offers insight on early variations on the concept applied to base metal removal, at relatively low flows of 2-7 m3/hr (Mayer 2006, Tsukamoto 2002). A pilot scale hybrid system fed with ethanol and molasses was tested on scrubber blowdown in the Minnesota Iron Range (Eger, 2004). Like passive treatment, hybrid treatment requires a system to sequester sulfide, usually based on contact of the water with iron compounds (ideally ferrous oxides or hydroxides). An example process flow diagram is shown in Figure 5, below.

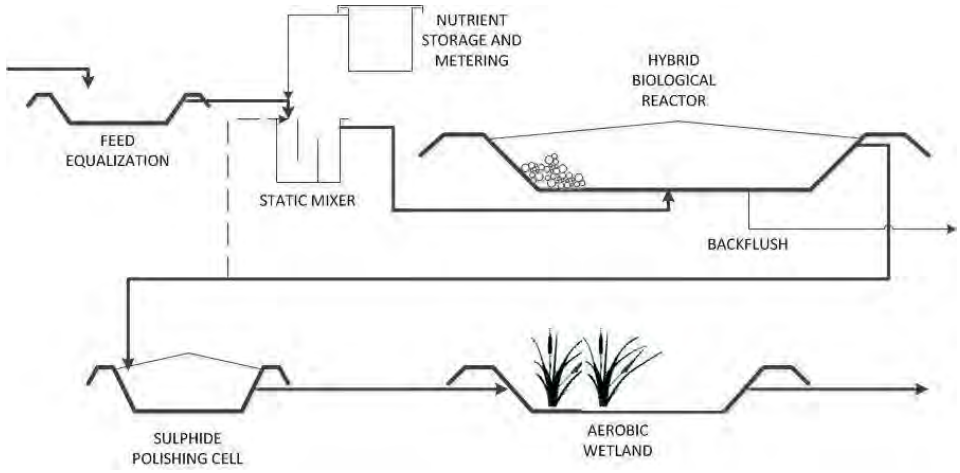

Figure 5 Example Hybrid System Process Flow Diagram

Sludge from the bioreactor back-flush is an organic material, mixed with feed suspended solids, and precipitated metal sulfides, depending on the application. The media in the sulfide polishing cell may be drawn from a range of locally available materials, ideally magnetite or other iron oxides. Depending on the specific feed water, part of the hybrid reactor overflow may be recycled to provide a ligand for specific influent metals. Lessons from the design of passive bioreactors inform the detailed design of hybrid reactors, such as: sizing, hydraulics, packing, flow distribution, and prevention of clogging and short-circuiting.

CONCLUSION

Active treatment, using membrane separations, has been demonstrated at a number of sites around the world, and has achieved commercial acceptance at large flow rates for advanced sulfate removal. Active treatment in general suffers from a high degree of complexity and as a result, a high cost. Furthermore, many operators require only partial removal of sulfate, for example, 50% removal, therefore less capital and operator intensive processes are more suitable.

Passive treatment has recently been successfully demonstrated for advanced sulfate removal. The process suffers from certain drawbacks, including the requirement for large land areas to treat large flow rates, and the risk of nutrient loss to the effluent. A key element of the most recent passive treatment case studies is the successful sequestration of sulfide using magnetite containing media, reducing the problems of sulfide gas release, or of reversion of sulfide to sulfate which in the past have hampered the success of certain passive biological sulfate removal case studies.

Hybrid biological treatment seeks to combine the best features of both active and passive treatment to offer cost savings for large scale sulfate removal projects without requiring a large land area. Hybrid treatment is an emerging concept, but is already commercially proven at least two sites for selenium reduction and has been demonstrated for base metal removal. Hybrid treatment seeks to decouple the processes that break down complex organic carbon sources from the sulfate reduction process. Such systems are designed to make use of readily available inert mine wastes as media to achieve a low unit cost for the bioreactor. Hybrid systems are unique compared to passive systems in that they may be back-flushed and thus offer longer reactor life spans.

Mine water treatability studies for passive treatment of coal mine drainage

2. *Coal Authority, United Kingdom*

ABSTRACT

The closure of coal mines in the United Kingdom, and the subsequent rebounding of the groundwater has caused widespread pollution of watercourses. This has largely been through the deposition of hydrous ferric oxides, commonly known as ochre. This research has been conducted to further the understanding of the treatability of mine waters with respect to the rates of ferrous iron oxidation and particulate ferric iron settling that occur. Iron oxidation and settling rates were measured in freshly emerged mine waters using a 2.5 m high, 45 L capacity settling column, with periodic sampling from three different depths over a 48 hour duration. Mine waters with initial iron concentrations of between 3 mg/L and 18 mg/L, from sites across South Wales (UK) and New Zealand were tested. The results indicated that the limiting step for treatment on waters above pH 6 and below 18 mg/L iron was settling, which has significant implications for design interventions intended to increase treatment efficiency. The results also demonstrate the complexity of the mine water in relation to the rate of iron removal and the need for a test to determine the iron removal rate for individual mine waters. Furthermore the effect of decreased temperature on mine water treatability, which is important for understanding seasonal effects and the impacts of heat extraction from mine waters with heat pumps, was also examined, with results showing a decrease in mine water treatability at temperatures between 17.6 ˚C and 1.6 ˚C.

Keywords: Oxidation, settling, passive, heat extraction

INTRODUCTION

Treatment of iron (Fe) bearing mine water using passive treatment systems has been occurring in the United Kingdom (UK) for two decades. A considerable amount of research has been conducted on the chemistry of the processes by numerous authors, which has been utilized in the design of passive treatment systems. These passive treatment systems in the UK are predominantly a combination of settling ponds and aerobic wetlands suitable for the circumneutral ferruginous mine waters issuing from former coal mines.

The design of past and current settling ponds has been based upon various criteria by different researchers. These include a 48 hour hydraulic retention time (NCB, 1982), anticipated Fe removal rate of 10 g/m²/d (Hedin, Nairn & Kleinmann, 1994) and 100 m² of pond area per L/s of mine water (PIRAMID, 2003). The calculation of the required area of wetlands is most often based upon one of two methods. The first was devised by Hedin, Nairn and Kleinmann (1994) and establishes a contaminant removal rate of 10 g/m²/d for a system that must meet regulatory standards or 20 g/m²/d for reasonable improvement (PIRAMID, 2003). Tarutis, Stark and Williams (1999) proposed that the removal rate of Fe in wetlands was by first order removal instead of zero order removal, which the previous criteria are based upon. These criteria produce sizably different scale treatment systems meaning that some are undersized, whilst others may be oversized (PIRAMID, 2003). Undersized schemes can lead to pollution incidents, whereas oversized schemes result in an unnecessary financial burden. A better understanding of the physicochemical processes influencing Fe removal for each site could reduce these uncertainties, taking into account the individual chemistry of the mine waters at each specific location.

The treatability of mine water with respect to the application of passive systems depends upon the rates of the processes governing Fe removal. Overall Fe removal in these systems requires (i) sufficient oxygen (O_2) transfer into the water to satisfy the O_2 demand of ferrous iron (Fe(II)) oxidation (ii) adequate residence time for Fe(II) oxidation and (iii) sufficient residence time to remove particulate ferric iron (Fe(III)) through filtration, accretion, or settling. The widely accepted rate law for oxidation of Fe(II) in pH >4 indicates a reaction that is influenced most significantly by the variation in pH (Stumm & Lee, 1961; Hove, Van Hille & Lewis, 2007; Millero, Sotolongo & Izaguirre, 1987). Studies on the rate of particulate Fe(III) settling are sparse and are usually combined with Fe(II) oxidation studies. One study on particulate Fe(III) settling rates using settling columns and laboratory simulated mine waters focused upon circumneutral and high pH waters in the range of 6-10 and found that there was no significant difference between settling rates of Fe at each pH tested (Hove, Van Hille & Lewis, 2007). Settling rates of particulate Fe(III) were found to demonstrate first-order behavior with respect to the concentration of particulate ferric iron, with settling rates varying for different mine waters (Sapsford, 2013). Hedin & Nairn (1990) suggested that "Fe removal rates are correlated with Fe concentration" for wetlands, but whether this is applicable to settling ponds is unknown.

Aeration of the mine water prior to flowing into the settling pond is seen as an essential step in the treatment of ferruginous mine water (PIRAMID, 2003). This is to ensure that the Fe(II) is oxidized to Fe(III) so that it may precipitate in the settling pond. For some mine waters aeration cascades benefit by stripping dissolved carbon dioxide, therefore raising the pH and increasing the Fe oxidation rate (Geroni & Sapsford, 2011; Stumm & Lee, 1961; Hove, Van Hille & Lewis, 2007; Millero, Sotolongo & Izaguirre, 1987).

Temperature affects the treatability of mine water and the kinetics of Fe(II) oxidation (e.g. Stumm & Lee, 1961; Millero, Sotolongo & Izaguirre, 1987). Temperature might reasonably be expected to affect settling behavior of particulate Fe(III), although literature is interestingly lacking on this subject. Heat extraction from mine water has been demonstrated to be feasible and economic (Banks et al, 2004), however little consideration has been given to the effects it may have upon the treatability of the mine water. In the UK mine water is typically at a temperature of 10-12 °C year-round (Banks et al, 2004). Decreasing this temperature by the typical 5 °C (Banks et al, 2004), would be expected to cause a subsequent decrease in the rate of oxidation of the Fe(II) and possibly impact settling rates.

This paper aims to (i) demonstrate a method for examining the treatability of different circumneutral ferruginous mine waters, which shows the rates of Fe(II) oxidation and settling of particulate Fe(III) under quiescent conditions for different mine waters, (ii) demonstrate the effect of aeration versus non-aeration and (iii) assess the effect of temperature reduction on mine water treatability.

METHODOLOGY

Iron removal tests were conducted for five mine waters from across South Wales and South Island in New Zealand. These studies were conducted using columns 2.5 m in height, (similar to a typical settling pond depth) and contained 45 L of mine water. Experiments were carried out on aerated and non-aerated mine water samples to determine the effects of aeration on the iron removal rates. Initial iron concentrations were between 3 mg/L and 17 mg/L. The experiments were run between 48 hours and 158 hours.

Iron Removal Rates

Mine Water Collection

A number of mine waters from coalfields in South Wales and New Zealand were used in the study, including active coal mine sites and passive treatment schemes. All of the samples from South Wales were collected prior to any aeration cascades. The sites were four passive treatment systems in South Wales (Glyncorrwg, Lindsay, Morlais, and Taff Merthyr) and one active mine in New Zealand, where the outfall from old mine workings pass over a waterfall prior to sampling. At each site 30 L containers were filled to the top to inhibit oxygenation in transit and transported back to the laboratory. Times varied from two hours to seven hours between sampling and commencement of the experiments.

Settling Column

The settling column was designed to replicate the processes occurring within a settling pond, although a difference in behavior might be expected where flow through the pond is not laminar. A relationship between the Fe concentration and column depth with time was determined by sampling every three hours from three sampling ports. An initial volume of 20 ml was extracted from each port and used to wash the beaker for each sample. A further 45 ml was extracted, from which 20 ml was used for total Fe analysis (i.e. particulate Fe(III) plus dissolved Fe(II)), 20 ml was filtered through a 0.2 μm syringe filter for total dissolved Fe and 5 ml was used for Fe(II) analysis. Prior to analysis 1 ml of 20% hydrochloric acid was added to the 20 ml samples.

Two settling columns were used for the water from each mine. In one column, the mine water was aerated by twice pouring the mine water between buckets held one meter above the other, in order to mimic the effects of an aeration cascade. In the second column, the non-aerated mine water was pumped directly from the 30 L container, through a pipe that passed down to the base of the column, thus minimizing the O_2 transfer into the mine water. The mine water was vigorously agitated in the sealed containers to re-suspend any sediment prior to being pumped into the columns. The columns were filled to within 0.05 m of the rim and remained undisturbed throughout the experiment.

Inorganic Elements Analysis

For the samples collected in South Wales total Fe was measured using a Perkin and Elmer Optima 2100DV inductively coupled plasma-optical emission spectrometer against certified standards. In New Zealand total Fe was determined using a portable Hach spectrophotometer with FerroVerr as the reagent. Iron concentrations above 3 mg/L were diluted using deionized water before analysis on the spectrophotometer. Ferrous iron from mine waters in Wales was determined spectrophotometrically using a Hitachi U1900 spectrophotometer at a wavelength of 510 nm. The reagent used was 1,10-phenathroline at Fe concentrations less than 15.0 mg/L. The mine water samples in New Zealand were measured using a portable Hach spectrophotometer with Hach Fe(II) reagent. Fe(II) concentrations above 3.0 mg/L were diluted using deionized water before analysis on the Hach spectrophotometer.

Data Logging

Throughout the duration of the experiment dissolved oxygen (DO), pH and temperature were measured using a HANNA 9828 multi-parameter probe. The probe was immersed in the mine water within the column at a height of 1.86 m. Calibration of the probe was undertaken before each experiment. Temperature, pH and DO were also measured in the field when the mine water was collected.

Heat Abstraction

Mine water collected from Taff Merthyr in South Wales was used for the heat abstraction experiments and was obtained in the same manner and analyzed using the same techniques as the column experiments above. The mine water was cooled during transport by storing in a cool box at reduced temperatures prior to refrigeration. The mine water in both columns was aerated prior to transfer into the column.

Settling Column

Two settling columns were used, one was kept at room temperature of 17.6°C and the second stored in a fridge at 1.6°C. The settling columns were 20 L square barrels, 0.55 m in height, 0.20 m in width and 0.20 m deep, filled to within 0.05 m of the rim. Samples were extracted from 0.1 m below the surface of the mine water. The experiment was repeated using different temperatures of 12.9°C for the room temperature and 4.3°C in the fridge.

RESULTS AND DISCUSSION

Iron Removal Rate & Aeration

The following can be inferred from the data presented below. Aeration of the mine water made little difference to the overall removal of iron for the mine water at Glyncorrwg (Figure 1), which was roughly linear with an iron removal rate of 0.07 mg/L/hr. This indicates that for this mine water particulate settling was likely to be the rate limiting step. At Lindsay (Figure 2) the data indicates that particulate settling was likely the rate limiting step for this mine water, with similar removal of total Fe after 48 hours between the aerated and the non-aerated columns. The impact of aeration on the Lindsay mine water is more evident and it is noteworthy that after 20—30 hours the majority of Fe was in particulate Fe form, which may have been easier to remove (by filtration) if the water was passing through an aerobic wetland at these times. Total Fe removal in Figure 2 did not follow a linear trend over the duration of the experiment at Lindsay. The mine water for Morlais was most clearly impacted by the aeration as seen in Figure 3, with the total Fe removal in the aerated column being approximately 58% lower in concentration than in the non-aerated column after 48 hours. This indicates that for this mine water, both the Fe(II) oxidation rate and particulate Fe(III) settling rate are important in the overall treatability of the mine water. Again the overall iron removal is approximately linear over the duration of the experiment and is circa 0.20 mg/L/hr.

The mine water Taff Merthyr indicates that for this mine water particulate Fe(III) settling is the rate limiting step and thus controls the overall removal of iron for this mine water (Figure 4). Iron oxidation rates are different between the aerated and non-aerated mine waters, but this has negligible impact on the overall Fe removal rate. The mine water at the active mine site in New Zealand (Figure 5) shows a case where there is no requirement for the oxidation of Fe(II) and that all the Fe is in the form of particulate Fe(III), thus Fe removal is solely governed by the rate of settling.

The Fe(II) and total Fe concentrations between the three sampling ports in the columns were found to be very similar in all cases, typically within 4.4% and 3.0% of each other for total Fe and Fe(II) respectively. Consequently the average value between the three sampling ports was used to create the following Fe concentration versus time graphs. This means that the settling rates of Fe(III) are irrespective of the depth, which has implications for design of settling lagoons.

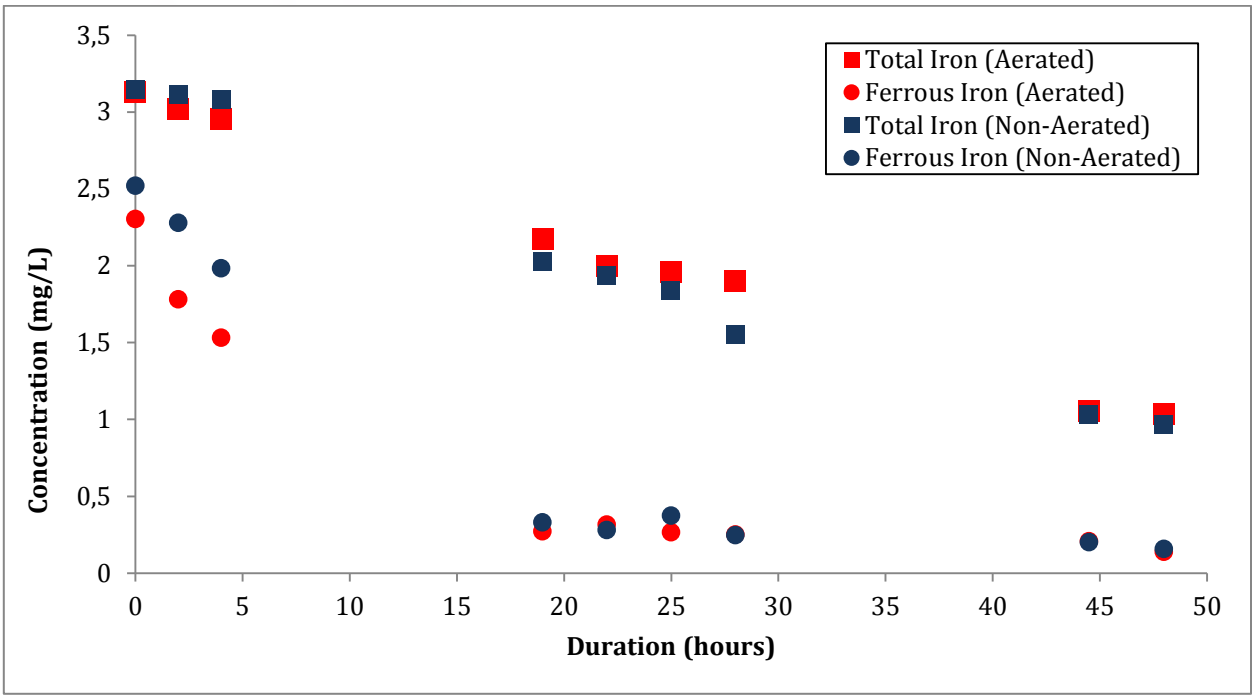

Figure 1 Change in Fe(II) and total Fe concentration with time in column at Glyncorrwg. Mean pH and initial DO during test = 6.52 and 4.99 mg/L respectively for aerated and 6.17 and 3.44 mg/L for non-aerated

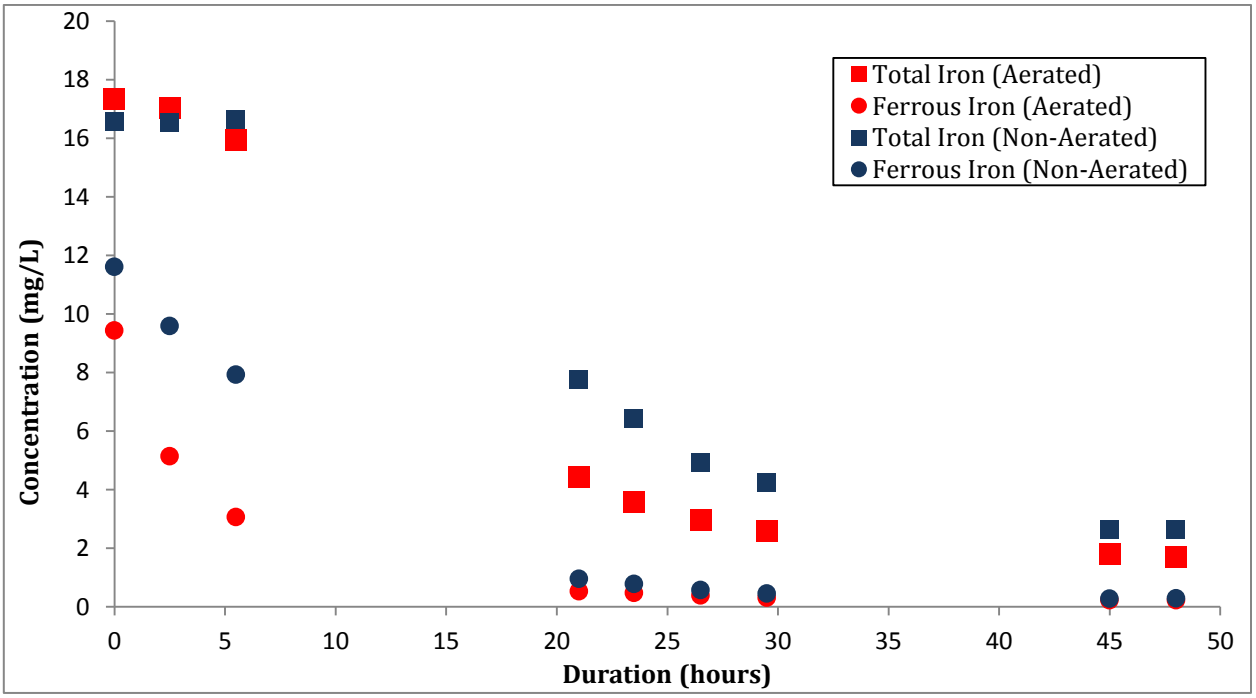

Figure 2 Change in Fe(II) and total Fe concentration with time in column at Lindsay. Mean pH and initial DO during test = 6.58 and 8.00 mg/L respectively for aerated and 6.59 and 2.67 mg/L for non-aerated

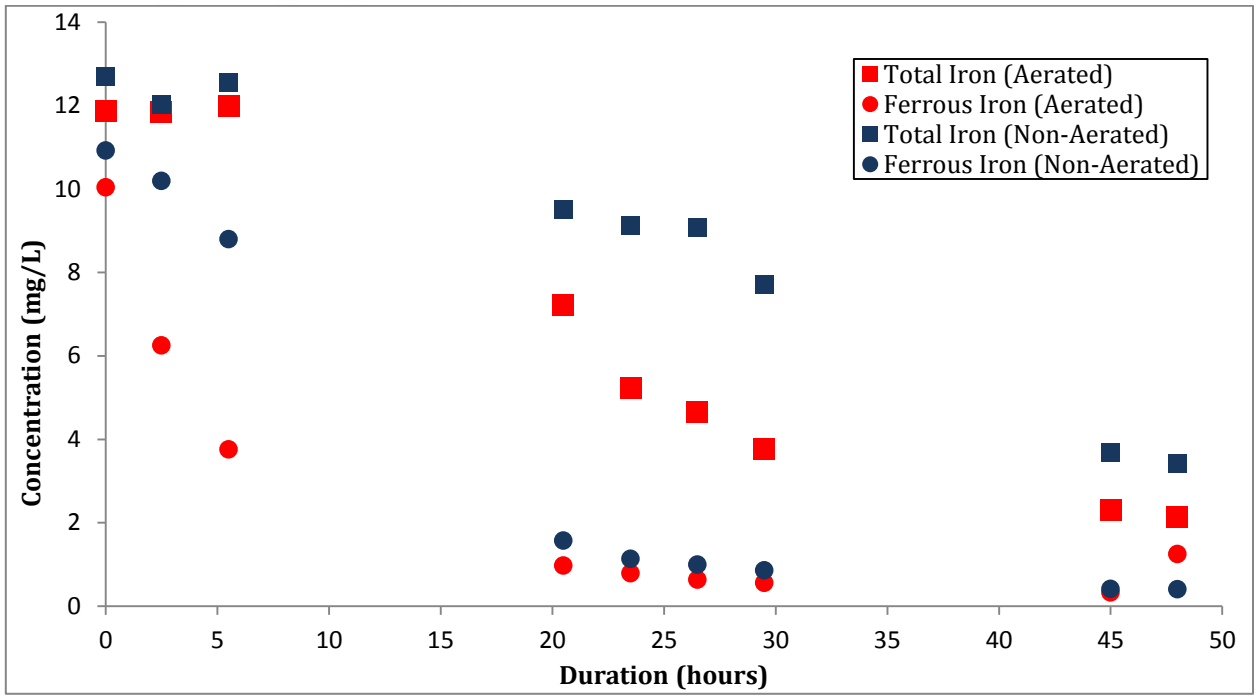

Figure 3 Change in Fe(II) and total Fe concentration with time in column at Morlais. Mean pH and initial DO during test = 6.06 and 5.01 mg/L respectively for aerated and 6.36 and 3.23 mg/L for non-aerated

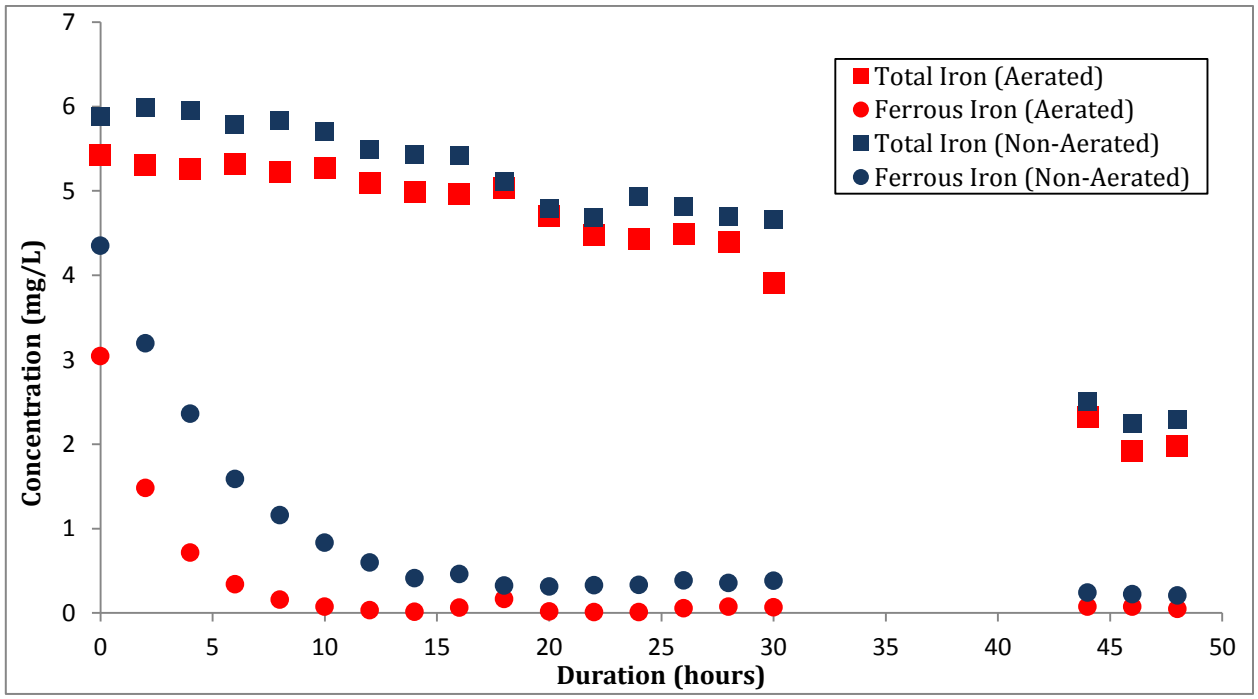

Figure 4 Change in Fe(II) and total Fe concentration with time in column at Taff Merthyr. Mean pH and initial DO during test = 7.09 and 8.52 mg/L respectively for aerated and 7.11 and 2.62 mg/L for non-aerated

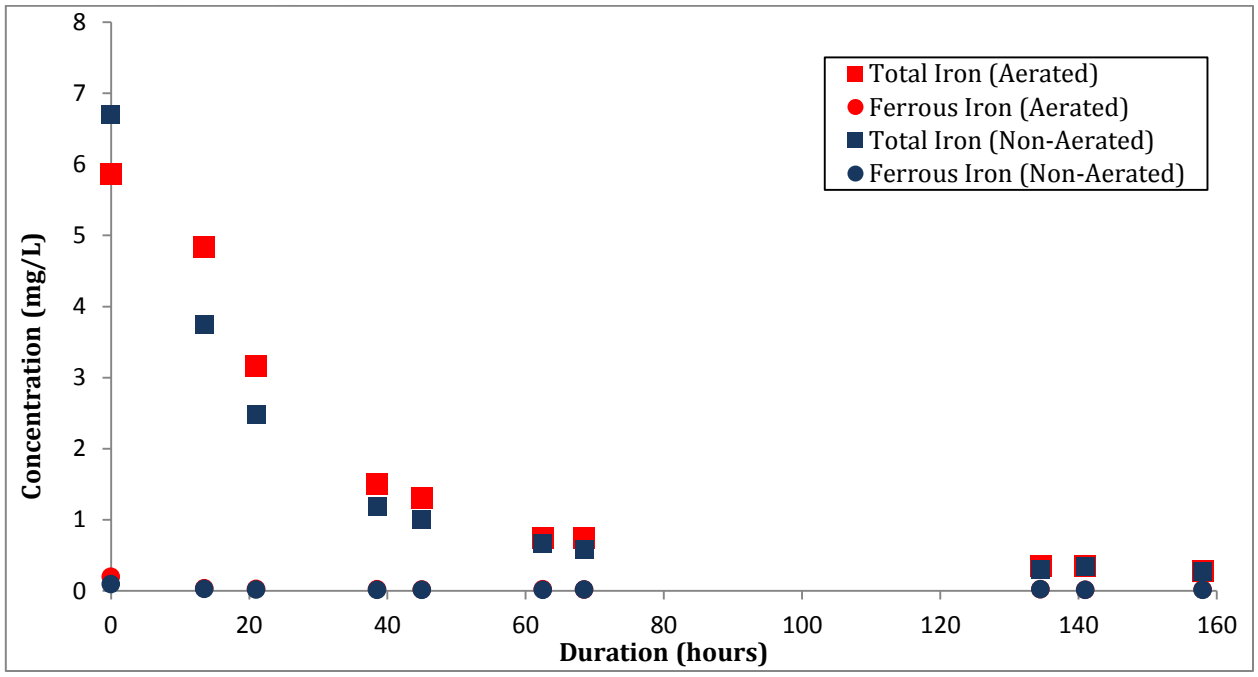

Figure 5 Change in Fe(II) and total Fe concentration with time in column at active mine site in New Zealand. Mean pH during test = 6.48 for aerated and 6.48 for non-aerated

Heat Abstraction

Experiment one was conducted at a mean water temperature of 1.6 °C for the refrigerated sample and 17.6 °C for the room temperature sample. Experiment two was conducted at 4.3 °C for the refrigerated sample and 12.9 °C for the room temperature sample. The Fe removal rates have a similar linear relationship between total Fe concentration and time to the previous column tests at Taff Merthyr.

Reduction in temperature in experiment one shows a decrease in the Fe removal rate between the room temperature sample and the refrigerated sample, with a difference in final Fe concentration of 0.8 mg/L after 48 hours. A similar decrease was seen in experiment two, with a difference in final total Fe concentration of 0.9 mg/L after 48 hours. Comparing the experiments shows that the Fe removal rates are variable and not solely dependent upon temperature, as the removal rate at 4.3 °C and 12.9 °C is higher than that recorded at 17.6 °C.

Table 1 Iron removal rates for mean temperatures of 1.6—17.6 °C, pH 6.4—6.8 and initial DO 6.0—6.2 mg/L, duration of 48 hours

Mean Temperature (°C)	Initial Fe(II) Concentration (mg/L)	Final Fe(II) Concentration (mg/L)	Initial Total Fe Concentration (mg/L)	Final Total Fe Concentration (mg/L)	Fe Removal Rate (mg/L/h)
1.6	2.32	0.12	5.13	2.24	0.03
17.6	2.49	0.27	4.85	1.39	0.07
4.3	3.22	0.13	5.13	2.09	0.07
12.9	3.30	0.13	5.20	1.24	0.08

CONCLUSION

In conclusion, the findings of this study were as follows:

(i) Particulate Fe(III) settling displays unusual settling behavior where the concentration is seen to decrease concurrently and equally at different heights within a column of quiescent mine water.

(ii) For mine waters of similar character (low Fe concentration, pH 6.0—7.5, DO 2.62—8.52 mg/L) the treatability of the mine waters is different and show instances where the relative rates of Fe(II) oxidation and particulate Fe(III) settling becomes more or less important. This information is very important for design, particularly where treatment efficiency is trying to be increased. The data presented thus demonstrate the importance of mine water treatability studies for each new mine water to be treated.

(iii) Decreasing the temperature of the mine water by between 8.6—16°C leads to a reduction in the treatability of the mine water.

ACKNOWLEDGEMENTS

The authors wish to thank the Coal Authority and the EPSRC for funding this research and CRL Energy Ltd for assisting with the research on the coal mine water in New Zealand.

ABSTRACT

The Fisher site is a backfilled and reclaimed (in 1984) surface coal mine in western Pennsylvania, USA. A post-closure toe seep at the site discharged acid rock drainage generated in pyritic rock zones that were identified using geophysical techniques. In 1995, sodium hydroxide and bactericide solutions were injected through cased boreholes into the pyritic zones in a two-step process: sodium hydroxide followed by bactericide. Prior to the event, the toe seepage had been treated with the addition of sodium hydroxide followed by a series of settling ponds and wetland zones. Post-injection, the seepage exhibited net-alkaline chemistry and the sodium hydroxide amendment was discontinued. Based on the prevailing wisdom at the time, the effects of the injection event were expected to be temporary. Almost two decades later, the beneficial effects of the two-step injection event persist and bond release for the site is pending. The seep chemistry has been monitored for over 25 years and the data suggest that the steady-state condition of net alkalinity in the seep water entering the ponds and wetland may be permanent. One current view is that the initial suppression of *Acidithiobacillus ferrooxidans* bacterial community with the sodium hydroxide and bactericide has been maintained by the seasonal infusion of bactericidal organic acids derived from the robust vegetative cover. The situation appears to be self-sustaining.

Keywords: sustainability, surfactant, coal, ARD, probiotics

INTRODUCTION

World-wide, reclaimed/re-vegetated mine sites (both coal and hard rock) continue to experience significant acid rock drainage (ARD) problems. The sites represent a perpetual treatment problem for the mine operator, contribute to environmental degradation of surface water and groundwater resources, and may prevent bond release. Conventional and passive treatment methods typically treat the symptoms of ARD, not its source. As evidenced by ARD being discharged from mines that were operated by the Romans over two thousand years ago, ARD can persist for millennia. Considering the billions of tonnes of acid-prone waste rock and tailings that are generated annually, a commitment to perpetual treatment is clearly not sustainable. ARD source control is clearly the "pathway to walkaway", but the mining industry seems to be reluctant to embrace unproven technologies. The recurring question is: "show us the data". Even when data are available, sampling protocols (if they are ever documented) can change over time, data gaps may occur for no reason, and even the sampling points can shift. This is the situation for this particular case history; the data set is not robust but the authors believe it is complete enough to be useful.

The iron-oxidizing bacteria, *Acidithiobacillus ferrooxidans (ATBFO)*, have proven to play a critical role in creating ARD and are strongly associated with the formation of acid rock drainage (Kleinmann, et.al. 1981; Schrenk et. al., 1998). Metals found in mine soils, including iron, manganese, aluminum, magnesium, lead, copper, zinc, cadmium, and selenium are solubilized, creating drainage that is toxic to the environment. Suppression of *ATBFO* has proven to significantly reduce the generation of ARD at mine sites (Rastogi 1996).

Bactericide usage history

Anionic surfactants are effective inhibitors of *ATBFO*, as they destroy the integrity of the cytoplasmic membrane of the bacteria thus allowing the acid that they create to enter the cells and destroy them. Their use was first promoted in the late 1970's and was successfully applied in the early 1980's (Kleinmann, 1979; Kleinmann and Erikson, 1983). However, skeptics in the mining community and mining regulators have argued (and rightfully so), that the inhibitory effects of anionic surfactants are temporary, as these highly soluble reagents can be rinsed from the treated mine wastes and *ATBFO* communities can rebound. To address this problem, commercial, slow release anionic surfactants such as ProMac™ were developed in the late 1980's.

More recently, researchers at the Wyoming Research Institute (Jin 2008) determined that a biofilm nurtured by waste milk or other dairy products, inoculated with a "probiotic" bacterial community, could out-compete *ATBFO* on the surfaces of pyrite grains and thus suppress ARD. Again, however, the question remains: what happens when the milk/dairy waste is consumed? Will the *ATBFO* community recover and dominate the situation?

Fortunately, anionic surfactants are not the only *ATBFO* inhibitors. Almost 35 years ago, Pichtel and Dick (1990) found that the following materials, some considered waste by modern society, can suppress ARD:

- Composted sewage sludge (biosolids),
- Composted paper mill sludge,
- Pyruvic acid (an organic acid), and
- A water-soluble extract from composted sewage sludge.

The ARD inhibitory effects of organic acids were cited by Sobek et al. (1990) as an important component in the long term (i.e., greater than three years) success of anionic surfactant usage. An excerpt from this paper follows.

> *Control of acid generation for prolonged periods greatly enhances reclamation efforts and can reduce reclamation costs by reducing the amount of topsoil needed to establish vegetation. Three natural processes resulting from strong vegetative cover for three years or more can break the acid production cycle. These processes are:*
>
> - *A healthy root system that competes for both oxygen and moisture with acid-producing bacteria;*
> - *Populations of beneficial heterotrophic soil bacteria and fungi that are re-established, resulting in the formation of organic acids that are inhibitory to T. ferrooxidans (Tuttle et al. 1977); and*
> - *The action of plant root respiration and heterotrophic bacteria increase CO_2 levels in the spoil, resulting in an unfavorable microenvironment for growth of T. ferrooxidans."*

Two reclaimed mine sites, one near Steubenville Ohio, USA and another near Clarksburg, West Virginia USA received slow release anionic surfactant treatments in 1984 and 1987, respectively (Rastogi, 1996). Increased vegetative growth was the primary goal of the surfactant applications; ARD suppression was a secondary benefit. The sites were investigated in 1994 and the benefits of the anionic surfactant persisted well beyond the normal longevity of the surfactant itself. However, the vegetative response in the treated portions of the sites was so strong that the ARD seepage was virtually eliminated. The somewhat less vegetated control plots still discharged ARD. Concurrent investigation results revealed that *ATBFO* populations in the treated soils were vastly outnumbered by beneficial heterotrophic bacteria by two to three orders of magnitude.

Despite the laboratory and overwhelming field evidence, the use of bactericides to suppress ARD was never a commercial success. It was not considered a permanent remedy. A decade of positive performance was apparently not enough.

SUBSURFACE INJECTION OF BACTERICIDE

As of the mid-1990's, anionic surfactants had only been applied to surface sources of ARD. That changed when Plocus and Rastogi (1997) demonstrated that subsurface application of anionic surfactants using injection techniques could successfully reduce ARD at the Fisher Site in Banks Township, Indiana County, Pennsylvania. This was accomplished by identifying the acid-generating zones using geophysical techniques and designing a multiple-stage borehole based injection program that targeted the ARD "hot spots".

Geophysical mapping with electromagnetic terrain conductivity meters and magnetometers were utilized to identify pyritic zones which were responsible for the high acid production on the Fisher Site. See Plocus and Rastogi (1997) for a more detailed discussion of the geophysical investigation.

The Fisher Site in Banks Township, Indiana County, western Pennsylvania USA represents a typical reclaimed mine site which continued to generate post-reclamation ARD. The Fisher Site layout is found in Figure 1.

A single coal seam (~2m thick) was mined in the early 1980's using surface mining techniques. Anecdotal information suggested that a high-ash coal containing pyritic shale partings had been buried in the pit during the coal removal process. Infiltrating precipitation and contact with

groundwater in these zones of concentrated pyritic material resulted in localized ARD production. A resultant ARD plume eventually surfaced as an acidic seep with levels of iron, manganese and pH exceeding effluent limits. Table 1 presents water quality data on the raw ARD seep on the Fisher Site and the associated limits for these parameters.

Site reclamation consisting of pit backfilling and re-vegetation; this effort was completed in 1984. The effluent from a small (0.25 ha) passive treatment system, constructed in 1985 to manage the raw seepage, did not meet Pennsylvania Department of Environmental Protection (PA DEP) standards. To remedy this situation, two treatment ponds were constructed after the passive treatment system; supplementary semi-active treatment with a sodium hydroxide solution comprised the long-term treatment plan for this reclaimed and re-vegetated surface mine. With the exception of the post-mine discharge which exceeded effluent limits, the Fisher Site had met all requirements established by the PA DEP for bituminous coal extraction and reclamation.

Table 1 Fisher Site ARD chemistry and regulatory limits

Parameter	Raw Seep Value	Pre-Injection Wetland Effluent	Regulatory Limits (Monthly avg.)	Regulatory Limits (Instant. Max.)
Iron (mg/L)	8 to 42	17.7	3.0	7.0
Manganese (mg/L)	6 to 12	12.4	2.0	5.0
pH (s.u.)	5 to 6	5.5	6.0 to 9.0	
Acidity (mg/L)	>alkalinity	Est. ~54	n/a	n/a

In 1993, the pollution liability of this site was transferred from the coal company to a third party. Because the site effluent met existing regulatory limits due the sodium hydroxide amendment as a fall-back position, this site was viewed an opportunity to evaluate ARD source control alternatives, in particular, the injection of anionic surfactants.

The prevailing theory (in 1993) was that the source of ARD on the Fisher Site was similar to other reclaimed sites: it was primarily located in the buried mine spoil. Unfortunately, conventional surface application of anionic surfactants is ineffective on re-vegetated sites as it cannot penetrate through subsoil, topsoil and vegetation. An alternative, more-invasive and focussed surfactant delivery method was needed and injection through multiple boreholes was a logical choice. Injecting surfactant into the entire mine spoil mass was not practical, however. As subsequently determined, neither was it necessary.

Plocus and Rastogi (1997) developed an innovative approach to (1) identify the source of ARD on the Fisher Site using geophysical mapping, (2) install subsurface injection wells, and (3) inject sodium hydroxide and an anionic surfactant into the toxic zones within the subsurface strata of the Fisher Site. Among the many uncertainties at the time was: if the procedure worked in suppressing ARD, how long would its effects last?

Site characterization and geophysical mapping

Identification of backfill zones with elevated pyrite concentration was critical in determining the target locations for installation of injection wells. Space limitation constraints preclude a detailed discussion of the relationship between these holes and those identified in Figure 1. A 3.2-ha portion

of the backfilled pit immediately up-gradient of the seep was mapped using data gathered with non-invasive geophysical techniques. Based on the results of geophysical mapping, three primary acid producing zones were suspected; the center of each zone received an exploratory boring and the cuttings were analysed for acid-base accounting parameters. This effort, coupled with geophysics data interpretation, yielded six target zones for surfactant injection. Three of the most significant target zones were selected for subsurface injection of the anionic surfactant.

Application of subsurface injection techniques

After the acid-producing areas were delineated, four deep wells were drilled in June 1995 into the acid aquifers for sodium hydroxide injection to neutralize the existing acid waters, and 25 shallower wells were selected to be drilled into the pyritic zones for injection of an anionic surfactant bactericide to prevent future acid generation. During drilling activities, mine spoil samples were collected at one-meter intervals for overburden analysis.

A series of twelve 11-mm diameter drill holes were placed at the source of the acid producing area. Grout packers were installed to permit pressure injection. Injection wells were cased with 50 mm diameter PVC pipe with 1.5-meter screens and sealed with bentonite and concrete. The screen helped in pressurized distribution of the sodium hydroxide and the anionic surfactant. The depth of the shallow injection wells was approximately three (3) meters while the depth of the 17 deep injection wells (28 wells total) and overburden wells averaged 16 meters. The location of injection wells, monitoring wells, artificial wetlands and treatment ponds are shown in the site map in Figure 1.

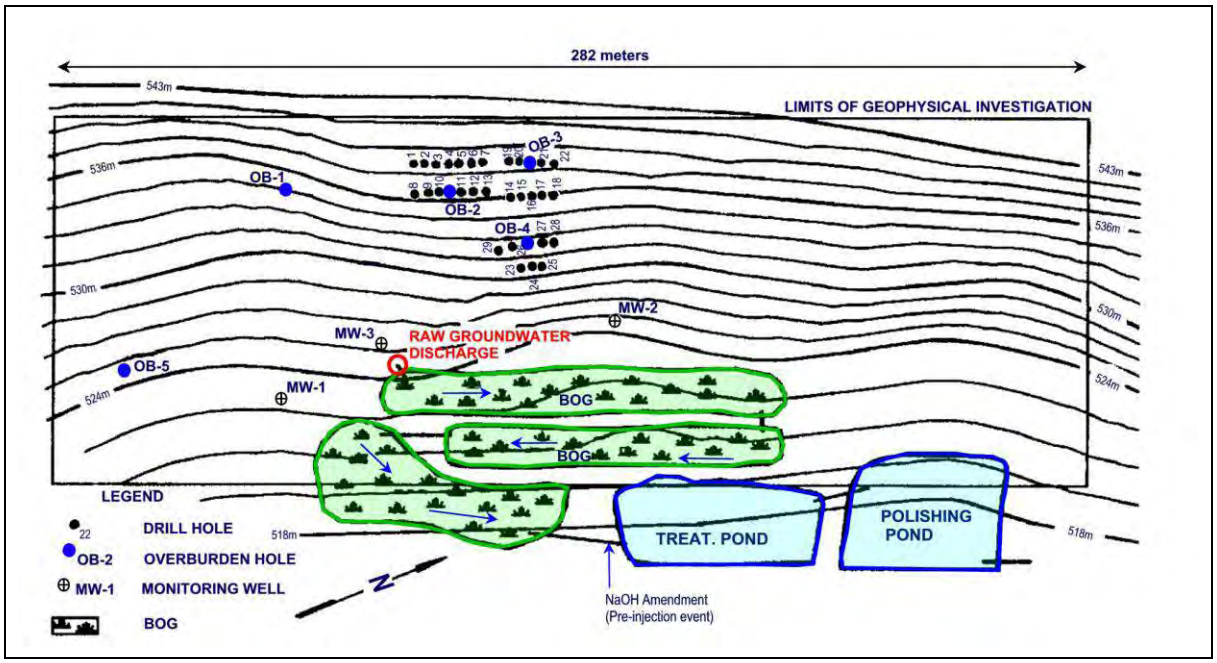

Figure 1 Injection site layout (After Plocus & Rastogi, 1997)

Injection of a 20% solution of sodium hydroxide began in mid-June, 1995 using pumps capable of pumping at pressures of 20.7MPa. Each injection well received about 1,140 liters of caustic solution.

This was followed by injection of about 570 liters of a 2% solution of the anionic surfactant bactericide. A total of six overburden wells were also injected with the anionic surfactant. In total, about 33,000 liters of 20% sodium hydroxide solution and 40,000 liters of 2% strength surfactant were injected over the span of 30 days. In 1995, the cost of these reagents was about $US8400.

The chemical amendment treatment system already in place at the Fisher Site was maintained for a one-month period after the initial injection. By that time, the quality of the raw seep prior to entering the passive treatment system had improved enough that the post-passive treatment chemical amendment addition was discontinued.

RESULTS

The raw groundwater discharge point (Figure 1) represents the acid seep discharge into the artificial wetland, or bog, which historically flowed at an average rate of 50 to 150 gpm. Figures 2 through 6 summarize results for alkalinity/acidity, pH, iron, manganese, and sulfate for this location, respectively. Rather than focus on instantaneous responses to drought or elevated flows, the discussion that follows will address long-term trends and offer plausible explanations in the context of the suppression of the acidophilic community.

Acidity, Alkalinity and pH:

Prior to subsurface injection, acidity typically exceeded alkalinity on the Fisher Site at the point of raw groundwater discharge. See Figure 2. After subsurface injection of sodium hydroxide and the anionic surfactant, alkalinity has exceeded acidity, and this condition was typically maintained even during and immediately after a prolonged drought. This is a condition necessary for bond release. The raw data is quite scattered due to the effects of drought and other unknown factors. Loading (flow times concentration) estimates are typically used to evaluate the overall effectiveness of a remedy. Figure 2 indicates a "tipping point" occurred about 13 years after the injection event when negative acidity results produced an even wider spread between acidity and alkalinity loading. The precise reasons for this apparently favourable situation are unclear and they may be an artefact of the analytical method. The pH results (Figure 3) for the same period do not reflect any dramatic improvement but about a year later, a pH improvement trend is evident and it continues to persist in 2014. On the average, pre-injection acidity loadings were about 7.1 kg/day; post-injection acidity loadings were about 1.0 kg/day and appear to be on a steady, stable (negative) trend.

The data in Figure 2 suggest that the positive effects of the injection event were quite pronounced in the three years following it. While the magnitude of the effects (the difference between acidity and alkalinity) appeared to abate, the conditions for bond release have been satisfied for the last 19 years.

Iron and Manganese:

Prior to subsurface injection activities, iron concentrations at the discharge seep ranged from 8 to 42 mg/L between 1984 and 1995 (Plocus & Rastogi, 1997). After the injection event in 1995, the seepage chemistry exhibited an overall decreasing trend in total iron and total manganese. On the average, iron loading decreased from 4.2 kg/day pre-injection to 2.4 kg/day post-injection. Manganese pre-injection and post-injection average loadings were 1.9 kg/day and 0.7 per day, respectively. Again,

post-1995 data is quite scattered but loading trends indicate a general and persistent decrease in iron and manganese mobilization from the treated area. See Figures 4 and 5. Note that the decrease in pH, iron and manganese occur a few years after the decrease in acidity loads. This suggests that iron and manganese levels did not account for the decreased acidity. Aluminum levels were not measured and this constituent may be the reason for the acidity data disconnection.

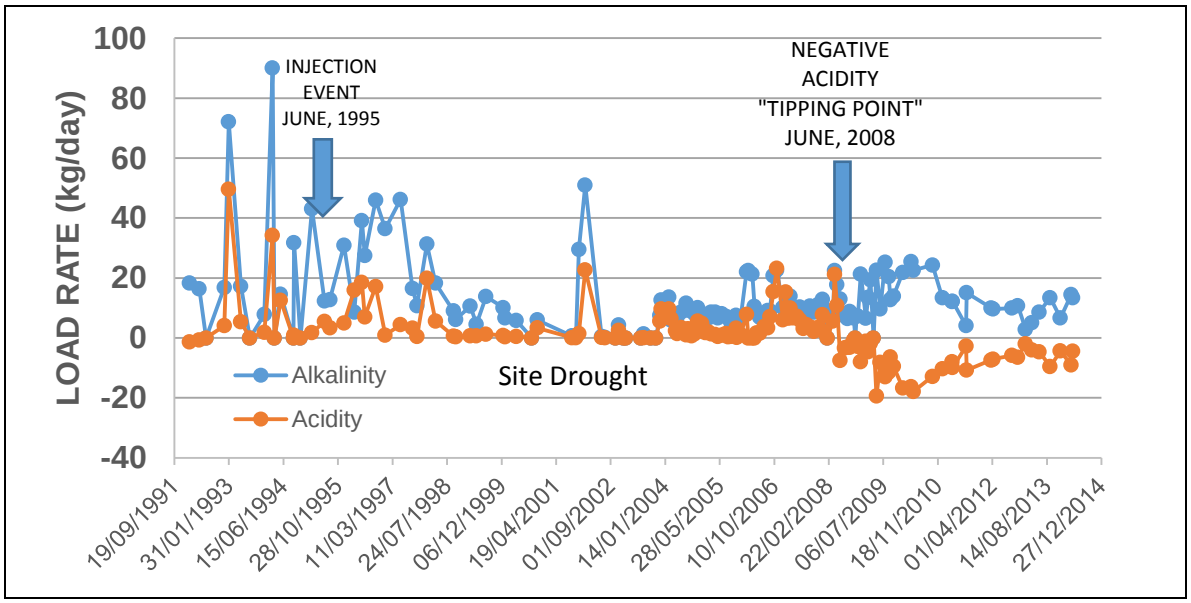

Figure 2 Seep acidity and alkalinity 1991 to 2014

Decreased sulfate levels:

As further evidence of the reduction of acid formation, sulfate concentration in the seep discharge decreased compared to pre-injection event levels. See Figure 6. This decrease, coupled with maintenance of an alkalinity level exceeding acidity levels indicates the quality is being maintained long after the immediate effects of alkaline injection and bactericide have worn off. The acidophilic community appears to be suppressed by mechanisms that are sustainable.

DISCUSSION

Granted, the chemistry of Fisher Mine MIW was not as "aggressive" as ARD from more challenging mining sites that are too numerous to name. However, the data presented in figures 2 through 6 suggest that the positive effects of a single anti-bacterial application/injection event can persist for almost two decades. These observations are encouraging. The acidity/alkalinity "tipping point" is worthy of additional discussion. Unpublished laboratory data (Clark, 2013) suggests that the concentrations of sodium lauryl sulfate in the injected solution used at the Fisher Site would have certainly decimated the acidophilic community. However, it also probably decimated the isolated populations of beneficial heterotrophic bacteria as well, leaving the treated zone in an almost sterile condition. Kirby and Cravotta (2005) discussed hot acidity testing protocol and found that the presence of ferrous iron (Fe^{+2}) may result in negative acidity values; the oxidation with hydrogen peroxide could force ferrous iron to ferric, which reaction consumes hydrogen ions, raising the pH. Unfortunately, iron speciation, dissolved oxygen, or oxidation reduction potential (ORP) data for the Fisher seep is non-existent.

If the ratio of acidophilic to heterotrophic bacteria counts was about equal, one might expect ferric iron to predominate the seep discharge chemistry. However, if the heterotrophic populations finally grew to outnumber the acidophiles, one might expect to observe ferrous iron (and the associated negative acidity values) in the effluent samples. Whether this could occur in as short a time span as suggested in Figure 2 is uncertain and is worthy of additional study. However, it appears to be a persistent condition for the past six years. Future research work at the site (or elsewhere) might focus on better understanding this phenomenon. It is interesting that the sulfate levels decreased slowly, whereas acidity, pH and iron and manganese levels decreased abruptly in response to the injection event. Residual gypsum or sulfate salts from 11 years of unsuppressed pre-injection pyrite oxidation (which would be slow to rinse) may account for a portion of this lag in sulfate response. Other microbial-related mechanisms could have also contributed.

CONCLUSIONS

The Fisher Site subsurface injection project represented the first time that a combination of geophysical mapping and well injection of alkaline materials followed by efforts to inhibit bacterial production had been used to mitigate acid seeps from a reclaimed site. Almost two decades of data suggest that the beneficial effects of the method appear to be permanent and may improve even more in the future. Granted, the Fisher Site may not have presented an "extreme" biogeochemical challenge. However, one must start somewhere and this technology (coupled with a better understanding of the biogeochemistry of a given site) may offer a permanent remedy to ameliorate discharge problems leading to protection of groundwater resources, elimination of permanent surface treatment facilities, and ultimately the release of mine reclamation bonds on re-vegetated mine sites currently experiencing ARD problems.

ABSTRACT

In surface freshwater streams the pH is typically controlled by the carbon dioxide, bicarbonate, carbonate buffer system. Photosynthesis during daylight hours leads to removal of carbon dioxide and/or bicarbonate from the water column with an associated increase in pH. Additionally, a locally strongly oxidizing environment can be created owing to production of high dissolved oxygen concentrations. These conditions can lead to enhanced removal of metals from the water column via precipitation of hydroxide and carbonate species, adsorption on sediments, or oxidation to insoluble forms.

This paper describes the findings from field and laboratory investigations of the removal of substantial amounts of manganese (Mn) and zinc (Zn) from a surface stream system, as a final polishing step for partially treated circumneutral metalliferous mine drainage produced from an underground lead/Zn mine. Diurnal pH modulation by the naturally occurring algal assemblage dominated by the filamentous cyanobacterium *Schizothrix calcicola* ,combined with formation of amorphous manganese dioxide coatings on the stream bed, were found to be the drivers of this process. Selective chemical extraction of the filamentous phototrophic biofilm material indicated that Zn was removed by surface adsorption or precipitation of carbonate phases and that Mn was largely removed by oxidation on the surface of the cyanobacterial filaments.

The findings from this work indicate the key role that photosynthetically driven pH cycles can play in metal removal in minewater treatment systems, and highlight the importance of maintaining shallow open water areas. The occurrence of diurnal cycles in metal concentrations downstream of mine water inputs emphasises the need to address this process in the design of water quality sampling programs being used to assess perfomance of these systems.

Keywords: mine drainage, diurnal pH cycles, metal removal, cyanobacteria, passive water treatment

INTRODUCTION

In aquatic systems dissolved metals can be removed from the water column by precipitation, adsorption to suspended sediment (followed by sedimentation), adsorption to the bed sediment, or by uptake by aquatic plants (Chapman, Jones & Jung, 1983). Precipitation, or co-precipitation of another metal present at lower concentration, followed by sedimentation can occur if the hydroxide or carbonate complexes become supersaturated. For trace metals (cations and oxyanions), pH is the key variable that controls the extent of adsorption and/or precipitation in oxic surface waters.

In most aquatic systems the pH is controlled by the carbonate buffer system. When photosynthesis occurs during daylight hours, carbon dioxide and/or bicarbonate is removed from the water column and the pH rises (Lucas & Smith, 1973). Additionally, a strongly oxidizing environment can be created locally as a result of the production of high dissolved oxygen concentrations. Variation in pH and oxygen concentrations due to photosynthetic activity can lead to fluctuations in the concentrations of contaminants in the water column as the solubility and/or state of adsorption-desorption equilibrium changes (Gammons, Nimick & Parker, 2014).

Over the past decade many observations have been made of diurnal cycles in concentrations of zinc (Zn) and manganese (Mn), in particular, in circum-neutral streams impacted by drainage from historic mines (Gammons, Nimick & Parker, 2014). The process is driven by the daily cycling of pH induced by the photosynthesis (light) and respiration (dark) of phototrophs attached to the stream bed. The importance of these processes in controlling metal removal, and their consequent relevance for obtaining meaningful measurements of metal concentrations downstream of mine water sources, has been the subject of a recent review (Gammons, Nimick & Parker, 2014). It is noted by these authors that although observed daily diurnal ranges of pH occasionally exceed one unit, in most locations they vary less than this.

There are few well-documented examples of the importance of diurnal pH cycling in driving metal removal in full scale mine water treatment systems. This study documents the findings from investigations of the passive water treatment system at the underground Hilton lead-zinc-silver mine located 20 km north of Mt Isa in central-northern Australia (Figure 1). Mt Isa Mines Ltd (the owners of the resource in the late 1980s) needed to dewater the underground ore-body in the lead up to developing production from the mine.

The concentration of Zn at site D3 (Figure 1) needed to meet the water quality discharge limit of 2 mg/L set by the Queensland state regulator. Coincidentally this target for removal of Zn also met the quality requirement for re-use of this water for mineral processing, an important consideration in this semi-arid environment. A 20 km pipeline transported water from the Hilton pump weir at D4 to the mineral processing plant at Mt Isa.

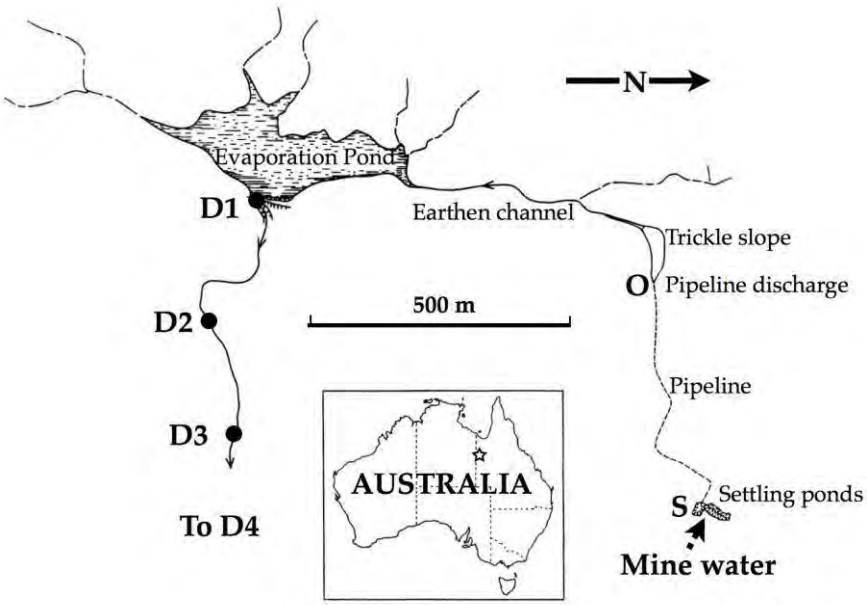

Figure 1 Location (star on map) of the Hilton mine and schematic of the mine water treatment system.

A passive treatment system was constructed to strip the metals from the mine water with the aim of meeting both process water and environmental discharge requirements for Zn. The present study was carried out to identify the specific removal processes involved to:

- facilitate optimization of contaminant removal, and
- to ascertain whether they could continue to operate satisfactorily into the future.

A detailed description of the complete treatment system for the pH circumneutral mine water has been published previously (Jones, Chapman & Jung, 1995). During the 18 month period of this study the total dewatering rate ranged between 2000-6000 m^3/day. There were no diluting inflows from other sources, such as rainfall or stream tributaries, to complicate interpretation of the results.

The focus of this paper is the downstream (from locations D1 to D4, Figure 1) section of the treatment system, wherein the residual dissolved Zn is further removed to acceptable levels. The stream between D1 and D4 was typically shallow (<0.3 m deep at the centre), with a maximum width of 2 m. It comprised sections of interconnected shallow pools punctuated by steeper riffle zones, as the watercourse descended by about 10 m over the reach. The gravel/cobble bed was covered by copious growths of green filaments (Figure 2).

METHODOLOGY

The field work described in this paper was conducted over three campaigns in October 1984, October 1985 and February 1986, with detailed chemical analysis work and laboratory experiments being conducted between the first two field visits and after the last one.

Figure 2 Mats of filamentous biofilm containing *S. calcicola* covering the stream bed

Water chemistry

Measurements of pH were made *in situ*. Water samples for total and dissolved (<0.1 μm) metals were collected in acid leached plastic bottles. All samples were preserved by the addition of nitric acid (to 0.1 %) within 1h of sample collection. The concentrations of major cations were determined by atomic absorption spectroscopy (AAS) or Inductively Coupled Plasma Atomic Emission Spectroscopy (ICPAES), and the concentrations of iron, Mn, and Zn measured by ICPAES. Sulfate was determined by ICPAES or ion chromatography and bicarbonate concentrations were measured in the field by titration with standardised hydrochloric acid.

Collection and analysis of microbial and sediment samples

Samples of the filamentous microbial material were collected from the bed of the stream at D1 and D3, and at several locations between, using plastic scoops. They were stored at 4 ℃ in plastic bottles for two days prior to being processed in the laboratory. Detritus such as leaves and twigs was removed by hand sorting. Filaments were washed by re-suspending them in 0.05 M NaCl solution. The sample was then consolidated by centrifugation. The supernatant was decanted and the washing and centrifugation step repeated.

Subsamples of the wet biofilm were separately extracted at room temperature with 0.1 M pH 4 acetic acid/sodium acetate buffer and 0.1 M hydroxylamine hydrochloride solution in the pH 4 acetate buffer to investigate the modes of binding of Zn and Mn in the algal filaments The extraction methods used were adapted from Tessier, Campbell & Bison, 1979.

Aliquots of supernatant solutions were withdrawn at 10, 20, 40 and 65 min to track the time course of increase in the extracted Zn and Mn concentrations. The concentrations extracted at 65 min were used to estimate the amounts of Zn and Mn associated with the phases targeted by the extract solutions, as the concentrations in solution approached an asymptote value at this time. Total extractable concentrations of Zn and Mn were obtained by digesting finely pulverised freeze-dried samples with a 1:1 mixture of concentrated HNO_3 and HCl acids. A similar digestion was used for the stream sediments. The concentrations of metals in the extract and digest solutions were determined by ICPAES. The oxidation state of Mn in the surface coatings on the stream sediments was determined using the iodometric method of Murray, Balistrieri & Paul, 1984.

Semi-quantitative powder X-ray diffraction (XRD) was used to identify crystalline mineral phases present in finely ground freeze-dried samples of the microbial material and the bed sediments.

Microbial strain identification

Samples of the microbial mat were collected from the stream bed between D1 and D3 were sent to the National Herbarium of New South Wales in Sydney for identification using optical microscopy. The dominant species was found to be a clumped ecoform of the widely occurring cyanobacterium (colloquially known as blue green algae) *Schizothrix calcicola*. It was noted by the phycologist at the Herbarium that this ecoform had a much higher amount of extracellular polymeric substances (EPS) associated with the filaments, than was usual for the species.

RESULTS AND DISCUSSION

Water chemistry

The concentrations of select major ions and of Mn and Zn between sites D1 and D4 in October 1984, are plotted in Figure 3. Only the data for 1984 are shown here as the behaviour of the solutes was found to be the same for the subsequent field campaigns.

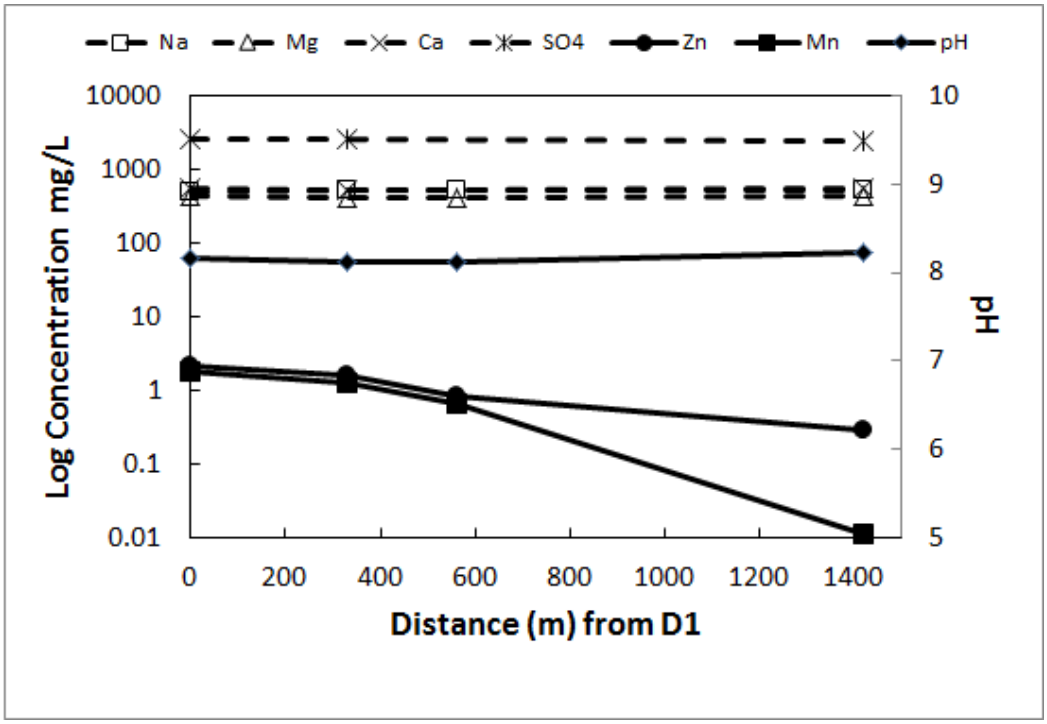

Figure 3 Concentrations of major ions, pH and Zn and Mn downstream of D1 (October 1984)

Only the dissolved concentrations are shown in Figure 3 as there were no substantial differences between the total and dissolved concentrations in this reach. The fact that the concentrations of the major cations did not change significantly between D1 and D4 indicates that there were no significant diluting inflows or losses of water by evaporation. In contrast to the major ions, the concentrations of soluble Zn and Mn decreased substantially (approximately 2.5 fold) between D1

(0 m) and D3 (560 m), with Mn concentrations being below detection limit (0.04 mg/L) at D4 (1420 m).

All of the water samples were collected in daylight hours within 30 min of one another. The possibility of artefacts being introduced due to sampling time, as discussed by Gammons, Nimick & Parker, 2014, was thus minimised.

Mineral Solubility

To determine which solid phases could potentially be removing Mn and Zn from solution, saturation indices (SI) were calculated using the MINEQL chemical equilibrium computer code (Westall, Zachary & Morel, 1976). The saturation index (SI) is defined as the logarithm of the ratio of the activity product of the component ions of the solid in solution to the solubility product for the solid. Values greater than zero indicate super-saturation and values less than zero, under-saturation. The SI calculations showed that calcium (Ca), Zn and Mn carbonates were marginally over saturated (SI values of 0.5, 1 and 1, respectively at D1) in the bulk flowing water downstream of D1, indicating that precipitation of these phases could be controlling the solubility of these metals. The SI for $MnCO_3$ declined below zero downstream of D3.

Investigation of the microbial material and stream sediments by XRD did not show the presence of Zn or Mn carbonate mineral phases, although low concentrations of Ca carbonate were detected. The non-detection of Zn and Mn carbonates does not mean that they were not present, as the limit of detection of XRD is typically around 1-2 wt % in a complex matrix (Chung F & Smith DK, 1999). Reference to Table 1 shows that the total concentrations of Zn and Mn in the microbial material, if all were present as carbonates, would be at or below the detection limit of this technique.

Mechanisms of metal removal– microbial mats

To investigate possible diurnal behaviour (an indicator of photosynthetic activity), the flowing water from mid-stream was sampled over a two-day period in October 1985 at D1 and at D3 (Figure 4). It is noted that the concentration of Zn at D1 at this time was approximately twice that in October 1984, whilst the concentration of Mn was about the same.

The concentrations of both Zn and Mn were considerably reduced (on average by factors of 2 and 4, respectively) along this reach of the stream. Moreover, there was a marked diurnal variation in concentrations which did not originate in the evaporation pond (the overflow of which corresponds to D1), but which occurred during the passage of the water between D1 and D3. Significantly in this reach of stream there was close contact between the water and extensive microbial filaments (primarily the commonly occurring cyanobacterium *Schizothrix calcicola*, hereafter abbreviated to *S. calcicola*) (Figure 2).

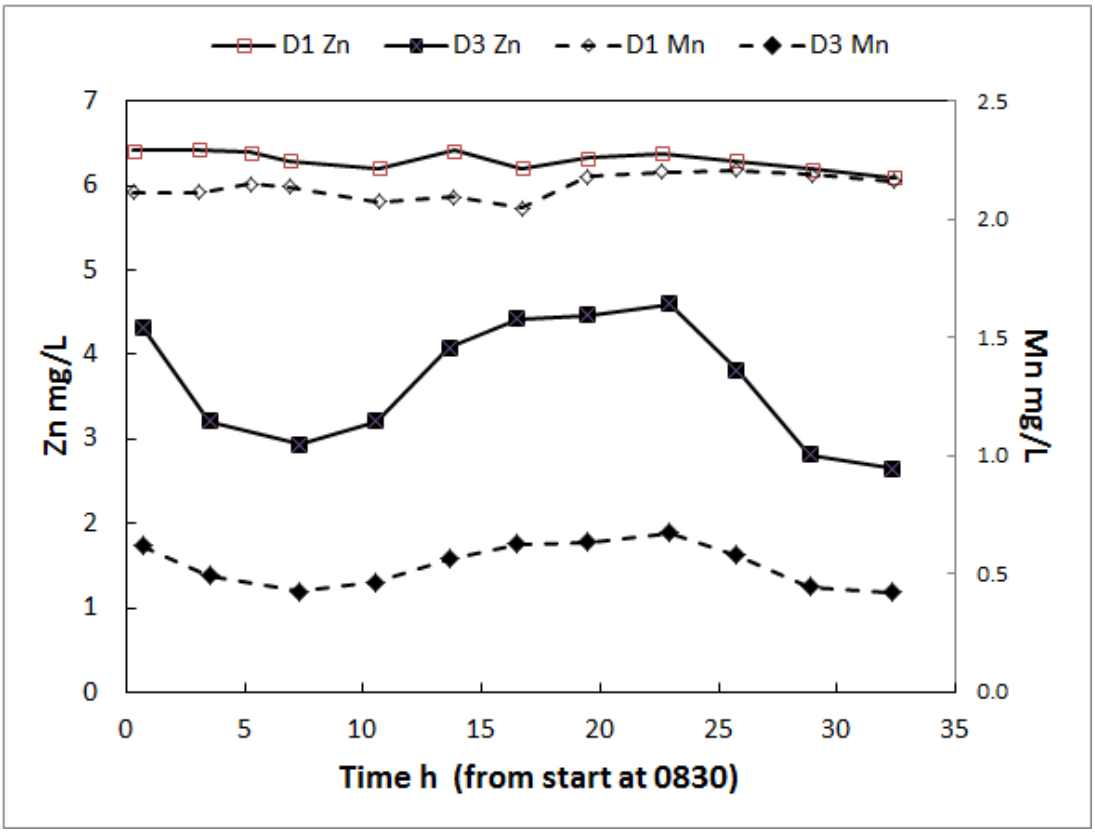

Figure 4 Concentrations of Zn and Mn at D1 and D3 over a two day period (October 1985)

A subsequent study was undertaken at D1 in February 1986 to test the hypothesis that the increase in pH associated with photosynthesis was a driver for metal removal. At this time the Zn concentrations were much lower than in October 1984 and 1985 because there was a lower proportion of the Zn-rich water derived from the orebody in the total volume of water being discharged.

The pH and concentrations of Zn close to a microbial mat were compared with that in mid-stream between sunrise and sunset (Figures 5 and 6). At sunrise, the pH values of both the stream water and the water close to the microbial mat were close to pH 7.9, with similar Zn concentrations (0.88 mg/L) at both locations. As the sun rose, the pH in the water close to the filaments rose steadily to a maximum value of 8.6-8.8, whereas the water in mid-stream remained close to 7.9. Coincidentally with the rise in pH near the *S. calcicola* filaments, the concentration of Zn in solution fell to 0.6 mg/L, whilst that in the bulk flowing water remained at its initial concentration. As the sun was setting, the pH near the *S. calcicola* filaments began to decline rapidly until, by nightfall, it had returned to its original early morning value. The pH increase measured in the field was consistent with *in vitro* laboratory measurements in a closed system that showed that the pH in vessels containing the *S. calcicola* varied by as much as 1.5 pH units over a simulated day/night cycle.

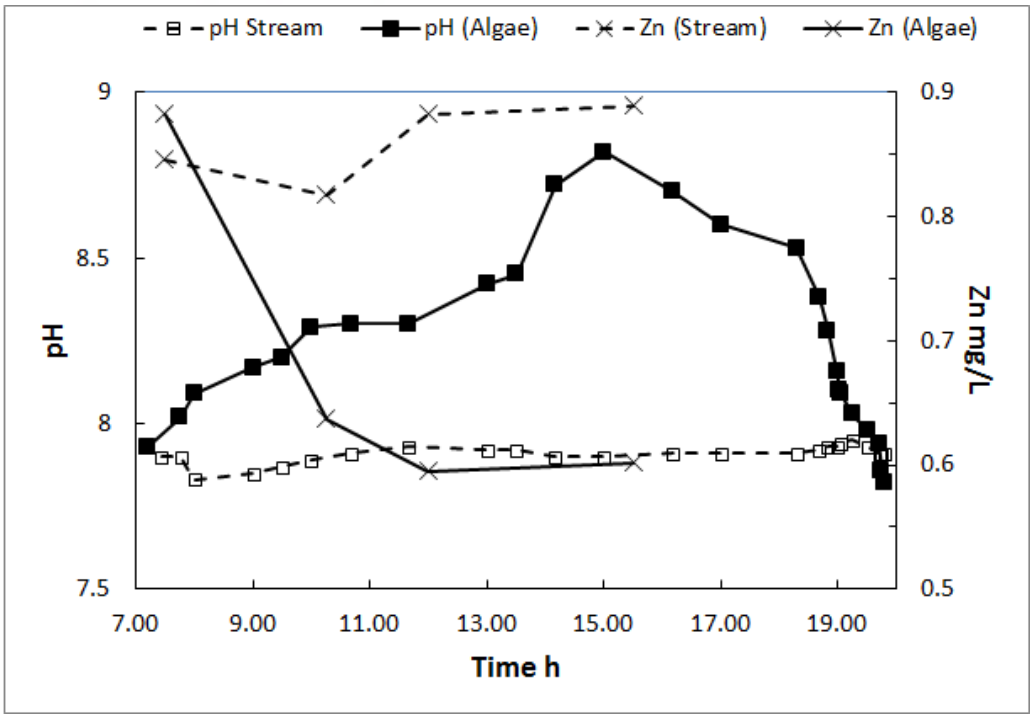

Figure 5 Comparison of pH and Zn concentrations in the middle of the stream and in a microbial mat at D1

Some properties of the microbial material collected at D1 are summarised in Table 1. The rapid rates of dissolution of the metals from intact *S. calcicola* filaments material by extraction reagents (pH 4 acetate buffer and 0.1 M hydroxylamine hydrochloride at pH 4) indicates that a high percentage of the total amounts of these metals are located on the surface of the *S. calcicola* filaments. In contrast to Zn, only 30 % of the Mn was extracted with the pH 4 buffer. However, the majority of the Mn was rapidly dissolved at pH 4 in the presence of a reducing agent (hydroxylamine) that is selective for Mn dioxide and Mn oxyhydroxides (Tessier, Campbell & Bison, 1979).

The extraction results are consistent with) metal removal by surface adsorption/complexation on and/or by enhancement of pH-dependent (precipitation, oxidation) removal processes on the surface of the cyanobacteria filaments. The EPS produced by the cyanobacteria may provide increased surface area for metal binding. The potential importance of EPS in binding and concentrating Zn on the surface of algal cells has been noted by others (Podda et al, 2000).

The increases in pH and oxygen concentrations produced as a result of photosynthesis may favour the precipitation of Zn and Mn carbonates and the oxidation of Mn(II) to produce insoluble Mn(III)/Mn(IV) oxides on the microbial filaments. Whilst concentrations of dissolved oxygen were not measured in the field, the occurrence of copious small bubbles on the surfaces of the microbial mats during daylight hours suggested the presence of elevated concentrations of oxygen in the vicinity of the filaments.

The role of photosynthesizing cyanobacterial or other types of phototrophic filaments in facilitating the precipitation of hydrozincite (a zinc hydroxy-carbonate phase) on their surfaces has been documented by Kwong et. al., 1994, and Podda et al, 2000. Support for these types of processes occurring downstream of D1 is provided by the findings from the selective extractions described above.

Table 1 Chemical extraction of Zn and Mn from D1 *S. calcicola* samples

Extract medium	Likely Phases	Zn	Mn
pH 4 acetate, 10 min	Adsorbed Zn and Mn, labile Zn and Mn carbonates (I)	62 %	23 %
pH 4 acetate, after 65 min	Adsorbed Zn and Mn, labile Zn and Mn carbonates(I)	77 %	30 %
pH 4 hydroxylamine, 10 min	(I) plus Mn oxyhydroxides and Mn oxides	65 %	84 %
pH 4 hydroxylamine, 65 min	(I) plus Mn oxyhydroxides and Mn oxides	90 %	98 %
Aqua regia digest (total)		17200 mg/kg dry weight	8330 mg/kg dry weight

The effectiveness of photosynthetically driven processes for metal removal will be a function of maximum day time temperature, day length and solar radiation intensity. The climate data (available from the Australian Bureau of Meteorology: www.bom.gov.au) for the Mt Isa region show that these parameters do not change substantially over the year at the Hilton mine. Consequently, it is not expected that there would be substantial variation in the effectiveness of biological removal processes through the year. This situation contrasts strongly with that existing in the temperate latitudes from which much of the published literature on diurnal cycling of metal removal has been produced.

Mechanisms of metal removal – inorganic sediments

Samples of the gravelly streambed sediment were collected 60 m downstream of D1. Gravelly soil was also collected from the banks of the stream at this location to provide a control for experiments to investigate the role that the bed material could play in removing dissolved Zn and Mn from the water. The only obvious physical difference between the two types of solids was that the gravel substrate from the channel bed was covered with a soft black coating. Samples of each (on-bank and in-stream) of these solids were agitated with aliquots of water from D1, and the decrease in metal concentrations monitored. Both sediment types removed similar amounts of Zn from solution (50 % after 20 h), but only the material collected from the stream bed removed Mn (97 % after 10 h for stream sediment, 0 % after 72 h for bank material).

Bacteria are known to catalyse the oxidation of soluble Mn(II) to insoluble Mn(IV) (Diem & Stumm, 1984). However, in this case the addition of the biocide sodium azide did not inhibit the removal of Mn by the stream sediment, indicating that the reaction must have been an abiotic process. X-ray diffraction, and chemical and redox speciation (Murray, Balistrieri & Paul, 1984) analysis of the black material coating the stream sediment particles showed it to be primarily amorphous manganese dioxide with considerable associated Zn (Mn/Zn=4). Pre-formed Mn(IV) oxides are known to catalyse the oxidation of initially adsorbed Mn(II) (Hem, 1978). The ability of Mn oxide

coatings on stream beds to remove Mn(II) from solution at pH values for which the abiotic rate of oxidation in solution would otherwise be very slow has been noted by others (Gordon & Burr, 1988) as has the ability of these types of coatings to absorb substantial amounts of Zn (Shope, Xie & Gammons, 2006).

Conclusions and significance of findings

Both abiotic (formation of Zn-rich manganese oxides on bed substrate) and biologically-mediated (adsorption and/or precipitation on *S. calcicola* filaments) processes have been shown to contribute to the reduction in Zn and Mn concentrations downstream of site D1 at the Hilton mine. The diurnal variations observed in the downstream concentrations of these metals occurring in concert with the daily cycling in pH adjacent to the *S. calcicola* filaments, imply that a significant proportion of the metals are removed as a result of the photosynthetically-induced pH oxygen concentration increases in the water close to the filamentous biomass in the stream channel.

Selective chemical extractions of the filamentous material indicated that Zn was removed by surface adsorption or precipitation of carbonate phases and that Mn was largely removed by oxidation. Uptake of Mn and Zn by manganese oxide coatings on the stream bed also contributed to the attenuation of these metals. Whilst it was not possible to definitively apportion the extent of Mn and Zn removal between the biotic and abiotic pathways, consideration of the physical context suggests that the phototrophic pathway may be the dominant one, as the *S. calcicola* filaments are in continuous intimate contact with the water column and the microbial mats provide a diffusion barrier to the Mn oxide coating on the underlying stream bed.

One of the primary objectives of water quality monitoring programs in surface water, whether it be a pristine or an impacted water body, is to obtain an accurate representation of the chemical status of the system. In the case of a mine-water treatment system, both regulatory compliance and metal removal efficiency typically need to be assessed. However, if diurnal variations in water quality are not adequately accounted for in the design of the monitoring program, then potentially flawed conclusions may be drawn. Indeed very different conclusions about system performance can be drawn depending on when in the day a system is sampled. This aspect has been well illustrated by a recent review (Gammons, Nimick & Parker, 2014). In the case of the Hilton Mine passive treatment system, substantive net removal of both Mn and Zn occurs throughout the diurnal cycle.

ACKNOWLEDGEMENTS

The permission of Mt Isa Mines Ltd (MIM) to publish the findings from this study and the assistance provided by MIM staff and CSIRO technical support staff for the conduct of this work is gratefully acknowledged by the authors. The National Herbarium of New South Wales in Sydney identified the cyanobacterium in the microbial-mat samples.

ABSTRACT

Wetlands are essential habitats in the environment since they fulfill a variety of ecological functions and support rich biodiversity. One major characteristic of wetlands is their ability to act as chemical sinks. There have been biogeochemical models developed for wetlands in Europe and North America but these systems differ from those found in South Africa, where most wetlands are river-fed and therefore undergo seasonal saturations, with periods of flooding in summer followed by drying during winter. High evapotranspiration rates also concentrate pollutants to very high levels. The nature, level and impact of mercury in the environment have not been extensively studied in South Africa, particularly in areas that have been significantly affected by gold mining activities.

Aims of this research were to determine the biogeochemical cycling of mercury in permanent and seasonal aquatic ecosystems (rivers, dams, natural and manmade wetlands) that have been heavily affected by mining activities (acid rock drainage) in semi-arid areas with extreme seasonal changes.

Research methodology included seasonal sampling, sequential extractions, determination of mercury speciation and modeling.

Results show that natural wetlands in South Africa have a greater capacity to trap mercury than manmade wetlands. Most leachable mercury exists in oxidizable form followed by unleachable residue. Organomercury species are produced in anaerobic deeper levels where organic carbon and reduced sulfur content is high. Evapotranspiration and surface precipitation during the dry season exhibited a strong seasonal relationship to acidity and redox conditions.

These research results are supported by a biogeochemical model may be used for identification and implementation of potential mercury remediation measures.

Keywords: mercury, wetlands, biogeochemical cycling, sequential extraction, bioavailability

INTRODUCTION

Changes in chemical and physical properties in the lithosphere can influence the release of heavy metals from mine tailings into the ecosystem and increase the likelihood of uptake by living organisms (Kim et al. 2001). These changes include acid rock drainage (ARD) (Durkin and Hermann 1994; Wildeman et al. 1991, Han et al., 2003).

Understanding the processes that influence the distribution, concentration, and bioavailability of potentially toxic metals, such as arsenic (As), cadmium (Cd), lead (Pb), mercury (Hg), and selenium (Se) is critical for successful management of chronically affected ecosystems. Such understanding can be used to identify and target pathways that have the greatest immediate and long-term impact on the environment. Such knowledge provides the scientific foundation for making decisions, developing strategy, and assessing remediation alternatives by governmental institutions as well as mining companies or local agencies charged with minimizing the environmental and health impacts of these toxic elements.

Gold mining has played a significant role in the socioeconomic life of South Africa (SA) for over one hundred years. Unfortunately, the wastes from this activity have been identified as a significant source of Hg and other heavy metals contamination of the environment. Heavy metals associated with mining are of particular interest for a number of reasons. They exhibit a tendency to accumulate in sediments and soils and persist as they are not biodegradable. Metals can be derived from the erosion of source rocks, or can accumulate following application of metal-enriched water as well as via deposition of atmospheric dust and fluvial reworking mined sediments (Getaneh W., 2006).

Acid rock drainage (ARD) is considered one of the mining industry's toughest challenges. Most water remediation techniques are time-consuming and costly, and ARD can continue in perpetuity, long after the mining activities cease. Constructed wetlands (CW) have been considered a possible solution to the long-term remediation of ARD. Wetlands successfully support improved water quality, providing a continuous, low-cost and effective solution to the ARD problem in some settings (Fennessy & Mitsch 1986; Kadlec 1985; Perry & Kleinman 1991; Snyder & Aharrah 1985). .

Wetlands functions that aid in the amelioration of ARD .include adsorption and ion exchange, bioaccumulation, biotic and abiotic oxidation, sedimentation, neutralization, reduction, and dissolution of carbonate minerals (Perry & Kleinmann 1991).

Processes within natural wetlands (NW) have been found to remediate contaminants found in ARD: imitation of these processes can work similarly in constructed wetlands. Wetlands have organic-rich substrates which capture/exchange dissolved metals (Wildeman et al. 1991). Wetland sediments are generally anaerobic below a thin oxidized surface layer and contain organic carbon needed for microbial growth (Gambrell & Patrick 1978). The anoxic zone of the sediments provide conditions which favor microbial and chemical reducing processes (Fenessy & Mitsch 1989). Soluble metals are converted to insoluble forms by the anoxic conditions of wetland sediments. Plants, microflora and bacteria also generate microenvironments that assist in oxidation and reduction processes (Wildeman et al. 1991; Mitsch & Gosselink 1986).

The toxicity of mercury depends strongly on the chemical form of the element (its speciation) but also on water environmental conditions like pH, redox potential, and the presence of dissolved and suspended carbon. Also dramatic differences may occur through time (high seasonality) and space. This is very important when establishing links between mercury emissions and levels in biota (Harris et al. 2005). The reactions and interactions may also vary with depth in wetland zones. For

example, the biogeochemical processes of complexation, adsorption, and precipitation may release or sequester certain metal species due to varying levels of biological activity (Baird and Cann 2012). Mercury behaves differently from other metals, forming volatile elemental mercury and even more volatile and toxic organomercury species under the anaerobic conditions which exist in deeper wetland sediments (Harris et al. 2005).

The nature, extent and impact of mercury in the environment have not been extensively studied in South Africa, particularly in areas that have been significantly affected by mining activities. To date, no analysis of seasonal changes in mercury bio-accessibility has been reported. This study addresses that gap, providing a detailed assessment and evaluation of the impact of mercury in Gauteng area of SA, very densely populated area with associated intensive water usage. The results would be useful in considering various remediation strategies.

Sequential extraction procedures (SEPs)

The toxicity, bioavailability and mobility of metals are related to their species (Quevauviller et al, 1994). However, the determination of chemical species is difficult and sometimes impossible. Therefore, the use of sequential extraction procedures for environmental studies provides an important tool for the determination of the different chemical forms or ways of binding between trace metals and sediment components (Rauret et al, 1999).

Sequential extraction procedures (SEPs) are employed to assess operationally defined metal fractions, which can be related to chemical speciation, as well as compound mobility, bioavailability or ecotoxicity. It is generally accepted that the ecological effects of metals (e.g., their transport, bioavailability, and ecotoxicology) are related to such mobile fractions rather than to the total metal concentration (Cordos et al, 2003).

Chemical fractionation schemes for partitioning trace metals in soils and sediments have been used extensively (Tessier, A., et al, 1979; Rauret G., et al, 1999; Han, F. X., et al, 2003; Ianni, C,et al, 2001; Navas, A., Lindhorfer, H. 2003; Hlavay, J., 2004. The European Community Bureau of Reference, the BCR method, standardizes SEPs (Ure et al. 1993) in order to: 1) minimize errors in the treatment and analysis of samples, 2) identify the most appropriate analytical procedure and 3) to supply reference materials for comparisons of the results. This standardized method appears to be more operationally effective than others previously proposed. (Sheppard and Stephenson, 1997).

METHODOLOGY

Sampling sites and sample pre-treatment

Samples were collected from a deposit of mine tailings (West Wits (WW)) in the Witwatersrand basin of South Africa (Figure 1). The sampling included natural and constructed wetlands, tailings and the soil next to the tailings. Redox potential, pH, temperature and conductivity were measured during sample collection. Samples were freeze dried and stored prior to analysis.

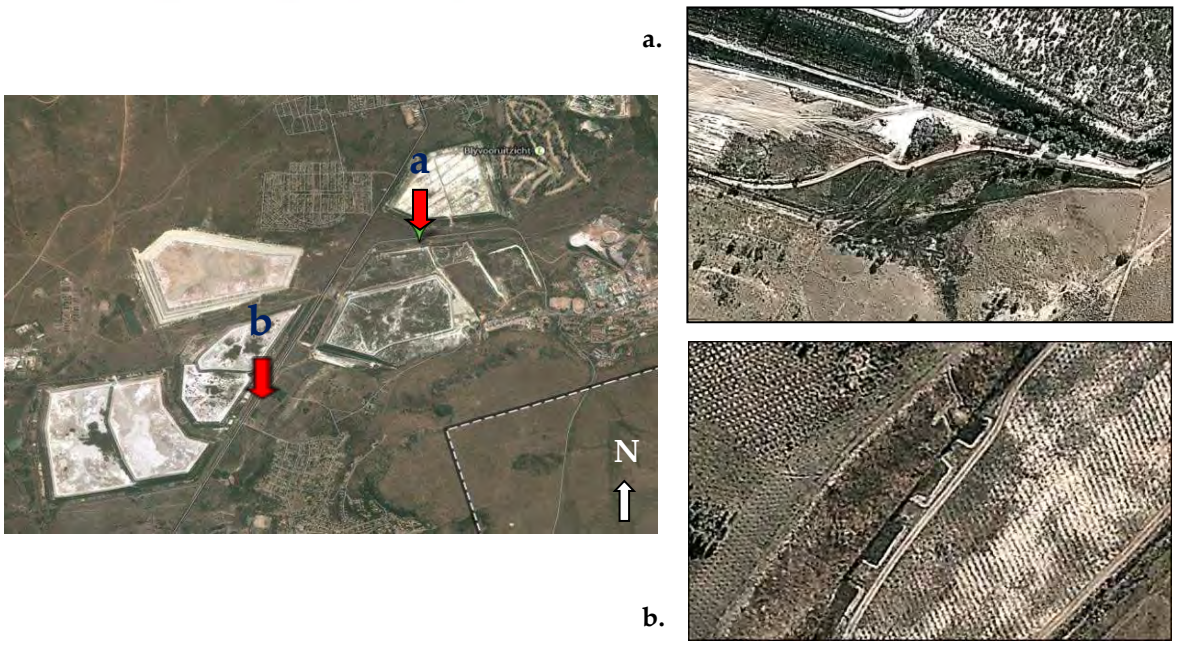

Figure 1 West Wits sampling site. a. natural wetlands (NW), b. constructed wetlands (CW)

Three stage BCR sequential extraction (BCR SE)

The BCR sequential extraction scheme with reagents and extracted fractions is shown on Figure 2.

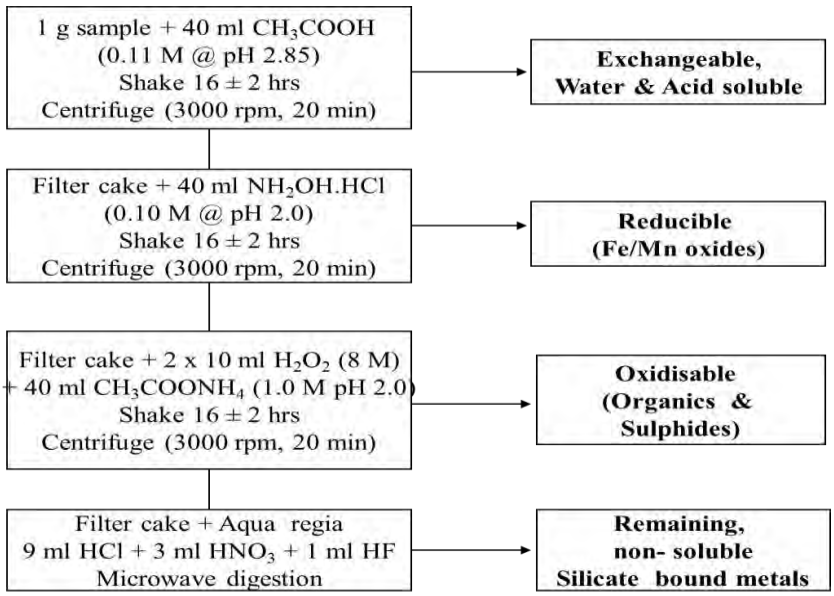

Figure 2 European Community Bureau of Reference (BCR) SE

Reagents and stock solutions

The following extraction solutions were prepared: (a) 0.11 M CH_3COOH solution adjusted to a pH of 2.0 by super pure grade HNO_3; (b) 0.10 M $NH_2OH.HCl$ solution adjusted to a pH of 2 with ultra-pure grade HNO_3; (c) 30 % H_2O_2 and 1.0 M CH_3COONH_4 adjusted to pH 2 with HNO_3 (d) ($HCl+HNO_3+HF$). Aqueous solutions of 3 % HCl (v/v) and 1.1 % $SnCl_2.2H_2O$ (in 3 % HCl v/v) were also prepared for the determination of Hg. Reagents used for Hg analysis were all certified heavy metals free (i.e. 99.999% pure).

Instrumentation

The determinations of metals in the extracts were performed by ICP – OES (Spectro, Germany) whereas Hg was analysed using an automated Hydride Generation Flow Injection Atomic Absorption Spectrometer (HG-FI-AAS, Perkin Elmer).

RESULTS AND DISCUSSION

The pH, Eh and organic carbon profiles recorded in wetlands sediments during the wet season are shown in Figure 3.

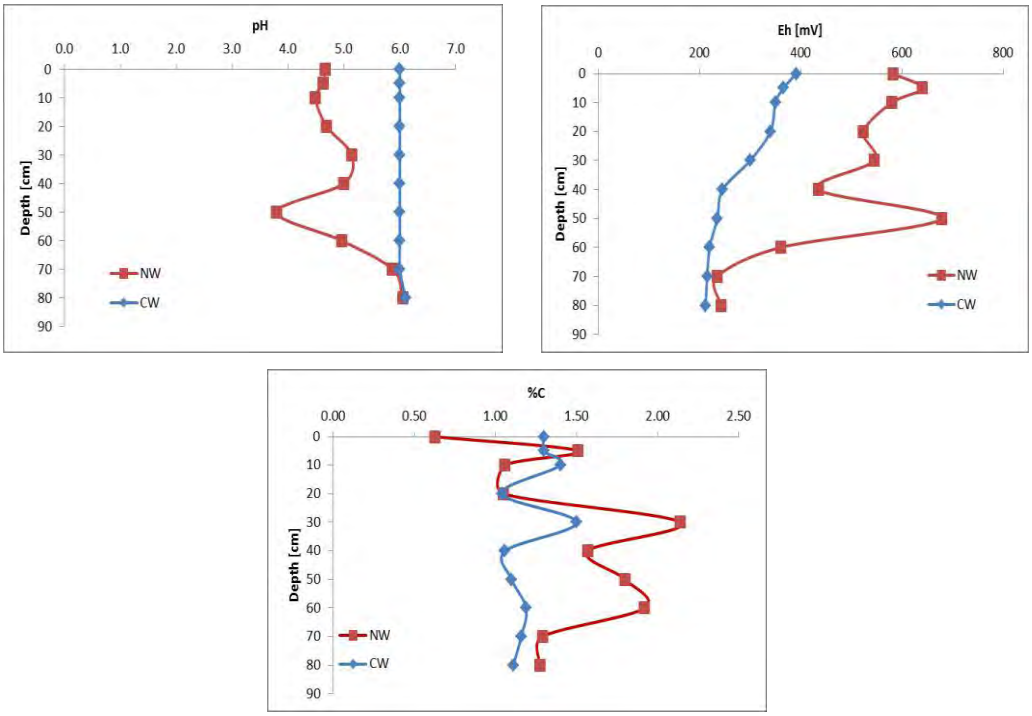

Figure 3 Sediment profiles of pH, Eh and carbon in NW and CW during wet season.

The CW profile was much more uniform to a depth of 70 cm, with a higher pH and lower redox potential and organic carbon content than the NW profile. , exhibiting almost the same levels in the lower-most sediments in both NW and CW. This might be attributed to the ageing process and to

the accumulation of organic matter. The CW is younger with sediments being removed operationally every few (3-4) years.

The total concentrations of Hg, iron (Fe) and sulfur (S), among others, were determined in wetlands, the tailings facility (TSF) and soil near the TSF (Table 1). The results of BCR sequential extraction for the same elements are presented in Figure 4.

Table 1 Total Hg, Fe and S in the wetlands and tailings

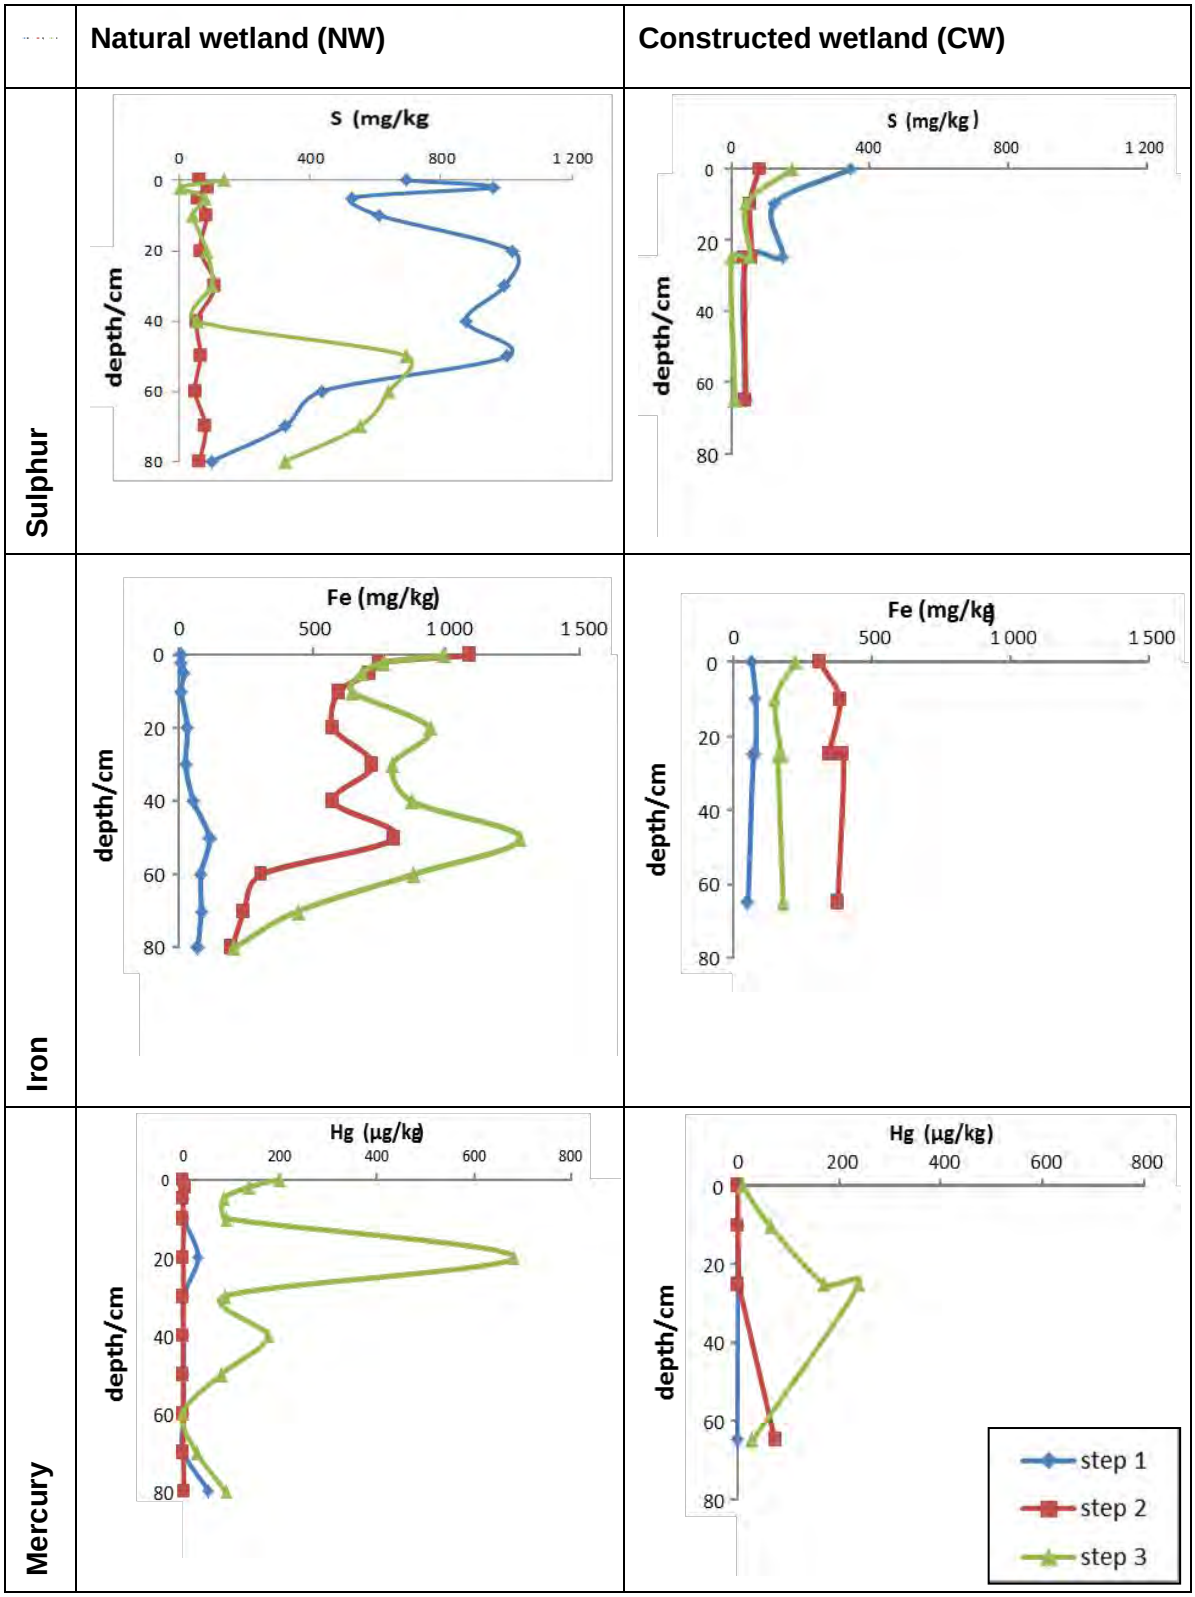

Figure 4 BCR sequential extraction (3 steps) for S, Fe and Hg in NW and CW sediments.

Mercury speciation in both wetlands shows the largest fraction leached in step 3 – oxidizable fraction; this situation is especially evident in the middle sediment levels. This is strongly correlated to sulphur and organic carbon for NWs. The relative quantities leached suggest the importance of ageing (maturity) in the case of CWs.

Seasonal distribution of mercury in wetlands

Distribution patterns for mercury were very similar in both wet and dry seasons. However, the total mercury (Hg^{TOT}) concentration in sediment was much higher in the latter (Figure 5). Also, in the dry season, pH was higher and redox potential was lower in water above the sediments. The equilibrium speciation modeling of Hg in wetlands waters was plotted on an Eh-pH diagram (Lewis and Plant, 2005) (Figure 6).

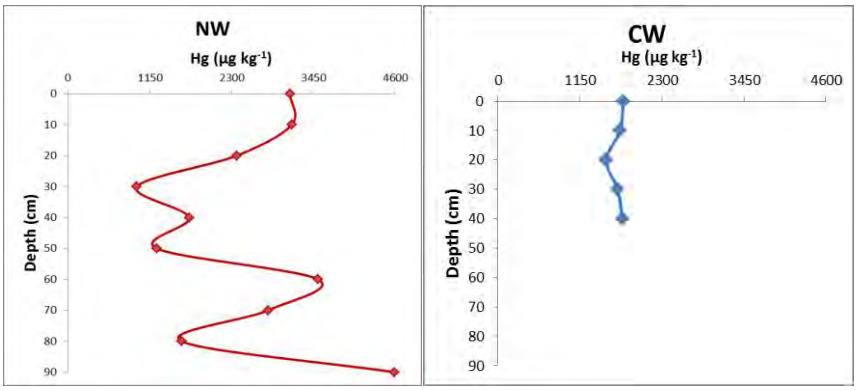

Figure 5 Comparison of Hg^{TOT} in constructed (CW) and natural (NW) wetland sediment in the dry season.

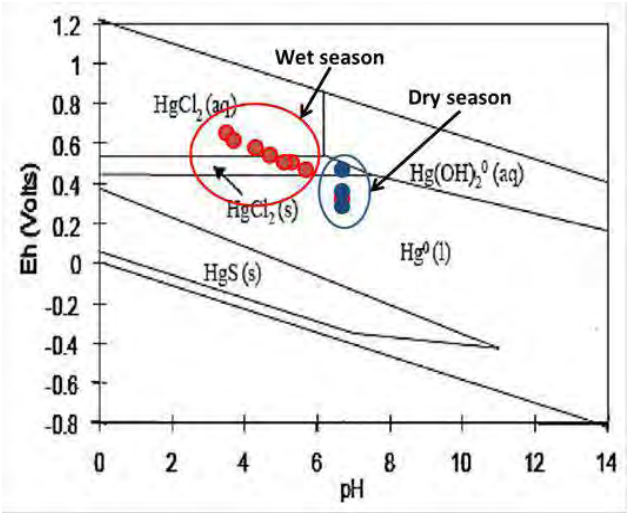

Figure 6 Eh-pH diagram showing seasonal mercury speciation in wetlands

The results showed that the predominant form of Hg in wet season waters is soluble $HgCl_2(aq)$ whereas the highly insoluble and volatile Hg^0 predominated in the dry season. This explains the elevated dissolved mercury concentration during the in wet season and its decrease in the corresponding sediment samples. This might be due to the acidification of the water during wet

season, which can occur when oxidation by products are flushed from mine tailings.. The lowering of the water pH during the rainy season is known to favour the solubilisation of heavy metals such as Hg, thus increasing Hg^{TOT}. There is, therefore a probable Hg remobilisation from the lower sediment horizons with the water's acidification during wet season and an eventual atmospheric release and/or re-precipitation during winter which explains its overall decrease in watersheds. The concentration of sulfate and chloride were also higher during the wet season, explaining the higher electrical conductivity values measured in these sampling time.

CONCLUSIONS

This study compares the performance of natural and manmade wetlands in trapping Hg as well the seasonal Hg distribution in both ecosystems. In general, natural wetlands performed better as "Hg sinks" compare to constructed ones. The lack of biodiversity in planting from the CWs and their younger ages could explain their lower effectiveness in Hg trapping. The constructed wetlands, therefore, require relatively more maturity and treatment prior to a meaningful assessment of their capacity retaining pollutants. Seasonal changes in Hg load in wetlands waters confirm that Hg is remobilized during the wet season and precipitates into sediment and/or evaporates into the atmosphere during the dry season. Selective extraction procedures revealed the predominance of in-soluble Hg compounds, especially at lower redox potential inorganic-rich sediments typical of wetlands. The fractionation of mercury in the BCR selective extraction depends strongly on the sample matrix as well as on the Hg concentration.

2. *Center for Biofilm Engineering, Montana State University, USA*

ABSTRACT

Until recently, our understanding of the microbial ecology of mined materials and ARD-affected water has been hampered by the selective effects of culturing microbial taxa (Archaea, Bacteria and Fungi). Recent advances in genomic technologies – such as next generation high-throughput DNA sequencing – now allows rapid, low-cost, and comprehensive investigations into microbial community diversity and function. From an environmental management perspective, analysis of microbial communities from ARD-affected water can provide insight into the effectiveness of mine management programs by rapidly indicating environmental impacts as well as changes resulting from remedial action. However, incorporating microbes as part of routine environmental assessment requires dealing with (as yet) unknown issues such as the effect of scale, determination of physico-chemical drivers, taxonomy, the potential effect of sequencing platform/bioinformatics on identification, and information organization and communication.

Here, using a community ecology approach, we explore the utility of genomic analysis to the management and study of mine-affected waters through case studies in the USA and Australia: 1. acidic pit lakes in Collie, Western Australia, and 2. the hydraulically plugged Glengarry adit near Cooke City MT. These case studies highlight how microbes can be used for identifying and evaluating the impacts of ARD in post-mine pit lake and hydraulically plugged underground mine workings, and as potential tools for environmental management.

ABSTRACT

Acid rock drainage (ARD) is a worldwide environmental problem. ARD is generated by microbially mediated oxidative dissolution of sulfide minerals and is characterized by low pH and high concentrations of sulfate and metals, thus representing an extreme environment for microbial life. Current knowledge about the structure and functioning of these communities is limited mainly because most studies characterizing ARD environments have relied on culture-dependent techniques or molecular taxonomy studies based on 16S rRNA information. Cultivation-independent metagenomic approaches are generating new opportunities to investigate community structure and the metabolic potential and functional significance of ARD microbes by directly assessing genomic information from environmental samples.

In this work, a comparative analysis of six microbial metagenomes has been undertaken from ARD sites: 5-Way and UBA biofilms from Richmond (biofilm), Kristineberg mine (biofilm and planktonic samples); Carnoulès mine (arsenic-contamined effluents) and Los Rueldos mine (mercury contaminated effluents). Taxonomic analysis of 384 Mbp of sequence information demonstrates that *Acidithiobacillus-like*, *Leptospirillum-like* and some Archaea are the most abundant and widespread taxa. Community-wise comparative analyses also showed that different ARD microorganisms partition according to specific environmental and geochemical conditions (e.g pH, temperature, etc.) and that in general one type of microorganism is dominant in each condition (e.g *Acidithiobacillus ferrivorans* in the Kristineberg metagenome). On these bases, and using available sequenced reference genomes, read recruitment analyses have been undertaken and strain-level variations assessed on high coverage genomic regions.

4. School of Biological Sciences, University of Wales, United Kingdom

Acid rock drainage (ARD) is an environmental problem resulting from the oxidative dissolution of pyrite and other sulfide minerals. The high sulfate concentration, extreme acidity and toxicity of metal-rich solutions derived from ARDs impose unique selective pressures to the microorganisms thriving in these econiches. Analysis of ARD microbial communities have been primarily based on 16S rRNA gene library sequencing, DGGE and/or T-RFLP profiling, providing relevant insights into the structure and evolution of acidophilic microbial communities. Nonetheless, these approaches lack the depth and coverage of modern sequencing techniques, thus little information has been collected on the microdiversity and the distribution of strain variants of the dominant taxa.

Here we combined Illumina-based technology with classic 16S phylogenetic (V3-V4 regions) and Multi Locus Sequence Typing marker analysis, an approach referred to as Targeted Metagenomics, to assess the microdiversity within the genus *Acidithiobacillus* in Mynydd Parys copper mine acid rock drainage. Mynydd Parys (Parys Mountain) mine, located in north-west Wales and now abandoned, contains a large body of acidic (pH ~ 2.5) metal-rich water that has accumulated within the underground workings, raising serious environmental concerns. High sequencing depth and resolution achieved through this strategy enabled us to analyze the microbial diversity in great detail, uncovering whole-community structure and sharp differences in species composition and abundance between sampling sites. Based on an improved SNPs-discovery routine diversity within the *Acidithiobacillus* was further explored providing insight into the strain-level richness. Results obtained also revealed the presence within the Parys acid rock drainage of several sequence clusters of undefined taxonomic assignment, further contributing to the understanding of the biodiversity of this system.

Bioaccessibility Testing of Sulfidic Rocks and Wastes

Eleanor van Veen[1], Anita Parbhakar-Fox[2] and Bernd Lottermoser[1, 2]

1. Environment and Sustainability Institute / Camborne School of Mines, University of Exeter, United Kingdom

2. School of Physical Sciences, University of Tasmania, Australia

ABSTRACT

Knowledge of the fraction of metal concentrations in mine wastes, which is accessible to plants, is integral to establishing effective and sustainable post-mining vegetation. Numerous tests have been designed to predict the bioaccessibility of metals in sediments and agricultural soils, however, it remains uncertain whether such tests can be applied to mine soils and in particular sulfidic rock and waste samples. This work aims to identify an appropriate test for the prediction of plant bioaccessibility of environmentally significant metals in sulfidic rocks and wastes.

Plant bioaccessibility extraction tests have evolved from extraction techniques used in the agricultural industry for almost half a century. Improvements in detection limits of analytical techniques to determine element concentrations in extractants (e.g. ICP-MS, ICP-AES) have allowed the use of less aggressive extraction reagents in more recent years. Sequential extraction procedures (e.g. Tessier and BCR sequential extraction procedures) can help determine the overall partitioning of total metals into different phases, however, they are expensive and time consuming. By contrast, single step extractions offer a snapshot of bioaccessibility and are operationally attractive being quicker. Simple salt solutions (e.g. $CaCl_2$, $NaNO_3$, NH_4NO_3) have gained favor in recent years over more aggressive complexing agents such as EDTA and DTPA. However, there are no universally accepted extraction solutions and the current snapshot may not be an indication of future metal bioaccessibility following weathering and oxidation of sulfidic waste rocks.

The results of a case study are presented, where the third step of the BCR sequential extraction procedure is applied to sulfidic rocks and wastes to predict the bioaccessibility of metals associated with sulfides in these materials. Based on literature review and case study analyses, this work is able to make recommendations for plant bioaccessibility testing of metals in sulfidic rocks and wastes.

Removing Heavy Metals from Acid Mine Drainage Through the Biological Generation of High-Value Metal Nanoparticles

Giovanni Ulloa, Bernardo Collao and José Manuel Pérez
Laboratorio de Bionanotecnología y Microbiología/ CBIB/ Universidad Andres Bello, Chile

ABSTRACT

Acid drainage affects a significant proportion of mine waste and is one of the major environmental problems faced by the mining industry. Its causes, prediction, and treatment have become the focus of a number of research initiatives commissioned by governments, the mining industry, universities and environmental groups. Ferrous and sulfur-oxidizing bacteria catalyze the oxidation of sulfides, reducing the pH of the solution and increasing the concentration of heavy metals such as Cd, As, Te, Pb, Se, etc.

The objective of the present work was to analyze the ability of bacteria present in the bioleaching processes and acid mine drainage (AMD) to biosynthesize nanobiotechnological products, such as fluorescent nanoparticles (quantum dots, QDs) (patent application PCT/CL2014/000074). QDs are semiconductor nanoparticles with potential application in biotechnological and industrial settings, including solar cells, new generation TVs, and biomedicine because of their optoelectronic properties.

In general, the nanoparticle synthesis protocol described in this work involves sulfur-oxidizing microorganisms currently used in Chilean mining industry, in the presence of inorganic phosphate and metals, which allow the cellular incorporation and tolerance of heavy metals. The method of QD synthesis is related to the degradation of intracellular granules of polymeric phosphate, and the release of hydrogen sulfide in the presence of metals. Here we demonstrate that divalent cations are incorporated in the presence of inorganic phosphate by atomic absorption spectroscopy. Sulfur reacts with cellular molecules containing fluorescent nanoparticles to generate compounds of heavy metals and sulfur with the spectroscopic characteristics typical of biosynthesized nanoparticle QDs.

The QD market is forecast to grow globally to a value of $67 million. This market is expected to grow over the next five years at a compound annual growth rate of 59.3%, reaching $ 1185.4. In Chile, the generation of nanoparticles by the mining industry will allow the creation of a new, sustainable and revolutionary business area.

Trace Elements of Economic Value and Environmental Concern in Acidic Drainage, Biofilms and Mineral Precipitates

Lori Manoukian[1], Bryn Kimball[1], Danielle Fortin[2], Heather Jamieson[1]* and Claudio Andrade[3]

1. *Department of Geological Sciences and Geological Engineering, Queen's University, Canada*
2. *Department of Earth Sciences, University of Ottawa, Canada*
3. *Barrick Gold, Canada*

ABSTRACT

Remediation of closed mine sites that continue to produce acidic drainage from waste rock, underground workings or tailings may require a commitment of decades of water managment and treatment. The overall objective of our research is to explore the possibility of decreasing the financial burden and environmental impact of water treatment by recovering elements of significant market value or isolating elements that are particularly problematic. Processes that occur in mine waste such as the concentration of elements of interest by precipitation of efflorescent minerals and microbial sequestration and transformation of elements have been investigated.

We have sampled drainage waters, mineral precipitates and biofilms where present at El Indio, Lagunas Norte, and Pierina mines. These are epithermal high-sulfidation gold deposits that tend to produce acid drainage and have a distinctive suite of trace elements. Water samples were analysed for major and trace elements in aliquots that were unfiltered, filtered to 0.45 μm and ultrafiltered to 0.01μm. Mineral samples were characterized using SEM-MLA, XRD, EMPA and synchrotron-based microanalysis. Identification of the microbial population diversity in solid and liquid samples has been carried out with DNA extraction and amplification.

Secondary sulfate minerals from these deposits are known to sequester Cu, Zn, Cd, As and other trace elements. From previous work, microorganisms are known to control the mobility of redox-sensitive trace elements such as As and Te. The results of our research will provide a detailed geochemical and microbiological characterization of these mineral-water-biofilm systems associated with epithermal high-sulfidation gold deposits and provide the basis for innovative management approaches to ARD.

APPLIED MINERALOGY AND GEOENVIRONMENTAL UNITS

Setting ARD Management Criteria for Mine Wastes with Low Sulfide and Negligible Carbonate Content

Stephen Day and Chris Kennedy
SRK Consulting, Canada

ABSTRACT

Evaluation of ARD potential for rock with low (less than <1% by weight) sulfide content using conventional acid-base accounting criteria (e.g. net neutralization potential and neutralization potential ratio) can result in invalid classifications because neutralization potentials do not adequately represent the ability of acid-consuming silicate minerals to neutralize weak acidity. Rocks containing low sulfide concentrations generate acid at low rates that do not necessarily require fast-reacting carbonates to buffer pH to near neutral levels. Instead, meteoric weathering of silicate minerals by carbonic acid can deliver sufficient dissolved bicarbonate to offset acid generated and buffer pHs well above 7. Because silicate minerals dominate the mineralogy of many common rock types, bulk neutralization potential is effectively infinite compared to acid generation potential, and the determination of ARD potential depends on the rate of silicate weathering relative to sulfide oxidation rate. Furthermore, the bulk sulfide oxidation rate is typically correlated to sulfide content allowing sulfide content thresholds to be used as management criteria.

This paper will present an example of the use of this conceptual model to develop waste rock management criteria for the NorthMet Project in the nearly carbonate-absent Duluth Complex of northern Minnesota, USA. The method involved measurement of silicate weathering rates for rocks containing negligible sulfide and development of a relationship between sulfide content and oxidation rates. Interpretation of the data obtained provided an explanation for the lack of net acid generation in decades-long kinetic-testwork performed by the Minnesota Department of Natural Resources on samples containing less than 0.2% sulfur as pyrrhotite and chalcopyrite. The findings were used to develop waste rock management criteria for the proposed mine using sulfur content.

Keywords: silicate weathering, silicate alkalinity, Duluth Complex, low sulfide

INTRODUCTION

Conceptual Geochemical Model – Contact Water pH Modification By Silicate Minerals

The tendency for mine wastes to yield contact waters containing unacceptable concentrations of regulated contaminants largely hinges on weathering pH because most of the the contaminants are metals and solubility is in part a function of pH typically represented by reactions such as:

$$Cu^{2+} + 2H_2O \leftrightarrow Cu(OH)_2 + 2H^+ \quad (1)$$

While higher pHs do not guarantee that concentrations will be below regulatory limits, the relationship between pH and metal concentrations indicates that concentrations will tend to be much higher at lower pHs. The trend is reversed when amphoteric behavior allows solubility to increase at higher pHs.

The weathering environment pH in mine wastes is commonly attributed to the balance between acid generating reactions represented by:

$$FeS_2 + {}^{15}\!/_4 O_2 + {}^{7}\!/_2 H_2O \rightarrow Fe(OH)_3 + 2SO_4^{2-} + 4H^+ \quad (2)$$

and the consumption of acid (H^+) by carbonate minerals:

$$4Ca(CO)_3 + 4H^+ \rightarrow 4Ca^{2+} + 4HCO_3^- \quad (3)$$

The balance between these reactions is usually evaluated by analytical methods which are proxies for the iron sulfide and carbonate minerals (for example, acid-base accounting, ABA, Sobek et al., 1978; Lawrence & Wang, 1991 and net acid generation, NAG, AMIRA International, 2002).

This conventional theory and the analytical approaches used to quantify acid generating and acid consuming mine waste components fall short of correctly incorporating the role of silicates in modifying contact water pH because silicate minerals react much less rapidly than carbonate minerals and weathering rates are a function of pH. For example, neutralization potential (NP) determined as part of ABA is commonly observed to yield more apparent acid-consuming capacity than can be accounted for by the carbonate content (for example, Day, 2009) and this difference is assigned to acid consumption by silicate minerals. The aggressive low pH of the test conditions in the NP procedure (and similarly in the NAG procedure) result in acid neutralization by reactions such as:

$$CaAl_2Si_2O_8 + 8HCl \rightarrow Ca^{2+} + 2Al^{3+} + 2SiO_2 + 8Cl^- + 4H_2O \quad (4)$$

Hydrolysis reactions for the resulting dissolved aluminum buffer pH in the range 4 to 5:

$$Al^{3+} + 3H_2O \rightarrow Al(OH)_3 + 3H^+ \quad (5)$$

Therefore, the low pH of the tests encourages silicate mineral dissolution, which buffers pHs through aluminum release (reaction (4)) at levels too low to usefully influence metal solubility relative to regulated limits. Furthermore, due to the slow weathering reaction kinetics of the consumption of acid by the above types of reactions and the method used to determine the amount of acid in the analytical procedures, the NP methods do not quantify the silicate mineral reservoir potentially available to neutralize acid.

The actual role of silicates in controlling contact water pH is represented by weathering reactions between carbon dioxide and silicate minerals, such as:

$$CaAl_2Si_2O_8 + 2H_2O + 2H_2CO_3^0 \rightarrow Ca^{2+} + 2Al(OH)_3 + 2SiO_2 + 2HCO_3^- \quad (6)$$

This reaction is comparable to reaction (4) but involves carbonic acid (i.e. dissolved CO_2) rather than sulfuric acid and yields dissolved bicarbonate which can in turn be involved in buffering contact water pH in the near neutral pH range through reversible reactions such as:

$$Ca^{2+} + HCO_3^- \rightarrow CaCO_3 + H^+ \quad (7)$$

The potential role of silicates in modifying contact water pH at higher pHs is therefore limited to the delivery of alkalinity due to slow weathering resulting in exchange of protons with alkali and alkali earth cations in silicates. These reaction rates are very slow relative to dissolution of carbonate minerals and are therefore probably unimportant in carbonate-rich systems. They become much more important in carbonate-deficient systems containing low sulfide concentrations where the rate of acid generation can be balanced by the slow generation of alkalinity by silicate weathering. Furthermore, the silicate mineral reservoir is far greater than the acid that could be generated by sulfide oxidation resulting in an effectively perpetual source of alkalinity even when passivation of silicate mineral surfaces by secondary silicates occurs. In this setting, the rate of acid generation by sulfide oxidation therefore becomes the controlling variable rather than the actual quantity of silicate minerals.

This paper describes quantification of silicate weathering for a nearly carbonate-absent geological environment and the resulting definition of sulfide sulfur management criteria for waste rock management.

Study Area – Duluth Complex

The Duluth Complex in northern Minnesota is a layered gabbroic complex intruded approximately 1 billion years ago. The base of the complex contains copper and nickel sulfides, and platinum group elements formed from sulfide melts. The dominant minerals in the Duluth Complex are olivine and plagioclase, and carbonates were not formed as part of the original magmatic processes. Deuteric processes resulted in localized formation of secondary carbonates but at very low concentrations which are commonly undetectable.

The State of Minnesota recognized the benefits of economic recovery of metals from the Duluth Complex and initiated studies to support resource development (State of Minnesota 1979). Interest in large-scale open pit and underground mining accelerated in the 2000s and several projects are in various stages of economic and regulatory assessment. This includes PolyMet Mining Inc.'s NorthMet Project, which is the subject of this paper.

Previous Studies

The Lands and Mineral Division of the Minnesota Department of Natural Resources (MDNR-LAM) continues to conduct several test programs designed to evaluate the long term weathering of Duluth Complex rocks (e.g. Lapakko & Antonson, 2006). These have included chemical and mineralogical characterization, conventional humidity cells (ASTM, 2001) and other custom-designed laboratory kinetic tests, and monitoring of drainage from small field test piles and full-

scale waste rock piles. The latter are stockpiles of Duluth Complex rocks resulting from stripping to access iron ore in the LTV Steel Mining Company's Dunka Pit.

The laboratory kinetic tests operated for over 18 years by MDNR-LAM (Lapakko & Antonson, 2006) have shown consistent leaching features including lack of pH depression in samples containing about 0.2% sulfur (Figure 1a), correlation of timing of pH depression and sulfur content (Figure 1b,c,d), recovery of pH following pH minimums (Figure 1b,c), and correlation of sulfide oxidation rates with sulfide content.

Program Design

The NorthMet Project would be an open pit mine with a proven and probable ore reserve of 275 million tonnes with a copper equivalent grade of 0.79% (Desautels & Zurowski, 2013). The sulfur block model for the deposit indicated that waste rock would contain sulfur concentrations ranging from 0.01% to greater than 1%. The majority of waste rock would contain less than 0.1%. A kinetic test program was designed in consultation with MDNR-LAM to develop waste management criteria. The detailed design evaluated the relationship between variables that could conceivably affect rock weathering behavior including sulfur content, rock type (variability between plagioclase- and olivine-rich troctolite end-members), sulfide mineralogy (iron versus copper and nickel sulfides as represented by samples of waste, low grade ore and ore), stratigraphic layer in the complex, and waste rock particle size. The influence of test protocol on outcomes was evaluated by parallel testing using conventional ASTM and MDNR-LAM-designed methods. The distribution of sulfur concentrations tested is shown in Figure 2. Several samples were selected containing 0.02% sulfur thereby indicating weathering chemistry for rock essentially containing no sulfide. Samples containing the highest sulfur concentrations in the test program were from the surrounding host rocks of the Duluth Complex rather than the intrusions themselves.

METHODOLOGY

Sample Acquisition and Preparation

Samples were selected from drill core using logged characteristics and analytical data in the exploration database. Two sections of each core interval were retained for mineralogical characterization and the balance was crushed to meet the specifications of the various test methods.

Mineralogy

Mineralogy was described using optical methods on polished thin sections. For each mineral, the crystal shape, grain size and texture were described. Electron microprobe was used to determine concentrations of major element oxides, arsenic, cobalt, copper, iron, nickel, titanium and zinc in grains of all major silicates, oxides and sulfides.

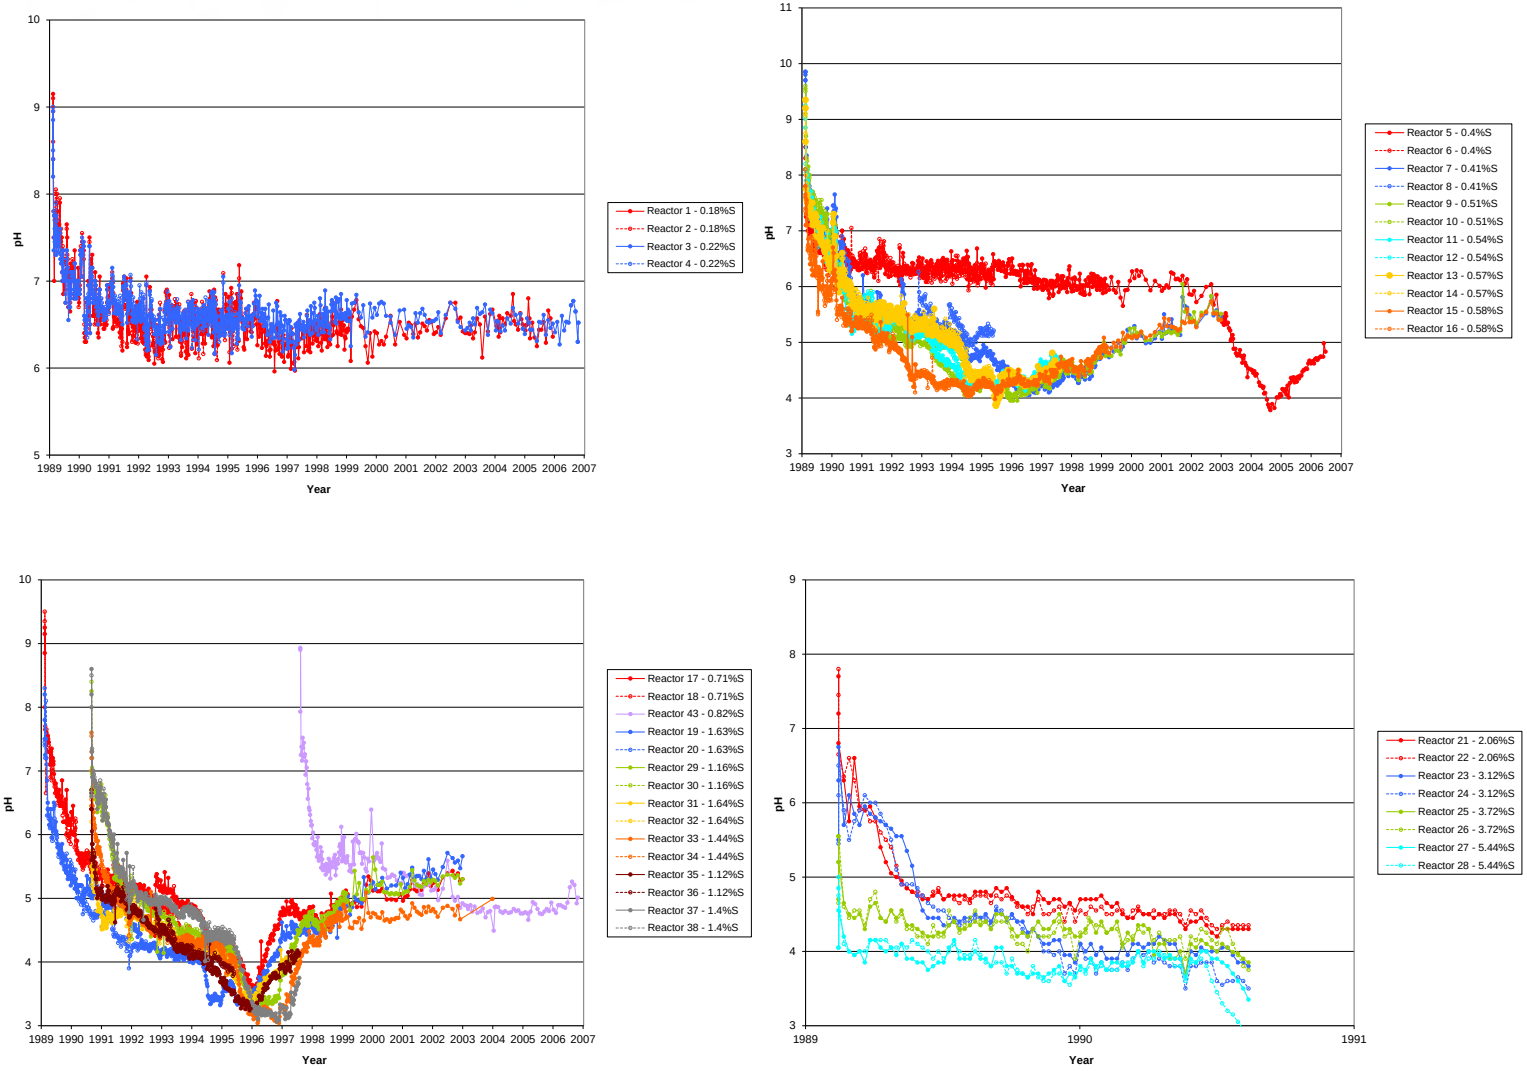

Figure 1 pH Trends for a selection of long term laboratory kinetic tests operated by MDNR-LAM

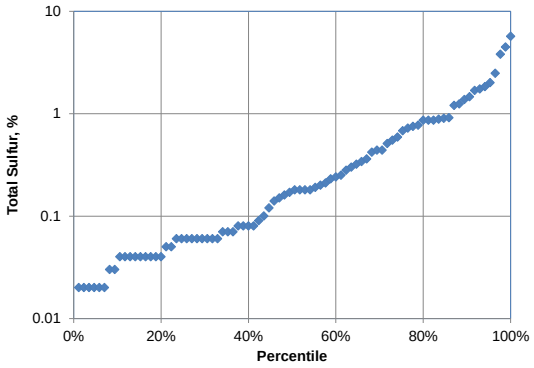

Figure 2 Distribution of sulfur concentrations in rock humidity cells for the NorthMet project. Each symbol is one test.

Humidity Cells

Humidity cells were performed using the ASTM (2001) methodology. The sample charge was 1 kg and the weekly leaching volume was 0.5 L. Leachate analysis included weekly pH, conductivity and ORP; sulfate, acidity, alkalinity, chloride and fluoride every two weeks, and an element scan every two weeks. For every fourth week, the element scan was performed using a low level ICP-MS method. ICP-OES was used for the intervening weeks. This approach recognized that the test work was expected to proceed for many years and therefore was selected to control costs. As the program proceeded, analytical frequency was further reduced. Some humidity cells have now been operating for over 10 years.

Quality Assurance and Quality Control

Routine quality assurance measures included analysis of 10% of solids and leachates in duplicate. In addition, 10% of all kinetic tests were operated in duplicate and blank kinetic tests.

RESULTS AND DISCUSSION

Mineralogical Characteristics

The dominant minerals in all Duluth Complex samples were plagioclase and olivine. Clinopyroxene and orthopyroxene were present in minor quantities with chlorite and serpentine as alteration products. Using microprobe data, plagioclase was determined to be of approximate labradorite composition being calcium enriched and the average composition of olivine was 57% forsterite (Mg_2SiO_4) and 43% fayalite (Fe_2SiO_4).

Dominant sulfide minerals determined from thin sections were pyrrhotite ($Fe_{1-x}S$) and chalcopyrite ($CuFeS_2$). Chalcopyrite was dominant when sulfur concentrations were very low (<0.05%) and in low grade and ore grade samples. Otherwise pyrrhotite dominated. The dominant nickel sulfide was pentlandite ($(Fe,Ni)_9S_8$) and cubanite ($CuFe_2S_3$) tended to be present in comparable amounts to pentlandite. Trace levels of various cobalt, copper, lead, nickel, iron and zinc sulfides and arsenides were identified. Calcite was very rarely identified.

Humidity Cell Results

Leachate Chemistry

Leachate pH trends for two groups of waste rock cells are shown in Figure 3. Samples containing less than or equal to 0.05% sulfur have consistently yielded pHs near 7 following initial decline in pH which lasted approximately 1 year. There has been a slight overall tendency for pH to increase over time in the long term testwork. Samples with more than 0.05% sulfur have also mostly yielded pHs between 6 and 7 with only three samples containing sulfur concentreations exceeding 0.4% showing lower pHs. Alkalinity concentrations have been consistently detected above 1 mg $CaCO_3$/L and tend to be less than 10 mg $CaCO_3$/L.

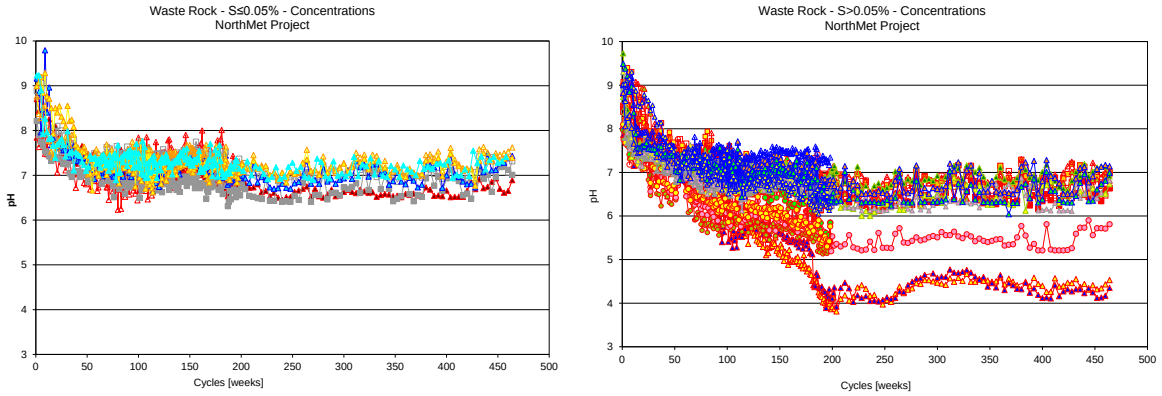

Figure 3 Selected humidity cell results for Duluth Complex samples from the NorthMet project grouped according to sulfide content

Interpretation of Sulfide Threshold for Acid Generation

Method

Long term test work on Duluth Complex samples performed by both MDNR-LAM and PolyMet Mining Inc. shows that samples with 0.4% and greater initial sulfur content generate acidic leachates under laboratory conditions. In this instance, acid generation is defined as a pH of 5.5 which is consistently below that of the deionized water used to leach the samples. MDNR-LAM's long term test work also shows that samples containing about 0.2% sulfide do not generate acid after 20 years of weathering. A sample containing 0.2% sulfur in the NorthMet program has shown pH near 5.5 (Figure 3) but detectable alkalinity (> 1 mg $CaCO_3$/L) is also released. These test data imply that a sulfur criterion for segregation of waste rock should be between 0.2% and 0.4%; however, a residual concern is that any of the MDNR-LAM or NorthMet Project tests with 0.2% sulfur could start to generate acid in the future. The NorthMet data were therefore interpreted to evaluate what the potential threshold of alkalinity release from weathering of silicates could be in order to offset acid generation from sulfide oxidation. The interpretation method used was as follows:

- Leachate from samples containing lowest sulfur concentrations were interpreted to determine if the chemistry was consistent with the silicate minerals that appear to be weathering, and were then used to establish alkalinity generation rates in the near absence of sulfide minerals.
- The correlation between oxidation rates and sulfur content was evaluated.
- Acid generation rates were compared to alkalinity generation rates to determine if a threshold sulfur concentration could be identified and used as a waste managemetn criterion.

Mineralogical Interpretation of Leachates

Selected typical leachates from six humidity cells containing 0.02% sulfur and carbonate content at or below the detection limit of 0.2% CO_2 were modeled using Geochemist's Workbench® to evaluate if leachate composition was consistent with the mineralogy of the samples. Three samples were described as troctolite and three as anorthosite. The latter contains a relatively greater proportion of plagioclase compared to olivine. The minerals assumed to be reacting were chalcopyrite ($CuFeS_2$, reacting amount calculated from sulfate concentrations), anorthite ($CaAl_2Si_2O_8$, reacting amount calculated from calcium), albite ($NaAlSi_3O_8$, reacting amount calculated from sodium), forsterite (Mg_2SiO_4, reacting amount calculated from magnesium) and fayalite (Fe_2SiO_4. reacting amount calculated from magnesium and the composition of olivine indicated by microprobe). The reaction was assumed to occur at 20°C (laboratory temperature) in the presence of fixed atmospheric oxygen (fugacity of 0.2) and carbon dioxide (fugacity of $10^{-3.4}$). Controlling secondary minerals were assumed to be amorphous ferric hydroxide ($Fe(OH)_3$), malachite ($Cu_2CO_3(OH)_2$), gibbsite ($Al(OH)_3$), kaolinite ($Al_2Si_2O_5(OH)_4$) and amorphous silica (SiO_2).

Measured and modelled leachate pHs were strongly correlated though the model over-predicted leachate pH in all six cases (Figure 4). Over-prediction was greater for the troctolite samples. Modelled alkalinity was very close to measured alkalinity for all six samples (Figure 4). Average modeled silicon concentrations were 1.9 mg/L compared to average measured concentrations of 1.2 mg/L. This modeling demonstrates that measured alkalinity generation can originate from meteoric weathering of the dominant silicate minerals confirming the conceptual model and indicating silicate weathering is a long term source of alkalinity. Stability of long term trends (approaching 10 years for this dataset and 20 years for the MDNR's dataset, Figure 1) has provided sufficient time for stripping of carbonate minerals even if present at the detection limit.

Based on this finding, longer term stable data from humidity cells were used to calculate an average alkalinity generation rate of 3.3 ± 0.4 mg $CaCO_3$/kg/week. The 5th to 95th percentile range for the rates was 2.1 to 5.3 mg$CaCO_3$/kg/week. For subsequent calculations and comparison to acid generation rates, 2.9 mg$CaCO_3$/kg/week as the lower confidence limit (at α=0.05) on the mean was selected to represent long-term base-level alkalinity generation by weathering of silicate minerals. Because the humidity cell tests were operated by leaching with 0.5 L of deionized water, the rate used corresponds to a concentration of about 5.8 mg$CaCO_3$/L

Relationships Between Sulfide Concentrations and Sulfate Release

Average sulfate release rates (calculated after an initial flush of sulfate from the humidity cells had completed at the start of the tests) were compared to sulfide concentrations (Figure 5). The correlation was very strong for sulfur concentrations below 0.1% but was weaker at higher sulfur concentrations where it appeared that some samples yielded distinctively lower sulfate release for a given sulfur content, whereas

others showed higher sulfate release at the same sulfur concentration. Correlations of sulfate release and sulfide content have also been reported by MDNR-LAM researchers (Lapakko and Antonson, 2006).

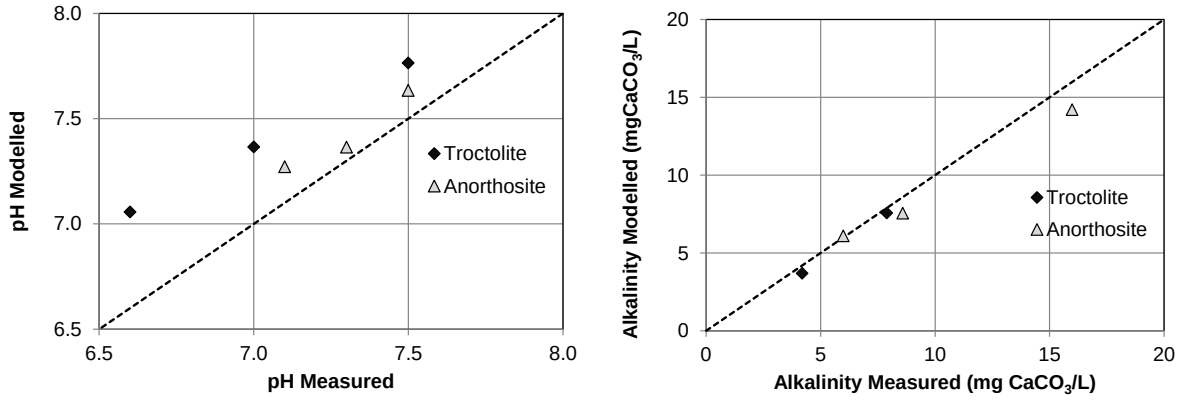

Figure 4. Comparison of measured and modeled humidity cell leachate pH and alkalinity for low sulfur samples. The dashed line indicates parity.

Grouping of samples according to Cu/S weight (mg/mg) ratios (i.e. reflecting the relative amounts of pyrrhotite and chalcopyrite) showed that samples with higher ratios (chalcopyrite enriched) yielded higher sulfate release rates whereas those with lower ratios (pyrrhotite enriched) yielded lower sulfate release. This finding applied across the range of sulfur concentrations including those with low sulfur content (Figure 5). Broadly, the ratio grouping correlates with the economic classification into low grade ore and waste. Three samples classified as lean ore but with lower ratios did not group with the waste rock samples but their sulfate release rates were unstable at the time of the interpretation and subsequently yielded low release rates.

The finding that chalcopyrite appears to oxidize faster than pyrrhotite was counter-intuitive because pyrrhotite is usually considered to be more reactive than chalcopyrite. It was expected that the difference in reactivity could be attributed to differences in mineralogical occurrence (e.g. grain size or crystallinity) but no satisfactory explanation was developed.

DEVELOPMENT OF SULFUR CRITERIA FOR ACID GENERATION POTENTIAL

The conclusion that sulfate release is correlated with sulfide content when Cu/S ratios are considered, was then used to propose sulfur criteria for acid generation potential because a direct link exists between sulfur content and the alkalinity required to offset acid generation. The data in Figure 5 were used to define the two regression equations shown:

$$\text{For Cu/S<0.3: Total S (\%)} = 0.40\ R_{SO_4}\ (\text{mg/kg/week}) - 0.70\ (n=15, r=0.98) \quad (8)$$

$$\text{For Cu/S>0.3: Total S (\%)} = 0.046\ R_{SO_4}\ (\text{mg/kg/week}) - 0.01\ (n=37, r=0.93) \quad (9)$$

The alkalinity generation rate (2.9 mg $CaCO_3$/kg/week) was used to calculate a balancing acid generation rate in sulfate equivalents of 2.9 mg SO_4/kg/week which was then used to calculate threshold sulfur

concentrations by the two regression equations. Due to the need to incorporate conservatism in the estimates for waste management, prediction envelopes were calculated for the regression equations based on a significance level of α=0.05.

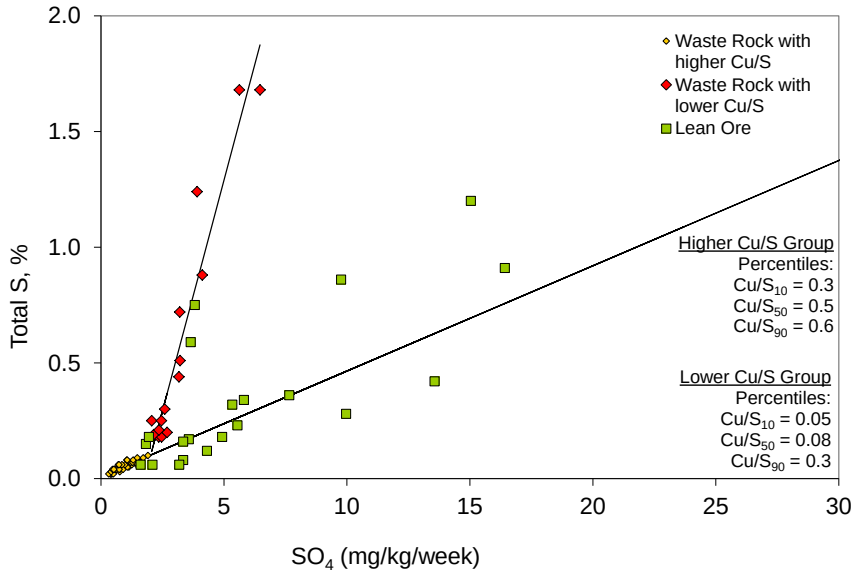

Figure 5 Relationships between average sulfate release and sulfur content

The resulting proposed sulfur criteria were 0.12% for higher Cu/S ratios and 0.31% for lower Cu/S ratios. Both criteria are consistent with the long term testwork performed by MDNR-LAM which showed acid generation occurred for samples with sulfur content greater than 0.4% and a smilar study by Campbell et al. (2012).

For the purpose of waste management, the project proceeded based on a single sulfur criterion of 0.12% due to the lack of an explanation for the difference in sulfide reactivity that resulted in the higher criterion of 0.31%.

CONCLUSIONS

Long term kinetic testwork performed on rocks from the Duluth Complex in northern Minnesota shows that alkalinity generated by weathering of silicate minerals provides a plausible explanation for the lack of acid generation in samples containing low sulfide concentrations. It is concluded that steady alkalinity generation offsets low levels of acid generation. Due to the overwhelming abundance of silicate minerals compared to acid generating sulfide minerals, waste segregation for acid geneation potential is appropriately based on sulfide content rather than coventional acid-base accounting methods. For the NorthMet Project, a site-specific sulfur criterion of 0.12% was adopted.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge permission from PolyMet Mining Inc. to publish these results. Interpretation of the testwork results have benefitted from numerous discussions with individuals at MDNR-LAM (particularly Kim Lapakko, Paul Eger, Mike Berndt, Zach Wens and Mike Olsen), PolyMet (Jim Scott) and Barr Engineering (Tamara Diedrich).

A Desulfurization Flotation Approach for the Integrated Management of Sulfide Wastes and Acid Rock Drainage Risks

Jennifer Broadhurst and Susan Harrison
Minerals to Metals Initiative, Department of Chemical Engineering, University of Cape Town, South Africa

ABSTRACT

Wastes from the primary processing of hard-rock sulfide ores and coal have the potential to cause prolonged pollution of the local environment as a result of the long-term generation of acid rock drainage (ARD). Changes in legislation and global thinking have prompted a growing trend towards the development of approaches that remove the ARD pollution risks in perpetuity. In this regard, a two stage process has been developed at the University of Cape Town, which uses froth flotation to both recover valuable material and remove pyritic sulfur from fine mineral waste.

The technical feasibility of this process has been demonstrated at the laboratory scale for porphyry copper and fine coal wastes, with results indicating that it is possible to recover a useable product whilst generating a tailings waste stream with a negligible ARD risk. On the basis of this work, an order-of-magnitude financial model for a fictitious coal waste treatment plant has been developed and applied to demonstrate the economic viability for a selected case study. Furthermore, a life cycle assessment (LCA) study indicated that the pre-disposal removal of sulfide minerals from base metal tailings results in reduced eco-toxicity and human toxicity impacts. However, the LCA revealed that climate change and fossil fuel depletion impacts are increased due to additional energy consumption by the desulfurization process. This LCA study also highlighted the potential to reduce abiotic resource depletion through further processing and recycling of the separated tailings fractions.

The overarching objective of these studies, the key findings of which are presented in this paper, is to improve the environmental sustainability of coal and metal sulfide processing operations by both maximizing resource productivity and minimizing environmental burden.

Keywords: sulfide mine wastes, acid rock drainage, desulfurization flotation, economic feasibility, life cycle assessment

INTRODUCTION

The extraction and processing of coal and sulfide mineral deposits give rise to large volumes of solid and slurry wastes, which are conventionally disposed of in surface impoundments. These mine wastes frequently still contain residual sulfide minerals, particularly pyrite, which can result in the formation of acid rock drainage (ARD) upon exposure to air and moisture (Lottermoser, 2007). Acid rock drainage from sulfide mine waste deposits is typically characterized by low pH, high total dissolved solids and elevated levels of trace elements, and can cause prolonged degradation and pollution of local environments (see for example reports by Bell *et al*., 2001; Lottermoser, 2007; Rosner *et al*., 2001). Solid mine wastes also frequently represent a loss of valuable mineral resources due to incomplete separation during ore processing.

The long-term costs of on-going remedial action, coupled with increasing legislative and public pressure on mines to improve their environmental performance, has prompted a trend towards the development of preventative approaches that are aimed at minimizing or avoiding the generation of ARD (Johnson & Hallberg, 2005). Currently, such approaches focus mainly on avoiding exposure of sulfide minerals to oxygen and moisture, and involve techniques such as backfilling, blending and co-disposal, as well as the use of covers and seals (Johnson & Hallberg, 2005). However, these techniques do not completely remove the risk of ARD formation over the long-term, and in most cases their ability to provide a "walk-away" post-closure situation is yet to be proven. An alternative, and more sustainable, approach is to selectively remove the sulfide minerals from the waste prior to disposal, thereby effectively eliminating the risk of ARD formation in perpetuity (Cilliers, 2006; McCallum & Bruckard, 2009). Previous studies have shown froth flotation to be a technically feasible and cost-effective technique for removing sulfide minerals from a number of base metal and gold process tailings (Benzaazoua *et al*., 2000 & 2008; Benzaazoua & Kongolo, 2003, Bois *et al*., 2004 and Leppinen *et al*., 1997). The conventional desulfurization process produces two mineral waste fractions: a large volume sulfide-lean fraction which can be land disposed without posing an ARD risk, and a smaller volume sulfide-rich fraction which can be used as backfill (Benzaazoua & Kongolo, 2003) or processed further into useful by-products such as sulfuric acid.

Ideally, the pre-disposal treatment of sulfide mine tailings should be used in an integrated approach that not only removes risks of ARD pollution, but also provides opportunities for value recovery and re-allocation of unavoidable wastes as feedstock for other uses (Benzaazoua *et al*., 2008; Hesketh *et al*., 2010a). In this regard, studies at the University of Cape Town have demonstrated that desulfurization flotation of a porphyry-type copper sulfide tailings can be conducted in stages through manipulation of the reagent regime, producing an additional metal-rich stream that could be recycled to the conventional metal recovery plant (Hesketh *et al*., 2010a). The concept of using froth flotation to both recover value and remove ARD risks from mine waste has subsequently been extended to fine coal wastes in a two-stage process that recovers coal by means of oily collectors in stage 1, followed by desulfurization flotation to remove pyritic sulfur in stage 2 (Amaral Filho *et al*., 2011; Kazadi Mbamba *et al*., 2012). Selected case studies have also been conducted to explore the economic viability (Jera, 2013) and broader environmental implications (Broadhurst *et al*., 2014) of the proposed desulfurization flotation approaches.

This paper presents the key findings of these studies, with a view to demonstrating the techno-economic and environmental feasibility of using froth flotation to both recover valuable material and remove ARD risks from fine metal sulfide and coal processing wastes.

METHODOLOGY

Laboratory-scale flotation tests

All flotation tests were carried out in a 3-liter modified Leeds batch flotation cell at the natural pH of the slurry in tap water (pH 6-8), an impeller speed of 1200 rpm and an aeration rate of 5-6 L/min. Detailed experimental procedures are outlined by Hesketh *et al*. (2010a) for the porphyry copper case study and by Kazadi Mbamba *et al*. (2012) for the coal case studies. Acid generating potential was determined using standard acid-base accounting (ABA) and net acid generation (NAG) static tests (Stewart *et al*., 2006), as well as the batch biokinetic test developed at the University of Cape Town (Hesketh *et al*., 2010b)

Porphyry copper case study

In this case study, an oxidized low-grade porphyry copper ore, milled to 70 % passing 150 μm, was used as a proxy for a typical porphyry-type copper sulfide tailings. The ore had a sulfur and copper grade of 3.84 % and 0.16 %, respectively. Pyrite (7.03 %) and chalcopyrite (0.12 %) were the major sulfide minerals. Flotation was carried out in stages (maximum 4), using methyl isobutyl carbinol (MIBC) frother (30 g/ton) and a diothiophosphate collector from CYTEC mining chemicals, at a dosage rate of 9 kg/ton for each stage. The retention time for stage 1 was 8 minutes, and thereafter 5 minutes for each stage. Solids were analyzed for iron, copper and total sulfur.

Coal waste case studies

Two-stage laboratory-scale flotation tests were carried out on the following coal waste samples: fine thickener underflow slurry waste from an operating colliery in Middleburg, South Africa-filtered and milled to 75 % passing 150 μm; fine flotation tailings waste from an operating colliery in Criciúma, Brazil; coal discard, generated through the destoning of low-grade coal by means of an experimental X-ray sorter at a South African coal-fired power plant, and subsequently crushed and milled to 75 % passing 106 μm.

Dodecane (1.86 kg/t) or oleic acid (2.89 kg/t) were used as coal collectors in stage 1, together with isobutyl carbinol (0.11-0.28 kg/t) as a frother. Desulfurization flotation of the coal flotation tailings was subsequently carried out using potassium amyl xanthate (PAX) as a sulfide collector (2.33 kg/t), dextrin as a coal depressant (0.93 kg/t) and methyl isobutyl carbinol (MIBC) as a frother (0.11 kg/t). All flotation tests were carried out at a solids content of 6-7 %, and collection periods of 5 minute and 20 minutes for the coal and desulfurization flotation stages, respectively. Samples were analyzed for ash and total sulfur content.

Economic assessment: coal case study

A framework was developed for providing an order-of-magnitude cost estimate (± 30 % to ± 50 % accuracy) for a fictitious two-stage coal flotation desulfurization plant to treat nominal coal fines from a dump of an abandoned mine in the Witbank/Middleburg coal field (Jera, 2013). The plant flow sheet was based on the laboratory-scale test results obtained for the South African fine coal waste, as described in the previous section, and included milling, flotation, filtration, thickening and pumping as key operations. A plant throughput of 100 t/h with a capacity of 720,000 tons per annum was assumed, at a plant life and availability of 15 years and 82 % respectively. Capital costs were based on major equipment costs in combination with Lang costing factors. Operating costs

were based on "rule of thumb" industry estimates and flow sheet data. Revenue was generated from the sale of the coal product at a price of 349 South African rands (R) per ton. The net present value (NPV) and internal rate of return (IRR) were calculated at a discount rate of 14 %, using Microsoft Excel.

Life cycle assessment: base metal case study

Two scenarios for the treatment of a base metal sulfide tailings stream were developed to evaluate the environmental consequences of incorporating a desulfurization flotation unit into a conventional tailings management plant, which entails dewatering in a thickener and disposal of the thickener underflow to a tailings impoundment (base case scenario). Input-output data for the two tailings management options were derived from a combination of literature information, in-house knowledge and mass balance calculations. An empirical base metals case study by Benzaazoua & Kongolo (2003) formed the basis of this study (Table 1), producing two output streams: a non-acid generating sulfide-lean tailings comprising 72% of the feed; and a sulfide-rich concentrate which could be recycled to the primary extraction plant for additional metal and/or acid recovery.

Background data for electricity production were derived from the Eco-invent database (version 2.2), whilst data for the production of xanthate were obtained from a recent in-house study of the local production of liquid ethyl xanthate at Senmin® International in Sasolburg, South Africa (Kunene *et al*., 2013). Life cycle assessment modelling for each of the scenarios was conducted at a reference flow rate of 100 tons of dry tailings per day, using Simapro Software (version 7.3.3) and USEtox (eco-toxicity and human toxicity impacts) and ReCiPe (climate change, fossil fuel depletion, terrestrial acidification, urban land occupation and natural land transformation) impact assessment methodologies. The detailed methodology and case study assumptions are outlined in Broadhurst *et al*. (2014).

Table 1 Desulfurization flotation LCA case study data[1] (after Benzaazoua & Kongolo, 2003)

Component	Stream compositions (mass %)			Recovery to concentrate (% of feed)
	Feed tailings	Desulfurized tailings	Sulfide-rich concentrate	
Pyrite	17.4	2.18	56.53	91[2]
Sphalerite	0.19	0.02	0.62	90
Chalcopyrite	0.10	0.07	0.19	61
Calcite	2.70	3.38	0.96	10[3]
Other (gangue)	79.61	94.36	41.67	15[2]
Sulfide sulfur	9.38	1.17	30.49	91
Total solids	100	100	100	28

[1]Desulfurisation carried out at pH 6-11, using KAX (potassium propyl xanthate) as a collector and Sasfroth Sc 39 as a frother (Benzaazoua & Kongolo, 2003); [2]derived from mass balance calculations; [3]assumed on the basis of literature information (Broadhurst *et al*., 2007).

RESULTS AND DISCUSSION

Laboratory-scale flotation tests: porphyry copper case study

Flotation tests on the porphyry copper sulfide sample indicated that, whilst the recovery of both pyrite and chalcopyrite increased on increasing the dosage of collector from 9 g/t to 27 g/t, the effect was more significant in the case of pyrite. This differential effect of collector dosage created the opportunity to selectively recover copper in a multi-stage process using 9 kg/t collector in stage one and an additional 27 kg/t collector in subsequent stages. This approach resulted in three tailings fractions: a low volume value-rich fraction containing 58 % of the copper; a low volume sulfide-rich fraction containing > 85 % of the sulfur; and a large volume sulfide-lean fraction containing ~ 90 % of the total mass and < 6% of the total sulfur (Figure 2 and Table 2).

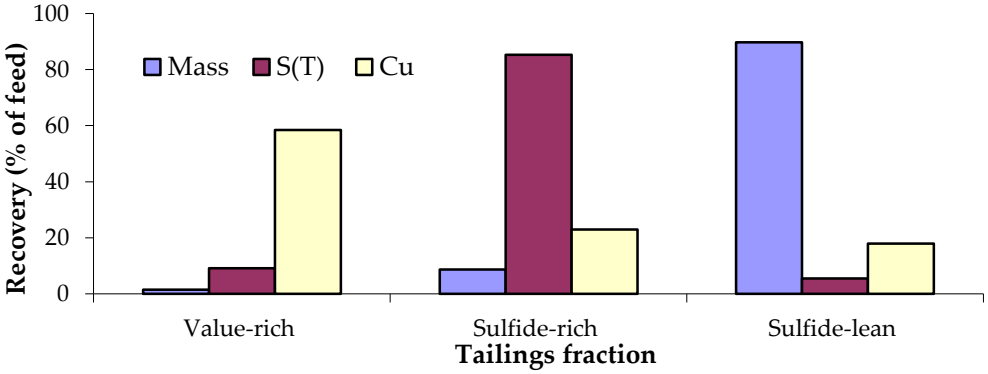

Figure 2 Recovery to tailings fractions in the multi-stage desulfurization of porphyry copper

Table 2 Flotation test results for the multi-stage desulfurization of porphyry copper

Stream	Content (mass %)		NAPP	ARD classification[1]
	Total sulfur	Copper	(kg/t H_2SO_4)	
Feed	3.8	0.16	97.4	Acid forming
Value-rich fraction	2.1	5.7	n/d	n/d
Sulfide-rich fraction	33.7	0.39	n/d	n/d
Sulfide-lean fraction	0.21	0.03	-19.2	Acid neutralizing

[1]In accordance with standard static and biokinetic test results (Hesketh *et al.*, 2010b)
Where: NAPP is net acid producing potential determined by the standard Acid Base Accounting (ABA) method, and n/d is not determined

Laboratory scale ARD prediction tests, using both acid base accounting (ABA) and net acid generating (NAG) protocols, indicated that the sulfide-lean tailings fraction, with a sulfur content of 0.2 %, can be classified as non-acid forming (Hesketh *et al.*, 2010a). Subsequent biokinetic tests confirmed that this sample was net-acid neutralizing, even under conditions of microbial activity (Hesketh *et al.*, 2010b).

Laboratory-scale flotation tests: coal waste case studies

Experimental results for the two-stage flotation process are presented in Table 3 and Figure 3.

[1]After Kazadi Mbamba *et al.* (2012) [2]In accordance with standard static and biokinetic test results

Where: NAPP is net acid producing potential, PAF is potentially acid forming, AF is acid forming, UC is uncertain, NAF is non-acid forming, n/d is not determined.

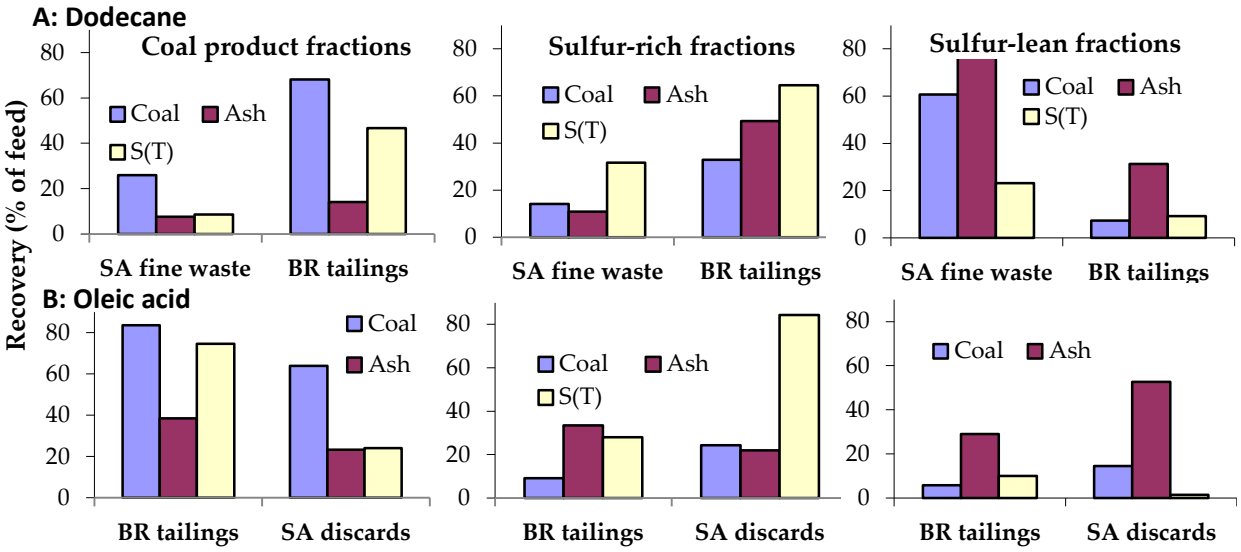

Figure 3 Deportment of key coal components to the flotation output streams, using dodecane (A) and oleic acid (B) as coal collectors (stage 1), and PAX as a sulfide collector (stage 2)

The results indicate that the relative deportment of key components (coal, ash and sulfur) to the flotation output streams varies quite significantly for different coal wastes. This variability can probably be attributed largely to differences in the mineralogical, petrographic and surface characteristics of the coal wastes (Kazadi Mbamba *et al*., 2012). The type of collector also appears to have a significant effect on coal yields in stage 1, with oleic acid resulting in higher recoveries of coal from the Brazilian coal tailings than dodecane. A similar trend has been observed for other coal wastes, and has been attributed to the stronger interaction between the hydrophobic component of the coal surface and the carbon-oxygen double bond of the oleic acid molecule (Kazadi Mbamba *et al*., 2013). Performance variability notwithstanding, in all case studies the two-stage flotation process resulted in a coal product with reduced ash and sulfur contents, and a final tailings fraction with reduced sulfide content and negligible ARD risk potentials.

Economic assessment: coal case study

The results of the order-of-magnitude economic assessment, for the specific coal waste case study described in the methodology section, are summarized in Table 4.

Table 4 Economic assessment results: fine coal waste case study

Item	Unit	Amount	Comment
Capital costs	R 000 000	198	Installed capital costs based on a combination of supplier estimates for major equipment and Lang factors
Operating costs	R 000 000 per annum	161	Based on a combination of flow sheet data and "rule-of-thumb" estimates from the industry and a contingency of 20%
Revenue	R 000 000 per annum	201	Based on a sales price of ZAR349/t
Project NPV	R 000 000	50	Calculated at a discount rate of 14% and based on earnings
Internal rate of return	%	19	before interest, taxes, depreciation and amortization

Although the financial model is based on one case study only, the results in Table 4 are indicative of the potential economic viability of the two-stage flotation process for the recovery of coal and removal of sulfur from coal wastes. Reagent costs were relatively high, contributing 54 % to total operating costs (Jera, 2013). The net present value (NPV) was found to be particularly sensitive to coal sales price, coal yield and reagents costs (Jera, 2013).

Life cycle assessment: base metal case study

The life cycle inventory (LCI) results for the conventional and desulfurization flotation treatment scenarios are compared in Figures 4A and B.

The desulfurization flotation process scenario consumes more carbon than the conventional tailings treatment scenario (base case), and results in higher emissions of carbon dioxide and sulfur dioxide, due largely to the higher consumption of fossil-fuel based electricity in the flotation circuit (Broadhurst *et al*., 2014). However it also results in a decrease in aqueous emissions, whilst simultaneously enhancing the potential to recover water and metal values from the tailings.

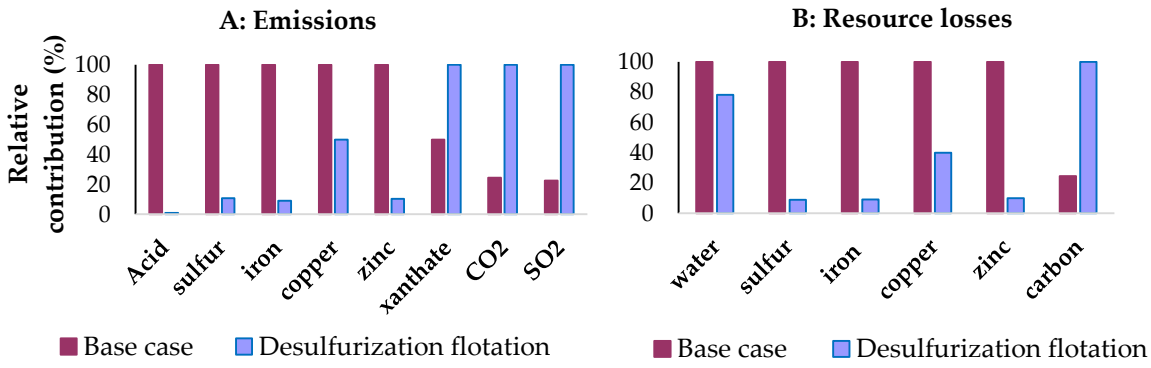

Figure 4 Relative environmental emissions (A) and resource losses (B) for the two tailings treatment scenarios (Broadhurst *et al*., 2014)

The results of the subsequent life cycle impact assessment (LCIA) modelling (Figure 5) indicate that the desulfurization flotation scenario results in higher climate change, fossil fuel depletion and terrestrial acidification impacts than the conventional treatment scenario, which can once again be attributed largely to the higher consumption of fossil-fuel based electricity in the flotation circuit (Broadhurst *et al*., 2014). Desulfurization flotation also results in a considerable reduction (more than 80 %) in both eco-toxicity and human toxicity impacts, due largely to a decrease in the amount of zinc that deports to the tailings and is thus available for subsequent release into the environment (Broadhurst *et al*., 2014). Incorporation of a desulfurization flotation unit into the conventional (base case) tailings treatment circuit also results in lower urban land occupation and natural land transformation impacts than the base case scenario, due to the smaller volumes of land-disposed tailings.

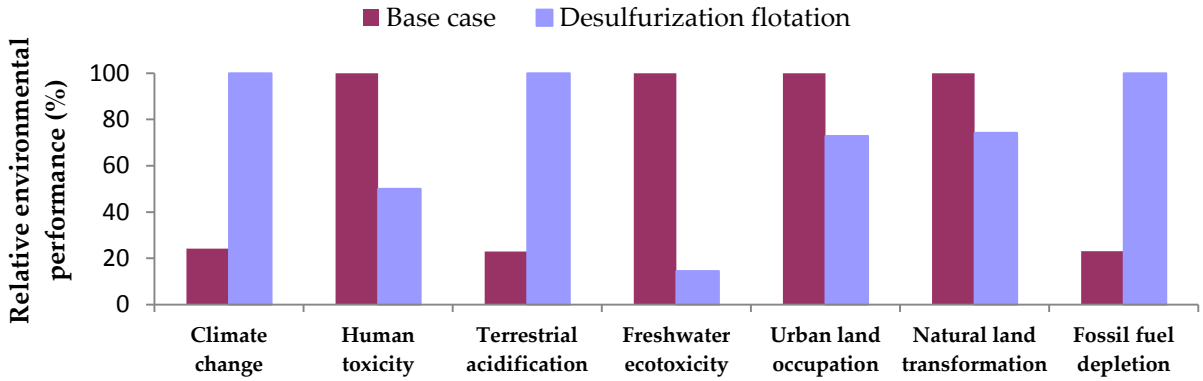

Figure 5 Relative environmental performance for the two tailings treatment scenarios

The study also highlighted the deficiencies of current LCIA tools, in terms of their ability to adequately assess the environmental impacts associated with solid mineral wastes and their management. This pertains, in particular, to aqueous acidification, salinization and trace metal impacts (Broadhurst *et al*., 2014).

CONCLUSION

The technical feasibility of using froth flotation in a two-stage process to both recover valuable material and remove sulfur from mine waste has been demonstrated at a laboratory-scale for the case of porphyry-copper and a range of different coal processing wastes. All case studies resulted in a sulfide-lean tailings stream, which is non-acid generating, thus effectively eliminating long-term ARD risks. Furthermore, a preliminary economic assessment showed the potential viability of the desulfurization flotation treatment process when combined with value recovery. A holistic environmental study using life cycle assessment tools highlighted the environmental benefits of the desulfurization flotation tailings management approach in terms of reduced aqueous emissions and waste burden as well as enhanced resource recovery. However, the flotation process also consumes additional electricity, which results in higher climate change, fossil fuel depletion and acidification impacts in cases where the production of electricity is coal-based.

Studies are in progress to identify and evaluate downstream management options for the sulfide-rich and sulfide-lean phases, with a view to further reducing waste burden and maximizing utilization of mineral resources. Further research and development is also currently underway to optimize the two-stage process in terms of key performance variables, particularly electricity, reagent consumption and waste characteristics, and to extend the techno-economic-environmental studies to a range of sulfidic mine wastes. These studies will form the basis for future publications.

Pre-mining Characterization of Ore Deposits: What Information Do We Need to Increase Sustainability of the Mining Process?

Bernhard Dold
SUMIRCO (Sustainable Mining Research & Consultancy), Chile

ABSTRACT

The efficiency of the metallurgical process can be increased by the incorporation of mineralogical data during the process. Moreover, mineralogy plays a key role in the efficiency of biomining operations and is necessary to predict the formation of acid mine drainage. Decision making in mining operations is currently mainly based on element concentrations (e.g. ore grade, cut-off, acid base accounting) assuming mineral associations of these elements (often with or without sufficient mineralogical data). This can lead to inefficiency of the mining process and environmental problems. Standard prediction methods for acid mine drainage are not accurate enough and there are no methods available, for example, to predict the stability of mine waste under reducing conditions as would apply to submarine tailings disposal (STD), a tailings management strategy that is seeing a revival in the mining industry. To overcome these problems, advanced methodologies have to be applied to characterize new ore deposits before exploitation starts. This approach gives the opportunity to design optimized processes for efficient metal recovery of the different mineral assemblages in an ore deposit and at the same time to minimize the future environmental impact and costs for mine waste management. Additionally, the whole economic potential is evaluated including strategic elements such as rare earth elements (REE). The methodology should integrate high-resolution geochemistry by sequential extractions and quantitative mineralogy in combination with optimized kinetic testing (oxidizing or reducing conditions, depending on the final waste deposition environment). The resulting data set allows the identification of units with similar geochemical behaviors in the ore deposit and to predict the behavior of each economically or environmentally relevant element throughout the mining process and in the final deposition site.

Keywords: process efficiency, acid mine drainage, prediction, geometallurgy, biogeometallurgy

INTRODUCTION

Metal mining is the base industry for the technological development of human society. However, metal mining has not always been very efficient in processing and has had many environmental problems associated. Therefore, it is necessary to predict and improve the efficiency of the mining process from the beginning of an operation through to the final closure plan including waste management and environmental protection (Dold and Weibel, 2013). Together with a social license to mine, these are the basic goals needed to achieve a more sustainable mining process (Dold, 2008; Dold and Weibel, 2013). Most of the problems concerning efficiency of the mineral processing is based on the use of incorrect parameters for decision making during mine operation, and also for the prediction of environmental problems such as acid mine drainage (AMD). This work highlights the problems associated to today's mining process and suggests a methodology to predict the geochemical behavior along the flow-path of the mineral during the mining process (Figure 1).

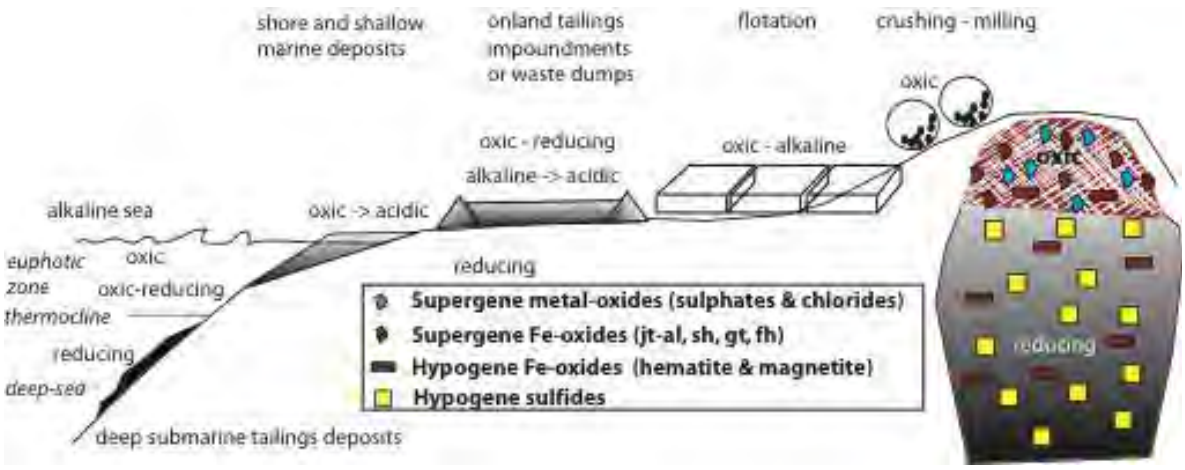

Figure 1 Overview of the flow path of the form the ore deposit with its different mineral associations through the mineral processing and the final mine waste deposition and the geochemical regimes in the different compartments of the process.

Currently, decision making is mostly based on element concentrations (e.g., cut-off grade, and acid-base account), but the metallurgical processes depend on the interactions between mineral surfaces and reagents, for example the flotation process and biomining operations (Dold, 2014b). For example, chalcopyrite is not acid leachable and it also is not efficiently oxidized by bacteria below 50°C, so that in most large scale bioleaching operations (dump leaching), chalcopyrite is not efficiently oxidized. However, this mineral responds well to flotation. In contrast, the presence of covellite and chalcocite in the mineral assemblage lowers the recovery of copper in the flotation, but these minerals are easily acid leachable (Dold, 2014b). Therefore it is crucial to know which minerals are sent to which processes in order to ensure the highest possible recovery rates. This goal is only possible if the mineralogical information is available.

The same is also true for acid mine drainage prediction, where currently very simple and mostly unsuitable tests are used to predict if a material will produce acid drainage and release certain elements into solution. Here, element concentrations such as from sulfur are also calculated as pyrite equivalent for the acid potential and a titration is used to calculate the neutralization potential. However, there are many other sulfide minerals that produce less acidity than pyrite and some even produce no acidity. On the other hand there are carbonates, such as siderite, that may even produce acidity due to hydrolysis of the iron ion. Iron hydroxides, such as ferrihydrite and goethite, and hydroxysulfates, such as jarosite and schwertmannite can acidify the system due to their dissolution chemistry (Alarcon et al., 2014). Thus, mineralogy is similarly key for the correct prediction of acid mine drainage (Dold, 2010).

Therefore, an advanced mineralogical and geochemical approach is suggested in order to predict accurately the behavior of the mineral assemblage throughout the mining process towards final deposition of the waste material.

METHODOLOGY

In order to predict accurately the geometallurgical, metallurgical, bioleaching, and environmental behavior, quantitative mineralogy is needed. This information allows for the possibility of predicting the behavior of the material in the communition process (e.g. crushing, milling and flotation); during hydrometallurgy in the bioleaching process, or for the accurate prediction of acid mine drainage formation (acid-base accounting). Today advanced technologies are available for automated mineralogical analysis such as QEMSCAN® or MLA. If thoroughly calibrated with the ore mineralogy, these techniques give an accurate quantification of the complete mineral assemblage, degree of liberation, as well as grain size distributions, all of which are important ito increase the efficiency of the extraction process. For example in case of the Andina Mine (CODELCO), the utilization of this information could increase the recovery by 2 % (Cruz et al., 2012).

However, this methodology does not give information on trace element associations to specific minerals or mineral groups. This information is crucial to predict if a certain contaminant may be liberated from its host mineral, or to develop a methodology for recovery of economically valuable trace elements such as rare earth elements (REE). Therefore, the mineralogical data are combined with high-resolution geochemical data from a seven-step sequential extraction procedure developed for the primary and secondary mineralogy present in typical porphyry copper deposits (Dold, 2003). These seven steps are as follows: step 1 liberates the water-soluble fraction (1.0 g sample into 50 mL deionized H_2O shake for 1 h at room temperature (RT)), step 2 liberates the exchangeable fraction (1 M NH_4-acetate, pH 4.5, shaken for 2 h, RT), step 3 addresses the Fe(III) oxyhydroxides fraction (0.2 M NH_4-oxalate, pH 3.0, shaken for 1 h in darkness, RT), step 4 dissolves the Fe(III) oxides fraction (0.2 M NH_4-oxalate, pH 3.0, heat in water bath 80 °C for 2 h), step 5 (35 % H_2O_2 heat in water bath for 1 h) dissolves organic matter and supergene Cu sulfides and partly primary sulfides, step 6 ($KClO_3$ and HCl, followed by 4 M HNO_3 boiling) dissolves more resistant primary sulfides, and step 7 (HCl, HF, $HClO_4$, HNO_3) dissolves the residual fraction (silicates). The leach solutions are then analyzed by inductively coupled plasma–atomic emission spectroscopy. In addition to the typical elements measured in the leachates, REE are analyzed in the different steps by inductively coupled plasma–mass spectroscopy (ICP-MS), in order to identify additional extractable byproduct commodities in the ore deposit and its mineralogical associations. The

sequential extraction data can additionally be used to perform a high-resolution acid-base account (ABA) (Dold 2010) and should be correlated with the mineralogical data for quality control, and in order to predict AMD formation and element liberation of any mined material. It is important to note that this extraction sequence must be adapted to the solubility of the specific minerals (primary and secondary) present in an ore deposit, as this may differ significantly among different ore deposit types.

RESULTS AND DISCUSSION

Exploitation efficiency

As described above, we extract minerals in the mining process, not elements, but the elements are associated with minerals. Therefore, we have to consider the mineralogy in order to develop efficient exploitation methods, to predict the stability of certain minerals during the extraction process, and in a long-term, for environmental protection.

Each mineral has a specific set of conditions where it remains stable. If we expose this mineral to other geochemical conditions, for example during the mining process (Figure 1), it will destabilize, resulting possibly in its oxidation, reduction, and/or dissolution. In these processes, associated trace elements from the mineral may be liberated and therefore possibly contaminate the process solution or the environment. Thus, if we know the exact mineralogy and the trace elements associated with those minerals prior to mining, we will be able to predict how these mineral will behave along the production flow-path, and we can even model this behavior with geochemical codes.

The evaluation process begins with the exploitation technique of the ore deposit. For example, it makes a difference if we exploit an open pit in the Atacama desert (e.g. Chuquicamata or Escondida) or if we exploit a porphyry deposit by block-caving in a more humid climate (e.g., El Teniente in Central Chile). In both cases, sulfide minerals are extracted. In the case of El Teniente, a slight pre-oxidation of the ore is observed (redox potential is slightly oxidizing and pH slightly acidic) due to the fracturing of the ore-body related to block caving and contact with rainwater percolating through the mineralization. These effects are evident in sequential extraction data for example through the association of Mo with secondary Fe(III)hydroxides (Dold and Weibel, 2013). In the crushing and milling process, water and reagents are added, so that the geochemical system then becomes more oxidizing before it is sent to an alkaline flotation process (Eh ~ 200-300 mV; pH ~ 9-11). Due to this geochemical change, secondary Fe(III) hydroxides are destabilized and may undergo reductive dissolution and adsorbed oxyanions such as molybdate or arsenate may be desorbed and enter into solution as a contaminant. This process can continue in an active tailings impoundment as the geochemical conditions maintain a reducing setting (Eh ~ 100-200 mV; pH ~ 8-10) at this stage (Smuda et al., 2014; Smuda et al., 2008). If operations then cease, the geochemical system of the tailings will change to oxidizing and acidic conditions may ensue due to sulfide oxidation (Dold, 2014a). Sulfides will be depleted in the oxidation zone and the iron will form secondary Fe(III)hydroxides, which serve as sorbents for oxyanions such as arsenate, molybdate, and sulfate at low pH condition (Dold and Fontboté, 2001). If we would now change again the geochemical system to reducing conditions by re-deposition of fresh tailings as in the case of Talabre/Chuquicamata (Smuda et al., 2014) or by an implementation of a cover system or flooding (Jenk et al., 2009), then the sorbent (Fe(III)hydroxides) will be destabilized and undergo reductive dissolution, liberating the adsorbed oxyanions into solution, possibly producing secondary

contamination (Jenk et al., 2009). A similar effect is observed when tailings containing Fe-oxides are deposited in the deep sea (Eh ~ -200 - +100 mV, pH 8) through submarine tailings disposal (Dold, 2014c). Thus, if we have exact knowledge before exploitation regarding which mineral contains which trace elements, we can predict their stability in the different geochemical systems during the exploitation process and thus increase exploitation efficiency and assess final and secure waste disposal scenarios.

Biomining

The relationship between ore and waste mineralogy and their fate has also been observed in the so called biomining operations, where in many giant mining operations, valuable metals can be recovered from the material that has an ore grade below cut-off but above the waste definition line (in case of porphyry copper systems usually between 0.1-0.2 and 0.3-0.6 wt.% Cu (Dold, 2014b)). The material of this grade is normally from the primary ore zone (without supergene enrichment with minerals such as covellite and chalcocite) and contains principally chalcopyrite as ore mineral. Chalcopyrite is not acid leachable and cannot be oxidized efficiently by the microbial community present at temperatures below 50°C. Thus the bioleaching process is very inefficient (10 - 20 % recovery). Recoveries can reach 40 % only if significant amounts of supergene Cu-sulfides are present, as in case of Escondida. However, this result is not due to efficient bioleaching, but to acid leaching of the supergene mineral assemblage. Thus, a thorough mineralogical characterization is also necessary in order to increase the efficiency of biomining. Here, the assessment of the presence of toxic trace elements in the ore minerals for the microbial community is also needed to predict efficiency of the bioleaching operation. These data can be obtained from sequential extractions.

Acid mine drainage (AMD) prediction and environmental assessment

As discussed above, standard AMD prediction, includes an acid-base accounting calculation based on sulfur concentrations, calculated as pyrite equivalent and neutralization potential, calculated based on a titration of the carbonate neutralization potential. All these calculations have many drawbacks and fundamental sources of error in the calculation (Dold, 2010). Therefore, if we rely on quantitative mineralogical data (such as optical microscopy, QEMSCAN or MLA), a more precise ABA can be estimated (Figure 2). A high resolution ABA can be performed even with sequential extraction data. If both methods are available, a thorough quality control is possible.

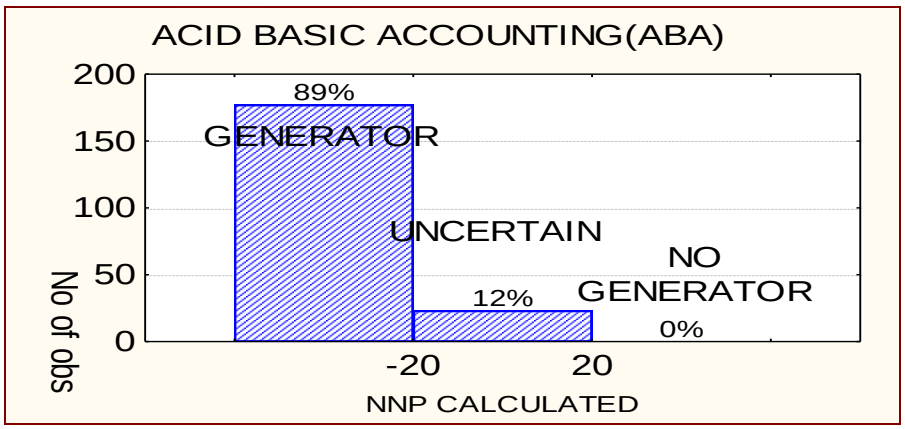

Figure 2 Example of the distribution of acid-base accounting data of a typical porphyry copper deposit calculated based on quantitative mineralogy, showing that 89 % of the samples are AMD generating and 12% range in uncertainty.

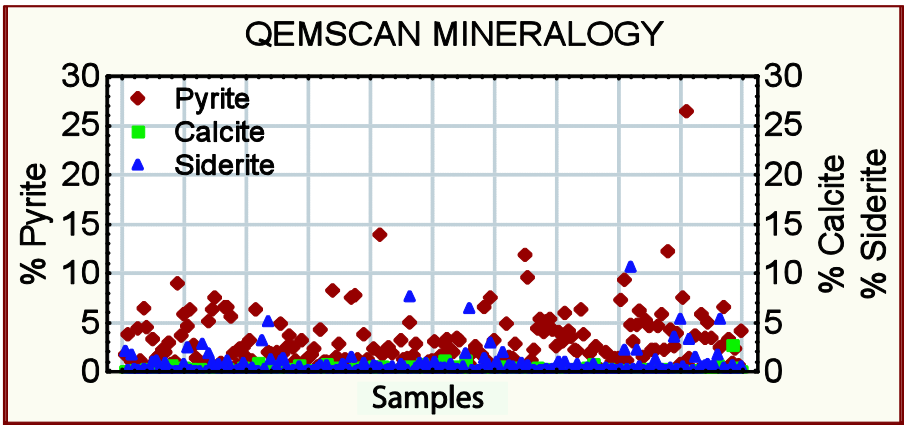

Figure 3 Quantitative mineralogy (QEMSCAN®) data for pyrite, calcite, and siderite of a typical porphyry copper deposit, showing the carbonate neutralization potential is mainly associated to siderite and not to calcite, so that standard ABA calculation would attribute higher neutralization potential, as the acid potential from the liberated iron from siderite (mobility of ferrous iron under reducing conditions or hydrolysis of ferric iron) is ignored.

For example, if unoxidized material from a porphyry copper deposit has 1.5 % pyrite (which has 1 % associated arsenic), 7 % siderite and 3 % anhydrite (Figure 3). A simple ABA would suggest that this material will not produce AMD. However, with the information given above based on quantitative mineralogy and sequential extractions, it can be predicted that this material in the active tailings impoundment will produce concentrations of approximately 1500 mg/L of SO_4 in solution due to equilibrium with gypsum (hydrated from anhydrite). Once operation has ceased, AMD will be produced, as siderite is not able to neutralize all the acidity produced by the pyrite oxidation. Siderite can be even a net acidity producer depending on the circumstances (Dold, 2010). Additionally, the AMD will carry significant amounts of arsenic.

CONCLUSION

The examples described above show that only if we rely on an accurate quantitative mineralogical characterization and chemical data on the trace elements with these minerals, can an accurate prediction of the behavior of the material in the different geochemical conditions during the extraction process, and during final deposition of the waste material be made. This approach is crucial to increase the efficiency of the extraction process, and to ensure environmentally sound waste management.

ABSTRACT

After a long time of dumping, tailings are characterized by hydrogeochemical reorganization processes that are reflected in weathering zones (mobilization) and accumulation zones (immobilization). These processes are connected to substantial secondary mineral formation. Accumulation zones are thereby often connected to iron phases and also have an increased content of trace elements. This knowledge is relevant for Chilean mining dumps because some of them are already affected by these long time processes.

Chilean mining companies are interested in information on the occurrence and extractability of secondary minerals and strategic elements (minor and trace elements of economic interest) from tailings. The German-Chilean project SecMinStratEl (Secondary Mining of Strategic Elements) aims to provide an understanding of the accumulation processes and will also evaluate opportunities for selective extraction. The project is actively supported by significant Chilean mining companies and universities.

Tailings considered in the study consist of granular material, which was ground during primary mining. Due to its potential content of elements of economic importance, the material is nowadays becoming an interesting resource for secondary mining. Exposed tailings suffer from weathering processes; mine waters, especially dump leachates, are enriched in some metals and trace elements which may also constitute a potential environmental hazard.

By means of specific characterization of accumulation horizons in dumps, a description of metal contents and their mobilization behavior is possible. Differentiation between the elemental contents of different layers is achieved with XRF analyses. Furthermore, a sequential extraction is performed in order to describe the partitioning of elements in mineral phases. Thus, the extractability of major, minor and trace elements can be estimated. With these findings, conclusions about extraction technologies for these elements and the environmental risk potential can be made.

Keywords: tailings, secondary mining, mine water

INTRODUCTION

Chile is the world's largest producer of copper ore. Extensive mining and processing over almost a century has left a large number of old mining legacies, which also have associated environmental issues (dust, acidic water, geotechnical instability). As metal production from processed ores was mostly directed towards copper, the tailings and heaps still contain significant amounts of other metals and minor and trace elements of economic interest. Furthermore, by today's standards old tailings are characterized by high copper contents due to earlier less efficient ore processing technology. The tailings are therefore an interesting target for secondary mining efforts.

The state-funded German-Chilean project "SecMinStratEl" (Secondary Mining of Strategic Elements) investigates minor and trace element content, distribution and extractability in Chilean tailings and the formation of secondary minerals. It aims to better understand reorganization processes due to the mobilization of the elements. Methods for the extraction of trace metals from relevant tailings will be evaluated on a conceptual level. In this context, the Institutes for Mining, Mineralogy and Mineral Processing Machines of TU Bergakademie Freiberg are cooperating with the Chilean universities Universidad de Concepción (UdeC) and Universidad de Atacama (UdA). As the project is still ongoing and deals with many different locations and tailings, only a small part of the whole investigation can be discussed here.

This article deals with one tailing of Chilean copper mining, which contains processed waste material from the copper production. The deposit has been exploited since the early 20th century, when the processing technology was much less efficient compared to today. The tailings consist of the processed material from the original ore body and its accompanying rock. Therefore, elemental contents of the mined deposits are of great interest. The tailing material originated from a porphyry copper-molybdenum deposit, which is characterized by copper sulfide minerals (bornite, digenite, chalcopyrite) and molybdenite. Furthermore, this deposit type is characterized by ore-bearing alteration zones accompanied by magnetite and rutile, as well as ilmenite and titanite (Buschmann 2014). Thus, it can be concluded, that the tailing material may contain concentrations of Au, Ag, Ti, Ga, Sn, W, Nb, In and other trace elements in addition to copper and molybdenum. Krause (2014) identified by means of XRD analysis quartz, micas (muscovite, phlogopite), chlorite, feldspars (andesine, albite, orthoclase), pyrite, and rutile to be typical minerals in the tailing material.

Due to the relatively long time of deposition of the tailings, they are affected by hydrogeochemical reorganization processes that are reflected in weathering zones (mobilization) and accumulation zones (immobilization). Accumulation zones are often related to secondary mineral formation of Fe phases with an increased content of trace elements. The intention of the study is a better understanding of the formation of these enrichment zones due to mobilization and immobilization reactions.

During an on-site sampling at the tailing in Chile, aqueous and solid samples were taken. At the surface of the tailing, the authors found efflorescent mineralization. It indicates a mobilization of metals with a subsequent accumulation at the surface due to the evaporation of pore water. Therefore, seepage waters from the tailings were sampled and analyzed to determine element contents. Solid samples were collected from different layers of the tailing at different sampling points, so that accumulation zones can be distinguished. The formation of different layers could be seen visually, however, for the geochemical description of the layer material, pXRF analyses and grain-size analyses were carried out. Another approach for the characterization of mobility inside

the tailings was sequential extraction on tailing material. Integrating these measurements, conclusions about the distribution of weathering, accumulation and enrichment zones can be made. Furthermore, ideas for the selective recovery and extraction of elements of economic interest can be developed.

METHODOLOGY

General Sample Characterization and Analyses

Solid samples were collected from freshly exposed profiles at a tailing, which was exposed approximately three years earlier. Back in Germany, the samples were homogenized and dewatered. After that, they were divided for different analysis methods, e.g. sequential extraction, X-ray fluorescence analysis and grain-size analysis (derived from German standard procedure DIN 66165 with 50 g of sample).

Water samples were taken from water outflows at the base of a tailing dam. On-site, environmental parameters (pH, pE, electrical conductivity) of the waters were measured. Water samples were bottled and acidified for the analyses of element concentrations in an external laboratory (ICP-MS, Actlabs Canada).

X-Ray Fluorescence Analyses

The X-ray fluorescence (XRF) spectrometer is an instrument used for non-destructive detection of major elements and selected trace elements during the investigation of rocks, ores and soils. A portable X-ray fluorescence (pXRF) analyzer allows operating on-site for immediate analysis. Field measurements, which were carried out by means of pXRF at exposed profiles, provide an overview about the elemental distribution (of major elements) in different horizons and help characterize tailing.

For this study, a pXRF Niton XL3t980 analyzer (equipped with an Ag-Anode 50 kV X-ray tube and Silicon-Drift-Detector 8 mm spot) was used. Raw data were visualized in spectra, where x-axes represent element-specific fluorescence energies (unit keV), and y-axes quantify counts of photons (unit cps) received by the detector. Analysis is possible for most of the elements with atomic numbers ranging from 12 (magnesium) to 92 (uranium), thus, for various trace metals a semi quantitative determination is possible. Results are comparable to wet-chemical analysis, though, pXRF has higher detection limits.

It should be noted that several factors have an effect on the measurement and the data output provided by the device: surface conditions (roughness), moisture content, matrix effects and calibration for the respective solid matrices (calibration used for quantification must be appropriate to the material of the sample analyzed). For major und trace elements device-specific, standard-based correction factors for normalized, homogenized and dried samples were developed, which were determined by measuring certified reference materials (publication prepared for CANAS 2015, Grimmer et al. (2015)). Values used in this article are corrected using these factors.

Sequential Extraction

Sequential extraction is an enhanced type of leaching of granular material, which distinguishes different bonding types of elements. The same material is treated with progressively stronger leaching solutions in order to determine extractable metal concentrations of each step. Seven pH-dependent extraction steps with water, followed by saline, complexing, reducing and oxidating reactants were carried out. By that, a correlation between extracted element contents and sequentially dissolved minerals, and therefore bonding types, is possible. An evaluation of the selective extraction method provides information about the extractability and thus mobility of different major and trace elements. The project partner GFI Dresden (Kassahun, Hache) developed a sequential extraction method, which is a variation from the method of Zeien (1995) and comparable to Dold & Fontboté (2001). In each step, eluates are analyzed for pH value, redox potential, electrical conductivity, TIC, Fe(II) and elemental concentrations (ICP-MS analysis). The steps of the sequential extraction used in this project are shown in Table 1.

Table 1 Overview of extraction steps of the altered sequential extraction method (modified from Zeien (1995) and Graupner et al. (2007))

Step	Extracted phase	Leaching solution	Conditions
It	Water soluble	Ultrapure water	
II	Exchangeable	Ammonium nitrate	pH 7
IIIa	Carbonates and specific bonds	Ammonium acetate	pH 6
IIIb	Reducible	Ammonium acetate Hydroxylamine hydrochloride	pH 6
IV	Organically bound (Oxidizable)	EDTA	pH 4.6
Va	Amorphous and poorly crystallized iron and aluminium hydroxides	Ammonium Oxalate Oxalic acid	pH 3.25
Vb	Crystalline iron and aluminium hydroxides	Ammonium Oxalate Oxalic acid Ascorbic acid	pH 3.25

RESULTS AND DISCUSSION

X-Ray Fluorescence Analyses – Field measurements

Eleven profiles (spatially relatively close to each other) were registered on the tailing. An exemplary result is the distribution of the copper concentration with depth in Profile 4 (left diagram of Figure 1). In this regard, the direct field measurement (blue) is compared to the measurement of samples in the laboratory (orange). Visually and granulometrically distinguishable horizons are labeled A to G. The result of the sieve analysis, i.e. the grain-size characterization, is shown in between the two diagrams of Figure 1. The abbreviation FSa stands for fine sand, MSa for medium sand, si for silty (si2 means < 15 wt% of silt, si4 > 30 wt% of silt). Enrichment zones of copper in the lower horizon areas are clearly revealed. Horizon E, which consists of medium grained silt, shows characteristics of an enrichment horizon based on these results. However, sequential extraction results are needed to verify this conclusion – as this can also be a production/process-related phenomenon. In general, copper contents of the profiles range from 0.15 to 0.3 %, but locally reach 0.5 % and more.

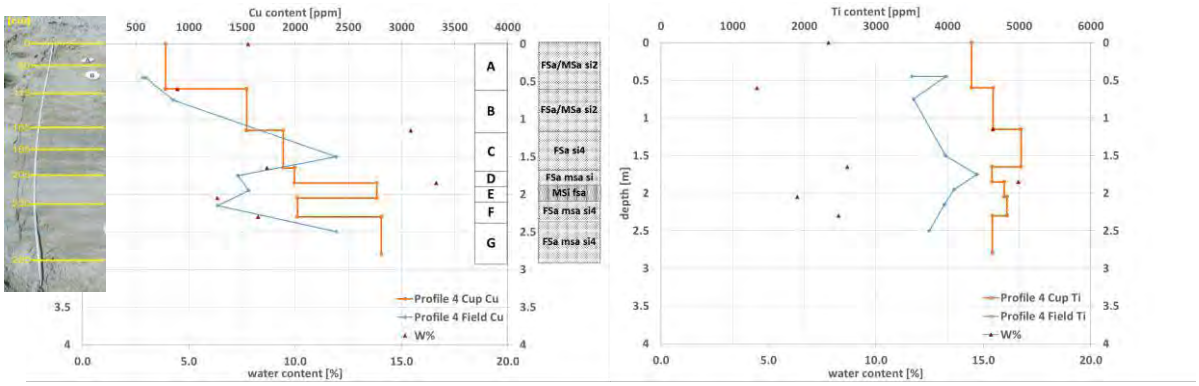

Figure 1 Copper and titanium distributions as function of the depth measured by means of pXRF; photo of profile at sampling site (left); grain size characterization of horizons (center)

These distribution diagrams were created for all profiles and major elements. In the right diagram of Figure 1, the distribution of titanium is shown. Titanium contents range within an order of magnitude of 0.5 %. This element shows less variation between the horizons than copper.

Unfortunately, results for rare earth elements analyses using complete chemical digestion are still pending at the beginning of 2015. Furthermore, deep boreholes (up to 60 m depth) were made into the tailing. They were characterized (e.g. color, granular structure) and sampled and provide an overview of the entire tailing body. From these, comparisons of oxidized and reduced deep zones and estimated element contents of the tailing can be conducted. These investigations are planned for 2015.

Grain-size analyses coupled with pXRF measurements

After sieve analyses, samples of the different fractions remain. These fractions were measured separately with the pXRF analyzer resulting in a distribution of elements depending on the fraction. For the lower horizons D to G of profile 4 the copper distribution is shown representatively in Figure 2.

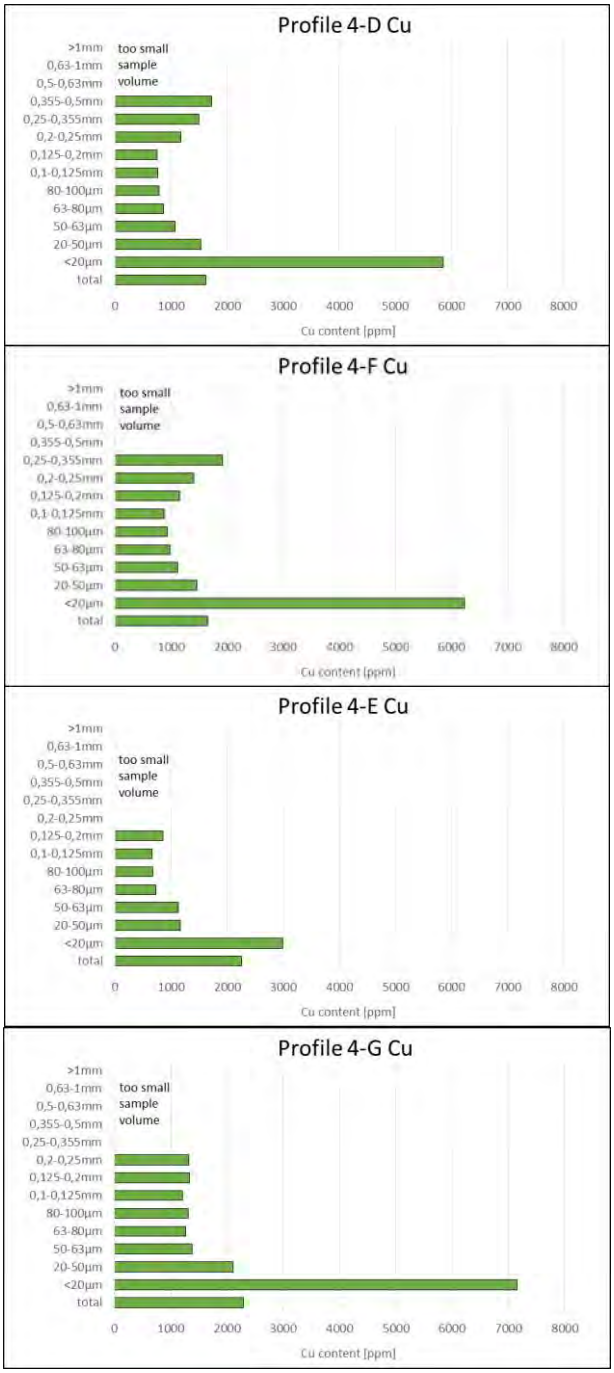

Figure 2 Grain-size dependence of copper content [ppm] measured by means of pXRF

It should be noted that the copper content in ppm refers to the respective particle size fraction whereas the masses of the fractions are not in the focus of this article. The knowledge of the fraction mass is used to estimate the fraction dependent copper contents or other elemental concentrations. In Figure 2 a higher copper content in the fractions 0.2 to 0.5 mm was identified. The highest concentrations are observed at grain sizes smaller than 50 μm.

In addition to copper, grain size dependencies were also examined for the following elements: Al, Ca, K, S, Si, Zn, V, Fe, Ti, As, Mo, and Mn. The results vary depending on the respective horizons, and show random enrichments of these elements in other fractions than <50 μm. Ongoing investigations will further elucidate these relationships.

Sequential Extraction

Evaluations of eluate analyses show varying characteristics of the extraction behavior of major and trace elements. A differentiation between a high and a low percentage of extracted element content has to be made. A low percentage means that after step Vb the bigger part of the element content still is bound to the remaining solid (especially sulfides, silicates). The pXRF measurements provide an estimation of the total element content in the original tailing material for the comparison with the extracted content. Another differentiation can be made between easily soluble/extractable elements, which are detected in the eluates from steps I, II and III and more strongly bound elements from the steps IV, Va and Vb.

Copper

Copper was the objective of primary mining processes. However, due to the evolution in ore processing technologies, the remaining copper content in the older tailings is nowadays of interest for secondary mining.

Figure 3a shows the results of the sequential extraction for copper. In comparison to total copper contents determined by XRF, copper is completely extracted by the leaching steps. Furthermore, except of layer A, which has experienced weathering processes, more than 75 % of copper is extracted from the tailing material within the leaching steps I, II, IIIa or IIIb. These results show the great mobility of copper in the sampled tailing.

(a)

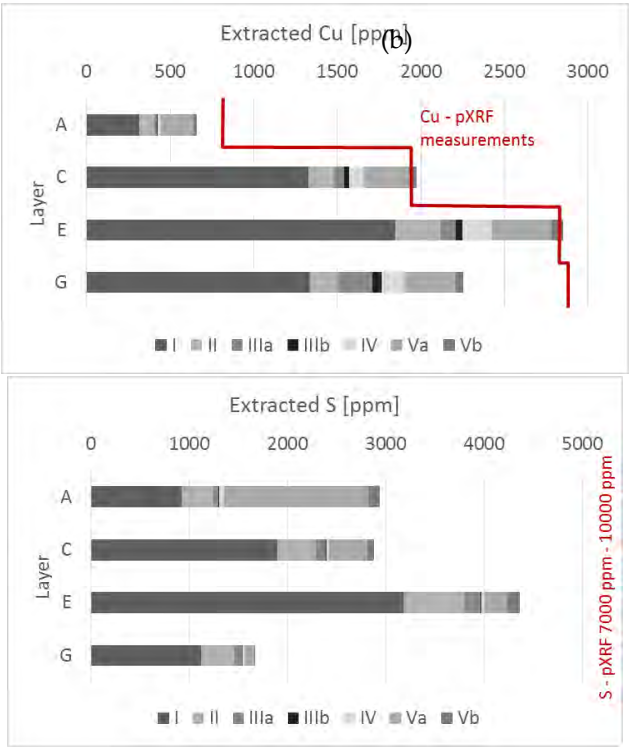

Figure 3 Extractable copper (a) and sulfur (b) during sequential extraction

More than half of the available copper can be recovered by a simple water extraction (step I). Solubility and thus removal of copper was also detectable as a loss of mass during wet sieving analyses. Copper complexes such as copper sulfate are very soluble and highly mobile. Thus, relocation to the depth (with seepage water) or due to evaporation and capillary action to the surface can lead to efflorescences. In this context, the formation of chalcanthite was observed in coarse tailing material with low moisture contents.

The remaining copper content is almost completely recoverable by means of ammonium oxalate as the extracting solution, i.e. during sequential extraction step Va (Table 1). This extractant dissolves amorphous and poorly crystallized iron and aluminum oxides.

Sulfur

Based on the assumption, that sulfur occurs mostly as (copper) sulfate inside the tailing, the sequential extraction of sulfur was examined. Figure 3b presents these results and furthermore shows the total sulfur amounts determined by pXRF (7000 – 10000 ppm). In contrast to copper, sulfur has not been extracted completely within the sequential leaching, as can be seen in comparison to the pXRF value. Extracted phases of sulfur are sulfates (step I), but also sulfur adhered to iron hydroxides (steps Va and Vb).

Arsenic

The behavior of arsenic shows the importance of considering the mobility of some elements. Arsenic levels up to 100 ppm are detected in tailing samples by pXRF. According to the findings from the sequential extraction, arsenic is barely dissolved until step Va (ammonium oxalate). This

means arsenic is difficult to mobilize, which is also confirmed by the analysis of tailing water outlets.

Other elements

In case of strategic elements, such as yttrium, cerium and vanadium, mobilization starts with extraction step IV (organically bound, oxidizable), which means they can be mobilized by EDTA. Molybdenum is partly dissolved during extraction steps IIIa, IIIb and IV, i.e. it is soluble with an acetic buffer. Therefore, these elements are more difficult to extract from the tailing compared to copper and they are less mobile.

Water Samples

Water samples were analyzed with ICP-MS in order to characterize mobile fractions, which were dissolved inside the tailing and transported with the seepage water. Due to dissolution processes within the tailing, specific elements are mobilized. It is assumed, that outflowing tailing waters mainly contain easily extractable elements. One example for that is arsenic, which is difficult to extract and in fact was not to be found in outflowing tailing waters.

Table 2 lists measured ranges of element concentrations of copper and selected light and heavy rare earth elements: cerium, dysprosium, gadolinium, lanthanum, neodymium, samarium and yttrium. Maximum copper concentrations of 888 mg/l are an indication for significant solubility and high mobility. In the second row, maximum concentrations measured in a pond at the base of the tailing are included. These values show the high potential capacity for element mobility within the tailing. Evaporation as a cause of enrichment has to be taken into account, as samples were taken during the summer. Nevertheless, the pond water accumulations show also a significant amount of rare earth elements, which originate from the tailing material.

Table 2 Overview of ICP-MS analysis results for copper and selected rare earth elements (contents in μg/l)

element	Cu	Ce	Dy	Gd	La	Nd	Sm	Y
Outflow waters - range	100000 - 350000	20 - 50	11 - 19	8 - 17	6 - 20	19 - 62	7 - 17	70 - 118
pond water	888000	275	75	53	90	183	48	510

CONCLUSION

During the first part of the investigation, eleven profiles at a tailing of a Chilean copper mine are characterized. Investigated tailing shows a formation of horizons, which are due to a variety of processes. The geochemical composition (e.g. copper content) of the horizons is initially influenced by the original ore body and by primary recovery processes or attributes such as coarseness, flotation fluids and their chemical properties, hydraulic dumping of the processed waste material, and exposure time among others. Apart from that, hydrogeochemical reorganization processes cause mobilization and immobilization of elements and also the formation of distinct horizons. It is possible to get a general idea of the horizontal zonation of the tailing and the approximate

elemental contents of the respective horizons by means of pXRF measurements. However, the tailing composition is not yet fully understood, especially in terms of mineralogy.

Understanding of hydrologic processes and especially the generation and location of accumulation zones inside the tailing is important. For instance, Dold & Fontboté (2001) described cases, "where evaporation exceeds precipitation, the water-flow direction may change to upwards migration via capillary forces. […] Supersaturation controls the precipitation of mainly water-soluble secondary sulfates (e.g. bonattite, chalcanthite) and leads to partly strong enrichment at the top of the tailings". Distributions of the fine granular materials are important, e.g. copper shows enrichments in the fine material (< 50 μm). Based on the sequential extraction results the following recommendations for secondary copper production from tailing sites can made: in the case of hydraulic mining, water is not only a transport medium, but also an extracting agent and should be completely collected, as already done with seepage waters of several copper tailings in Chile. Otherwise the majority of the copper content will be lost.

Future investigations will deal with the development of simplified extracting methods for leaching as a secondary mining solution. Furthermore, immobilization horizons will be characterized mineralogically in order to provide a basis for selective mining. For that, more detailed examination of the potential of minor and trace elements in the tailing samples will be conducted.

Tracking the Fate of Metals in Mining Waste Rock Using Metal Stable Isotopes

ABSTRACT

The characterization of metal release and attenuation in mining waste rock drainage has traditionally relied upon an array of mineralogical and geochemical techniques. Recent advances in analytical instrumentation now allow robust measurements of minute variations in the isotopic composition of metals in environmental samples, which have become a powerful new tracer of their fate. Here we provide an overview of the application of these "non-traditional" stable isotopes to characterize metal release and attenuation in mining waste rock. First, we briefly review the theoretical framework of stable isotope geochemistry and its application to environmental studies. Second, we present results from an isotopic investigation of Mo and Zn at the Antamina mine, Peru. At Antamina, isotopic compositions of Mo and Zn have been determined in waste rock drainage waters and ore-mineral samples as a first step to determine whether isotope analyses can serve as a tool to track the geochemistry of these metals in waste rock dumps. The range in isotopic compositions measured thus far at Antamina spans 1.88‰ for $\delta^{98/95}$Mo and 0.65‰ for $\delta^{66/64}$Zn. This variability confirms that isotopic fractionation is occurring during metal release and/or attenuation reactions and indicates the potential for metal stable isotopes to track the mobility of metals in mining waste rock dumps. Linking this variability to distinct release and attenuation mechanisms (e.g. dissolution, adsorption and secondary mineral precipitation) will require further investigations to characterize the isotopic signatures of these mechanisms.

Keywords: Metal stable isotopes, drainage geochemistry, waste rock

INTRODUCTION

The complex hydrogeological and geochemical nature of waste rock dumps makes a detailed characterization of the fate of metals in this setting particularly challenging to achieve using conventional geochemical methods. An alternative and complimentary tool is stable isotope analysis of metals to track release and attenuation processes which would otherwise be difficult to identify. Subtle but measureable variations in isotopic compositions of metals occur as a result of isotopic fractionation during chemical reactions. By measuring these isotopic variations, metal release and attenuation processes can be unveiled. Over the last sixty years, the stable isotope approach has developed into a mature technique for tracking the fate of elements C, N, H, O and S, often called the "traditional" stable isotopes. Moreover, recent improvements in mass spectrometry permit the analysis of isotopic variations of other elements, including the transition metals, opening the door to their application in environmental studies.

This paper's objective is to introduce the use of metal stable isotope analysis to characterize processes in mining waste rock. Part 1 provides a brief review of isotopic fractionation and its applications and analytical considerations. Part 2 presents early results from a survey of metal stable isotope compositions measured in waste rock drainage, waste rock and ore minerals from the Antamina mine, Peru. These samples were analyzed in order to identify whether variations in isotopic compositions of Mo and Zn are present in Antamina waste rock materials, and consequently whether these can be useful to identify sources and attenuation mechanisms.

THEORY, APPLICATONS AND ANALYTICAL CONSIDERATIONS

Theory

Stable isotopes co-exist for many elements in the periodic table. The isotopes of a given element differ by the number of neutrons they contain, while the number of protons is constant. It is this slight difference in atomic masses and nuclear properties which causes differences in reactivity and result in isotopic fractionation. These isotopic variations are denoted as per mil (‰) deviations in the isotopic ratios of a sample relative to a standard using the delta (δ) notation, where superscripts *i* and *j* denote two isotopes of a given element *X*:

$$\delta^{i/j}X\ (‰) = 1000 \times \left(\frac{\left(\frac{^{i}X}{^{j}X}\right)_{sample}}{\left(\frac{^{i}X}{^{j}X}\right)_{standard}} - 1 \right)$$

Mass-*dependent* isotope fractionation occurs as a result of the differences in the strength of chemical bonds involving light and heavy isotopes for a given element: heavy isotopes form bonds which are thermodynamically stronger than those involving light isotopes, and thus are less reactive. Mass-dependent isotopic fractionation is further broken down into two categories, *equilibrium* isotope fractionation and *kinetic* isotope fractionation, an overview of which can be found in (Weiss et al., 2008). Some elements also display mass-*independent* fractionation (MIF) which can be a useful tracer of environmentally-relevant reactions. While not the focus of this work, MIF has been reviewed elsewhere (e.g. Buchachenko, 2013).

Recent Applications of Metal Stable Isotopes

A growing number of studies have successfully used stable isotope analyses to track sources of metal release and attenuation processes in the environment which are summarized in reviews such as (Weiss et al., 2008; Baskaran, 2012). Efforts to apply stable isotopes to track metals in mining environments have begun, including some noteworthy case studies: (Foucher et al., 2009) used mercury stable isotope analyses to identify the release of Hg from a Slovenian mine to riverine sediments and were able to quantify the contribution of the mine to sedimentary Hg downstream from the release site. Copper and Zn isotopes have been useful in identifying processes controlling metal mobility in acid mine drainage such as dilution, weathering and adsorption (Balistrieri et al., 2008; Kimball et al., 2009; Fernandez and Borrok, 2009; Aranda et al., 2012). Strong isotope fractionation during Cr and U removal from groundwater via reduction reactions makes analyses of their isotopic compositions very useful to identify and quantify attenuation of these elements (Heikoop et al., 2014, Baskaran, 2012, A. Shiel, 2013, pers. comm., Oct 16). Taken together, these studies demonstrate the use of stable isotopes to improve our understanding of metal mobility in a variety of environments including mine sites.

Analytical considerations

The stable isotope analysis of metals from environmental samples is not trivial. Analysis is typically done using either thermal ionization mass spectrometry (TIMS), or multi-collector inductively coupled-plasma mass spectrometry (MC-ICP-MS); the latter is becoming the instrument of choice because of the ICP's more efficient ionization ability. Accurate and precise metal isotope ratio measurements require careful sample handling. High-purity grade reagents are used in sample processing, in a metal-free clean laboratory. Samples must undergo chemical purification prior to analysis in order to extract the analyte element from the rest of the sample matrix. Finally, during mass spectrometry, a rigorous correction scheme is required because the MC-ICP-MS system fractionates isotopes during the measurement by as much as three orders of magnitude more than the fractionation present in natural samples. Fortunately, these analytical challenges have been overcome and stable isotope ratio protocols exist for most metals and metalloids of interest to the mining industry (e.g. Cr, Fe, Ni, Cu, Zn, Mo, Cd, Hg, U, Se, W, Ag). At present, analytical capabilities are mainly available within university and government research laboratories where instrumentation is available and knowledge of analytical protocols exists.

STABLE MO AND ZN ISOTOPIC FRACTIONATION AT THE ANTAMINA MINE, PERU

At the Antamina mine a multi-isotope study is currently under way in which the objective is to determine whether stable isotope analyses can be useful to track sources of metal release and processes of metal attenuation in waste rock dumps. The Antamina mine extracts Cu-Zn-(Ag-Mo) ores from one of the world's largest polymetallic skarn deposits, located high in the Peruvian Andes. The deposit formed in association with a quartz monzonite intrusion into carbonate terrain, producing a heterogeneous array of local lithologies which include skarns, hornfels, marbles and intrusives. Good understanding of Mo and Zn release and attenuation processes in waste rock dumps comprised of these materials is critical in order to predict long-term drainage water quality. However, this is a challenging objective to achieve by conventional geochemical and mineralogical approaches, and is further complicated by the geological heterogeneity of waste rock. Stable isotope

analyses could prove useful to gain insights into the fate of metals in waste rock dumps. As a first step, the variability in Mo and Zn isotopic compositions of drainage waters collected from field barrels and experimental waste rock dumps as well as select ore-grade rock samples must be determined to investigate this possibility.

At Antamina, the hypothesized Mo release mechanism to solution from mining waste rock is oxidative weathering of molybdenite (MoS_2). Upon release to solution as molybdate $(MoO_4^{2})^{-}$, Mo may be attenuated via adsorption onto (oxy)hydroxide minerals and clays or via precipitation as secondary minerals. Adsorption of molybdate onto various inorganic substrates peaks at a pH range of 3-5 (Goldberg et al., 1998), while it is minimal in alkaline and very acidic conditions. However, Conlan et al., (2012) and Hirsche (2012) showed that Mo solubility in neutral to alkaline conditions can be limited by precipitation of secondary minerals, including wulfenite ($PbMoO_4$) and powellite ($CaMoO_4$).

To date, no studies have examined Mo stable isotope compositions in mining waste. However, a growing body of literature is shedding light on the isotopic behavior of Mo. It has been shown that light isotopes of Mo are preferentially scavenged during adsorption onto Fe and Mn (oxy)hydroxides leaving a residual aqueous Mo pool which is isotopically heavier (Barling & Anbar, 2004; Siebert et al., 2006; Wasylenki et al., 2008; Goldberg et al., 2009; Wasylenki et al., 2011). Molybdenum isotopic fractionation during chemical weathering in various conditions show that Mo leached from rocks may have isotopic compositions which are similar to, or heavier than the parent material by up to 1 ‰ (Siebert et al., 2003; Liermann et al., 2011; Voegelin et al., 2012). The isotopic fractionation occurring during secondary mineral precipitation of Mo has not yet been studied.

Zinc in mining waste rock is released from the weathering of sphalerite (Hirsche, 2012; Matthies et al., 2014a). Possible attenuation mechanisms include adsorption onto (oxy)hydroxide minerals and carbonates and precipitation as secondary minerals (e.g. $ZnCO_3$, $Zn(OH)_2$) (Al et al., 2000; Hirsche, 2012). Zn adsorption shows a strong pH dependency, with minimal adsorption occurring in acidic conditions (<pH 5) and greater adsorption occurring for mildly acidic to alkaline pH values (Pokrovsky et al., 2005).

A small, but growing literature has begun investigating zinc isotopic variations in mining wastes (Balistrieri et al., 2008; Fernandez & Borrok, 2009; Aranda et al., 2012; Matthies et al., 2014a; Matthies et al., 2014b). Zinc adsorption onto Mn, Al and Fe oxides exhibits a small isotopic fractionation of <0.2 ‰ (Pokrovsky et al., 2005). Consistent with Mo, oxidative weathering of sphalerite-rich tailings leads to aqueous Zn which is isotopically heavier by ~0.1-0.2 ‰ (Matthies et al., 2014a). Complexation with carbonates yields residual aqueous solutions which are up to 1‰ lighter than the starting solution (Pichat et al., 2003; Fujii et al., 2011).

Methodology for Antamina Isotope Study

Antamina's geochemical investigation program includes a series of ~10m high experimental waste rock piles (each containing 30,000 tonnes of rock) and ~1m high field barrels (each containing 350kg of rock) which were installed in order to characterize drainage water quality for different waste rock types (Fig. 1). Water samples from these field barrels and experimental waste rock piles were collected in order to determine the range in isotopic compositions associated with different waste rock materials at Antamina. In addition, Mo and Zn ore minerals (molybdenite and sphalerite) from

various locations in the open pit were also sampled for isotope analysis because it is the chemical weathering of these minerals which is expected to be the dominant source of Mo and Zn in waste rock drainage waters.

Figure 1 Experimental field barrels, 1m high and containing ~350 kg of waste rock (left); and experimental waste rock dumps, 10m high and containing ~30,000 kg of waste rock (right) at Antamina.

Water samples were filtered in 0.22 μm filters and acidified prior to shipment to the laboratory for analysis. Molybdenites and sphalerites were hand-picked from ore-grade rock samples and dissolved in inverse *aqua regia*. Mo and Zn concentrations were determined using an ICP-MS (Agilent 7700x, Agilent, USA). Sample aliquots were then reconstituted in 7N HCl and processed through an anion-exchange purification scheme modified from Shiel et al. (2013) which isolates Mo and Zn from the sample matrix. In order to correct for instrumental and laboratory mass fractionation, a ^{97}Mo-^{100}Mo double-spike was equilibrated with samples prior to ion-exchange purification (Siebert et al., 2001). Zn instrumental mass fractionation was corrected using a combined standard-sample bracketing and external normalization procedure as in Shiel et al. (2013). Isotopic analyses were conducted using a Nu Plasma MC-ICP-MS (Nu Instruments Ltd., UK) hosted at the Pacific Centre for Isotopic and Geochemical Research (PCIGR), University of British Columbia, Vancouver, Canada. Isotopic compositions in this study were normalized using the NIST-SRM-3134 for Mo and using PCIGR-1 for Zn as delta-zero per mil standards. PCIGR-1 is ~0.11 ± 0.05 ‰ heavier than the commonly used JMC-Lyon Zn isotope standard. All reagents used in the laboratory were prepared using ultra-pure <18.2 MΩ H_2O and commercial environmental-grade acids were sub-boiled in PFA sills to reduce contaminants to trace levels. Laboratory work was carried out in metal-free Class 1000 clean laboratories at PCIGR.

Results and Discussion

Isotopic compositions of Mo and Zn measured in Antamina samples show variations of up to 1.88‰ for $\delta^{98/95}$Mo and 0.65‰ $\delta^{66/64}$Zn. These isotopic ranges are well in excess of the analytical precision of <0.10‰ and <0.12 ‰ for $\delta^{98/95}$Mo and $\delta^{66/64}$Zn, respectively, indicating that significant and resolvable isotopic fractionation is occurring during release and/or attenuation of Mo and Zn at Antamina.

Molybdenum isotopes

Isotopic compositions of molybdenites exhibit a range of 1.09‰ among various ore samples collected in the deposit (Fig. 2) The range in isotopic composition of molybdenites analyzed here bear some relationship with the lithological origin of its host rock: intrusive-hosted molybdenite spans –0.79 to -0.04 ‰ while skarn-hosted molybdenite is isotopically heavier (-0.46 to 0.37 ‰), though there is some overlap. The observed variability in $\delta^{98/95}$Mo in molybdenites at Antamina is consistent with studies of other molybdenite deposits worldwide, and is thought to be caused by a kinetic isotope fractionation associated with Mo reduction from Mo(VI) to Mo(IV) in hydrothermal fluids during molybdenite hydrothermal precipitation (Hannah et al., 2007; Greber et al., 2014).

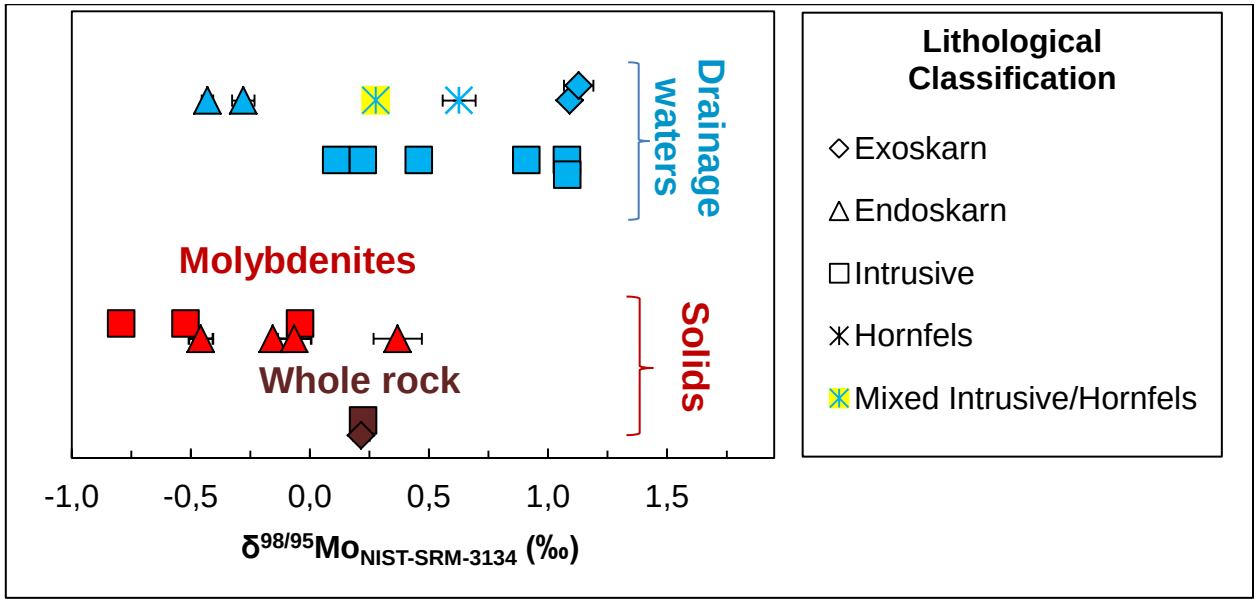

Figure 2 1-D representation of Mo isotopic composition of drainage waters (blue symbols), molybdenites (red symbols) and whole-rock (maroon symbols) by lithology (indicated by symbol shape) in Antamina waste rock material. Data are spread vertically for clarity. Error bars are ±2SD for a triplicate analysis on the MC-ICP-MS.

The range in $\delta^{98/95}$Mo in leachate water samples collected from field barrels and experimental waste rock piles is considerable, spanning 1.56 ‰. Leachate tends to be isotopically heavier than molybdenites, assumed to be the source of Mo. While at this point it is not possible to say specifically what causes this shift, it is possible to formulate hypotheses based on current knowledge of Mo isotope behavior. Heavier $\delta^{98/95}$Mo in drainage waters are consistent with previous studies, which have attributed this phenomenon to isotopic fractionation during oxidative weathering and adsorption onto (oxy)hydroxide minerals (Siebert et al., 2003; Barling and Anbar, 2004; Goldberg et al., 2009; Liermann et al., 2011; Voegelin et al., 2012). Sequential extractions and SEM analyses performed on Antamina waste rock dump material performed by Laurenzi (in prep.) show an association of Mo with oxidized mineralogical phases including Fe/Mn (oxy)hydroxides.

However, adsorption alone cannot fully explain Mo isotope compositions found in Antamina waters because the isotopically heaviest waters in this study included samples with pH ranges from 7.2-8.0, where Mo adsorption is expected to be minimal. Therefore another fractionating process can be invoked to explain this isotopic shift. Previous work shows that Mo attenuation via powellite

($CaMoO_4$) mineral precipitation is possible in these geochemical conditions (Conlan et al., 2012), although it is kinetically limited. While we cannot confirm which process is causing this isotopic shift at this point in time, a powellite precipitation hypothesis can be invoked as a possible explanation to explain this data: Ca- and Mo- bearing exoskarn is releasing Mo and Ca to solution, which then precipitate as $CaMoO_4$ albeit with a kinetic limitation. Kinetic isotope fractionation theory predicts that lighter Mo isotopes will be scavenged in this precipitation process, resulting in an isotopically heavy solution. Experimental testing of this hypothesis is an obvious next step. Finally, the endoskarn field barrel sampled in this campaign exhibited an opposite behavior to all other samples: water was isotopically lighter (-0.43 to -0.28 ‰) relative to molybdenite found in that field barrel (-0.16 ‰), suggesting another as of yet unknown process is causing isotopically light waters.

Zinc isotopes

In contrast with molybdenites, sphalerites at Antamina have a remarkably homogeneous Zn isotopic composition of 0.11 ± 0.01 ‰ (Fig. 3), which is consistent with a worldwide survey of Zn isotopic compositions in sphalerites by (Sonke et al., 2008). The range in Zn isotopic compositions measured in drainage water samples spans from -0.35 to 0.30 ‰, indicating that Zn isotopes are fractionated after release into solution from sphalerite oxidation. The isotopic composition of drainage waters is dependent upon the waste rock type: exoskarn and hornfels drainage is isotopically light, ranging from -0.35 to -0.02 ‰, while intrusive drainage is isotopically heavier, spanning from 0.03 to 0.30 ‰. One sample collected from an experimental waste rock pile (Pile 5-D) containing a mixture of hornfels and intrusive material had an intermediate isotopic composition of -0.01 ‰.

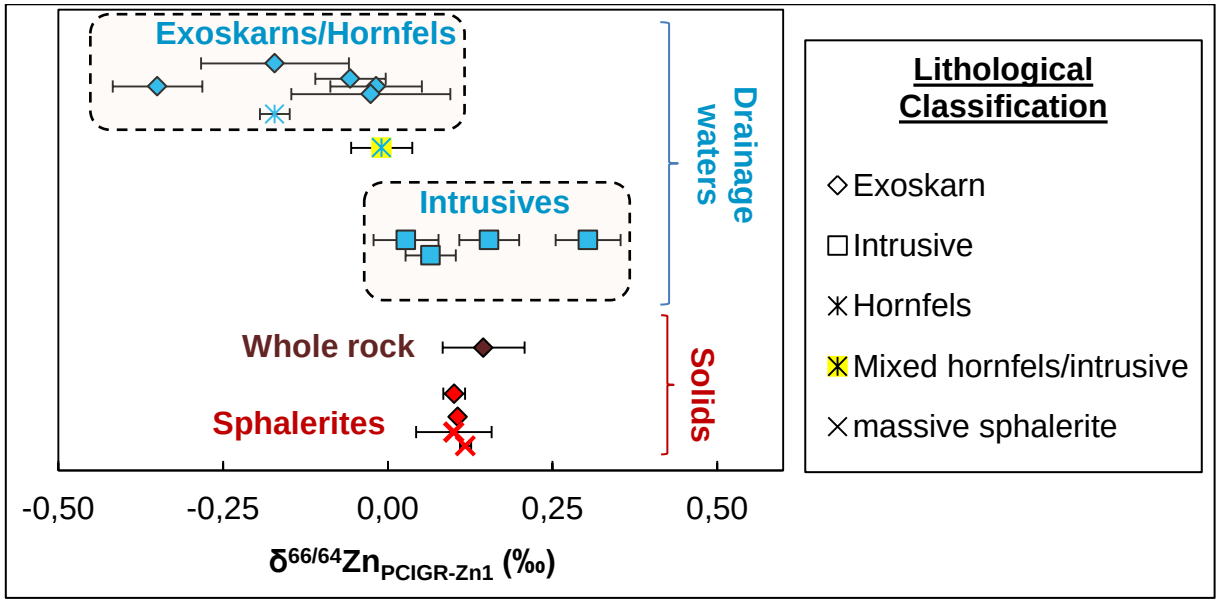

Figure 3 1-D representation of Zn isotopic composition of drainage waters (blue symbols), sphalerites (red symbols) and whole-rock (maroon symbols) in Antamina waste rock material by lithology (indicated by symbol shape). Data are spread along vertically axis for clarity. Error bars are ±2SD.

As is the case with Mo isotopes, at this point it is only possible to suggest hypotheses for the isotopic Zn variability measured at Antamina. Oxidative weathering, adsorption and precipitation of Zn-bearing carbonate minerals are all expected to cause some shifts in $\delta^{66/64}$Zn (Pichat et al., 2003; Fujii et al., 2011; Matthies et al., 2014a) and the variability measured here is likely an expression of one or several of these processes. The association of $\delta^{66/64}$Zn to waste rock lithology shows that Zn isotopes are a promising indicator for the provenance of Zn in waste rocks dumps which contain a mixture of different rock types. The intermediate isotopic composition of the hornfels/intrusive sample (Pile 5-D) could be an example of this application.

Laurenzi (in prep) has found evidence of Zn attenuation via adsorption onto Fe oxides and association with carbonate minerals in waste rock material collected from Antamina's waste rock dumps. Both of these attenuation mechanisms are possible in exoskarn waste rock material, because of its high carbonate content (2.8-31.3% by weight, (Peterson, 2014) and pH range (pH ~7-8) which is favorable for Zn adsorption (Pokrovsky et al., 2005). However, the shift towards isotopically light $\delta^{66/64}$Zn values in leachates from carbonate-rich waste exoskarn and hornfels materials are consistent with the precipitation of a Zn-carbonate mineral as an attenuating process (Pichat et al., 2003; Fujii et al., 2011).

SU MMARY AND CONCLUSION

Recent analytical improvements in MC-ICP-MS instrumentation allow the application of stable isotope analysis of heavy metals to track geochemical processes in mining waste rock and tailings. Mo and Zn isotope variations measured in Antamina waste rock materials are considerable and show that fractionation processes are occurring. Further experimental work will constrain the isotopic signature of environmentally relevant processes (e.g. adsorption, oxidative dissolution, secondary mineral precipitation) and improve our ability to use isotopes to diagnose the fate of these metals in full-scale waste rock dumps.

ACKNOWLEDGEMENTS

K. Gordon and Dr. M. Amini assisted in operating the MC-ICP-MS and developing analytical protocols. B. Harrison, M. Lorca-Ugalde, M. St-Arnault and L. Laurenzi assisted with sample collection along with Antamina field staff. B. Harrison, L. Laurenzi and M. St-Arnault and two anonymous reviewers provided invaluable comments to improve this manuscript. Funding was provided by NSERC and Compañía Minera Antamina.

Using Spatially Explicit Data and Modeling to Inform Ecological Risk Assessment at Mining Sites

ABSTRACT

The ecological effects of mine development are typically assessed using very conservative assumptions inherent in screening level ecological risk assessments (SLERAs) vis-à-vis toxicity and exposure estimates. We recommend a simple efficient SLERA followed by a focused population-level risk assessment designed by risk assessors in consultation with mine planners and geochemists. We provide an example of an evaluation of potential risk using spatially explicit modeled data and empirical site data for multiple media including soil and expected future sediment and surface water conditions at a mining site. These data were used in conjunction with an expanded list of toxicity values and exposure pathway models to evaluate risks to ecological receptors at the site. Results indicate a handful of chemicals of potential concern based on exceedances of low-effect criteria for bats, barn swallow, and spotted sandpiper. In an effort to focus risk management, a third-tier risk assessment was conducted using an individual-based model (IBM) to evaluate uncertainties in the risk assessment approach and characterize population-level impacts for the bat *Myotis* spp. as an example species. This population modeling effort expands upon the exposure scenarios and anticipated future site habitats used to evaluate both baseline risks and potential mitigation of risks by overlaying material to reduce exposure to areas with higher levels of chemicals of interest. The results demonstrate the usefulness of population modeling tools in assessing future exposure scenarios to meet risk management objectives in the real-world currency of natural resources (i.e., population abundance) as opposed to the pass/fail hazard-quotient paradigm currently utilized in risk assessment. This study also illustrates the importance, even at a screening level, of a robust, spatially explicit site-specific data set in understanding future conditions and site management alternatives.

INTRODUCTION

Ecological risk assessment (ERA) is a process for evaluating the likelihood that adverse ecological effects may occur or are occurring as a result of exposure to one or more stressors. Typically, ecological risk assessments use toxicological, ecological, and geochemical information to evaluate risk of impacts to wildlife and habitats from human activities such as chemical spills, resource extraction, and land conversion. If ecological risks are unavoidable, the ERA process can help identify opportunities to minimize or mitigate these risks (USEPA, 1998). This process at the lowest-tier consists of utilizing maximum exposure concentrations to ecological receptors which not surprisingly results in overly conservative risk estimates. At the second-tier, ecological risk assessors can utilize detailed spatially explicit site date including analysis of the mine activities, mine geochemistry, habitat formation, habitat access, and contributions of the pit lake water quality, sediment quality, and wall rock concentrations in evaluating ecological risk. A third-tier assessment involves investigating population-level effects for those ecological species which exhibited risk based upon the spatially-informed assessment (i.e., second-tier). This evaluation utilizes population models or population viability analyses built upon the body of scientific literature describing life history characteristics for the receptor of interest. A subset of these models, individual-based models (IBMs) allow the risk assessor to incorporate ecosystem complexities such as physiological factors, intra- and inter-specific interactions, resource availability, habitat structure, and abiotic factors. Ultimately, the results from IBMs provide a refined assessment with a potential range of risk outcomes in ecosystem metrics that are potentially simpler to conceptualize than the hazard quotient construct. These metrics include population abundance, extinction or quasi-extinction risk, and population growth rates relative to a control condition (i.e., no stressor in the system).

As an example of this three-tiered ERA approach, we present the results of an ERA which was conducted to evaluate a proposed expansion of the Twin Creeks Mine in the arid Great Basin ecosystem of northern Nevada, USA. State and federal permitting requires an evaluation of ecological risk associated with mining activities. In the case of proposed pit mine expansion, several spatial and temporal issues complicate the ERA approach. The assessment must be conducted for an ecosystem (a pit lake) that does not yet exist, using predictions of what hydrologic, chemical, and biological conditions are likely to be present several decades into the future as the lake infills. The ERA needs to account for spatial heterogeneity of chemicals to evaluate chemicals that animals will be exposed to once the pit lake exists. The risk assessment also needs to incorporate site geochemistry, which influences the bioavailability of metals and other chemicals to which wildlife may be exposed (Flynn *et al.*, 2003; Suedel *et al.*, 2006). These issues call for spatially and temporally explicit approaches in order to accurately predict risk and, if risks of adverse effects are found, inform the approach to reduce or mitigate these risks. The uncertainty associated with the dynamic lake condition offers another benefit to the three-tiered assessment approach whereby incorporating temporal and spatial variability in exposure profiles into a probabilistic population modeling scenario to further inform risk management.

METHODS

A screening-level ecological risk assessment was conducted, consistent with regulatory guidance (USEPA, 1997; USEPA, 1999; USEPA, 2001), which uses maximum concentrations of chemicals in the proposed pit vicinity, assumes complete bioavailability, and compares chemical data to conservative toxicological criteria. The conservatism of this approach resulted in a long list of metals that may cause risk, with substantial uncertainty about the realism of these risks under future conditions.

To address these uncertainties, a spatially explicit ERA was then conducted as a second-tier assessment. This approach incorporated an expanded set of modeled and empirical data over multiple time scenarios to evaluate expected future sediment and surface water conditions, including:

- Spatially explicit data sets were used to evaluate what concentrations of metals might be expected at the pit wall surface to which the ecological community could be exposed (Figure 1). This effort included detailed characterization of the vertical extent of concentrations throughout the geologic section (Figure 2).
- Estimates of pit lake surface water elevation and water quality was modeled over the complete 200 years of lake infill by other workers (Itasca, 2010; Geomega, 2010).
- A conceptual site model was designed to look at how ecological communities of the lake might be expected to develop after pit closure and infill (Figure 3).

These data sets and conceptual models were used to inform a site-specific wildlife exposure model. The model creates estimates of exposure to local wildlife that might be expected to colonize or forage in the habitats that develop as the pit lake is created and habitat is formed (Figure 4). These estimates of exposure were evaluated relative to toxicological criteria for concentrations of metals that have been shown in the scientific literature to cause no or low levels of adverse effects to wildlife exposed to these metals.

Based on the risk outcomes from the second-tier ERA, a third-tier assessment was conducted to illustrate the usefulness of population models for an example receptor which exceeded the low-effect criteria. We developed an IBM which accounts for the reality that individual organisms are distributed in a non-uniform way and may respond differently to identical environmental conditions depending on sex, age, and health. Hexsim is a publically available modeling software developed for the purpose of analyzing individuals within an ecosystem over time by layering prey, habitat preferences, and movement patterns in a probabilistic manner (Heinrichs *et al.*, 2010). The model is individual-based, spatially-explicit through user-defined spatial data which capture landscape structure, habitat quality, and stressor distribution, and trait-based through user-definitions such as age, sex, and fitness (Figure 4). The model was run using annual time-steps over the first 50 years of pit lake infill. Incorporating best-case and worst-case behavioral traits for the receptor species allows us to evaluate uncertainty in the evaluation. The results of this analysis allow us to compare population-level endpoints (i.e., abundance, population growth rate) over varying modeled assumptions and assist in gauging the environmental reality of presumed risks following the second-tier.

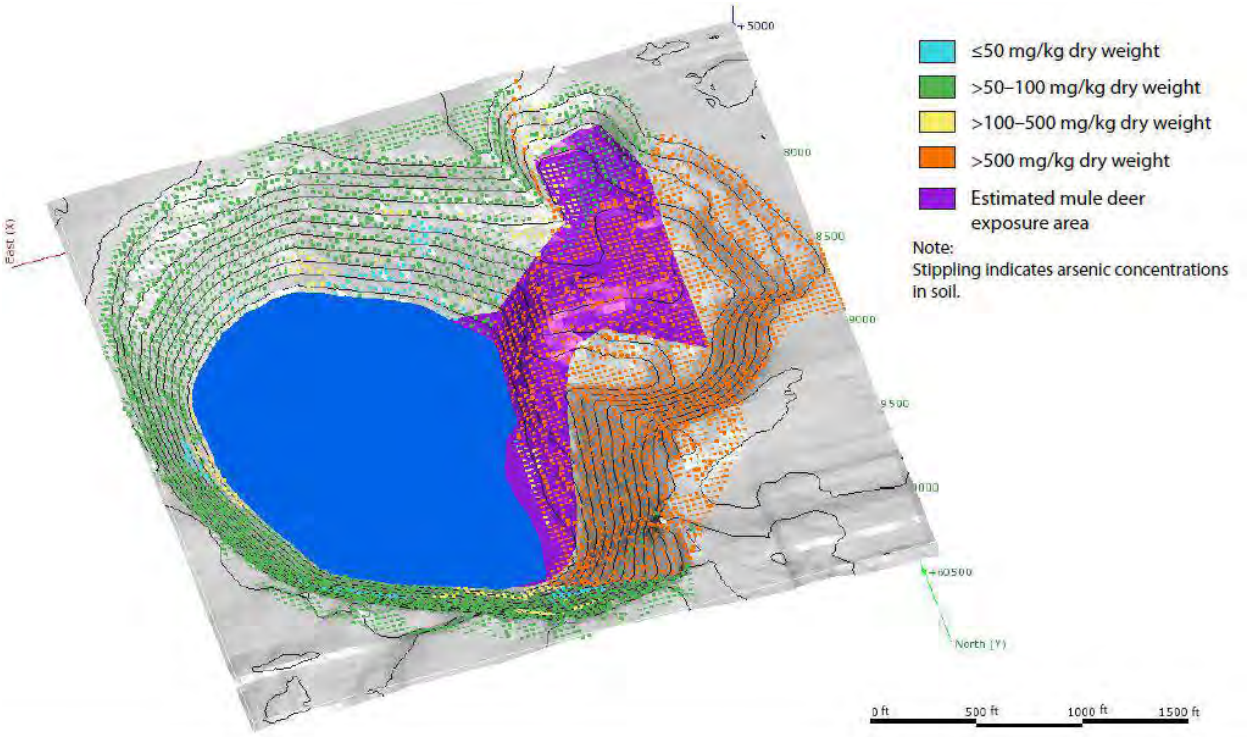

Figure 1 Predicted pit-lake geometry and arsenic distribution in the Vista Pit.

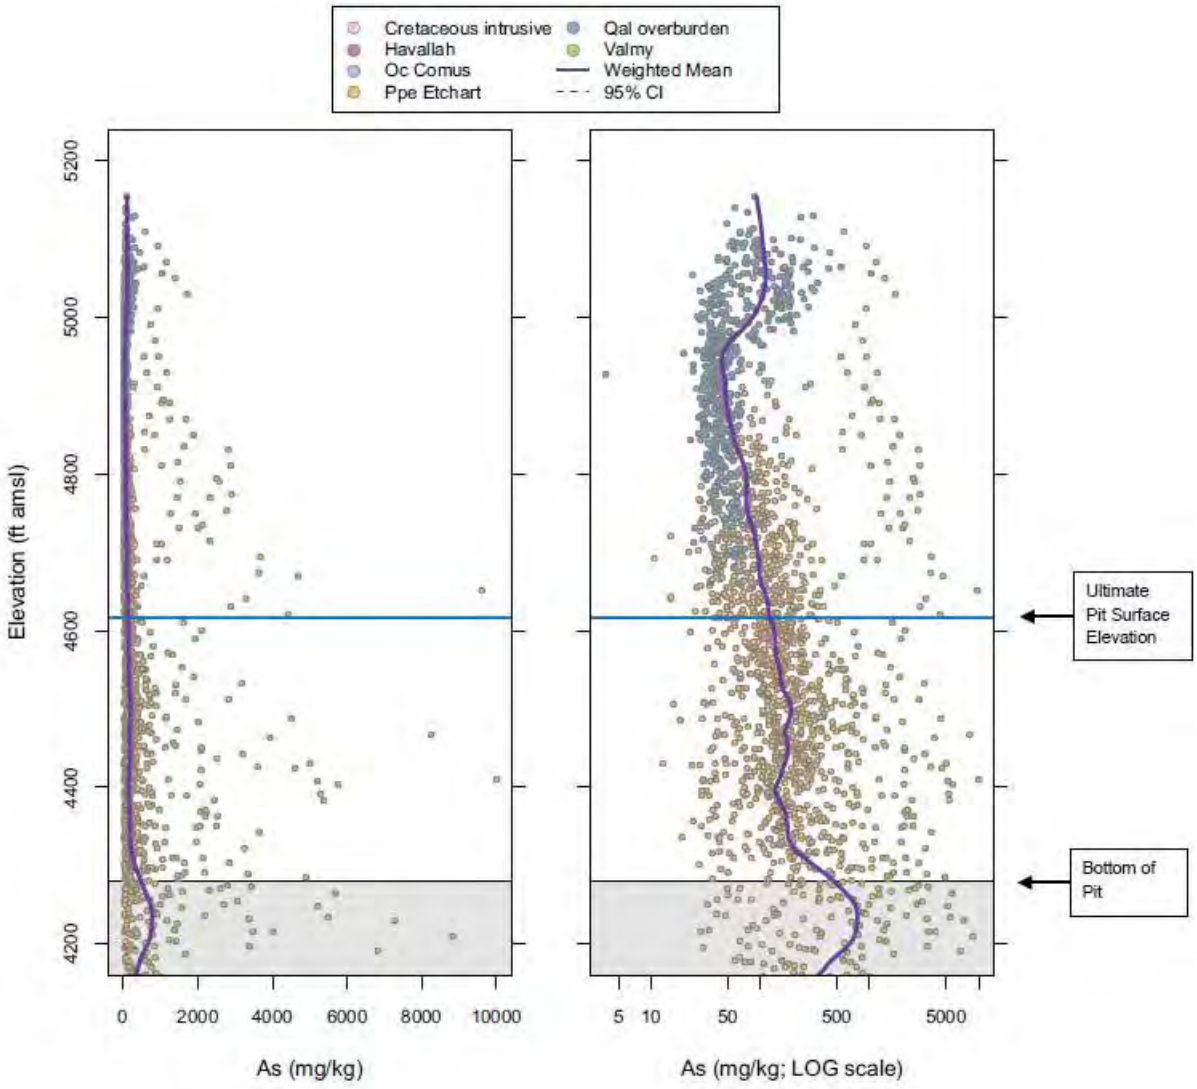

Figure 2 Arsenic concentrations as a function of depth in the proposed Vista Pit.

RESULTS AND DISCUSSION

Results of the wildlife exposure model included:

- No risks were predicted to modeled granivorous birds or ducks from exposure to chemicals at the site (Table 1).
- Low risks were predicted to ungulates, which could be redressed by considering pit wall mitigation. Exposures to antimony and arsenic were greater than the no-effect criteria for these metals if mule deer were conservatively assumed to spend all their time at the site. This risk could be eliminated if overburden (surficial materials removed prior to mining) is applied to the areas of the pit most likely to be frequented by grazing ungulates (Figure 2).
- A handful of metals were retained as chemicals of potential concern that exceeded low-effect criteria for one or more taxa of invertivorous mammals and birds (Table 1). However, there are important aspects of the model and the site conditions that are likely to reduce these risks:

- Predictions of risk were largely related to necessarily simplifying assumptions in the model of uptake factors from foods to consumers. When applied to bioaccumulation of metals, these factors often overestimate uptake, particularly at higher concentrations (Drexler *et al.*, 2003).
- The model assumes complete bioavailability of these metals; however, geochemical modeling indicates that at this site, several metals are likely to be in valence states or composite forms that reduce their bioavailability. For example, surface water pH greater than 5 is likely for this site, which would maintain aluminum in insoluble form, substantially limiting bioavailability of this chemical.

The availability of littoral habitat is likely to play a major role in shaping the ecological community of the site. Rapid infill rates over the first 20 years or so is likely to preclude the development of littoral habitat and will lead to the formation of a deep, mesotrophic pit lake. As lake infill slows, littoral habitat development will be regulated by the spatial proximity of shallow lake waters to horizontal pit wall benches that could allow for the development of a shallow vegetated photic zone. Low organic matter content in this arid ecosystem is likely to slow and limit shoreline soil capable of supporting substantial vegetation, further limiting habitat development.

CONCLUSIONS

The use of spatially and temporally explicit geochemical and ecological modeling to inform risk assessment has substantively improved our understanding of the ecological trajectory and potential for risk at the future Vista Pit lake. In an effort to further refine the risk characterization and weight-of-evidence for risk management alternatives, a third-tier assessment involving population model projections for receptor species of interest was conducted. Following closure and infill from groundwater, Vista Pit is likely to function as a deep, mesotrophic pit lake. The development of shallow littoral habitat capable of supporting wildlife will depend on the intersection of pit geometry and final surface level equilibrium, is likely to be prevented during initial rapid infill rates, and will be limited in the long term by low rates of organic matter accumulation in this arid ecosystem. Most chemicals that were evaluated were not found to be present at concentrations that suggest the potential for adverse effects on wildlife. Steps such as the use of overburden to cover pit wall surfaces that present a high likelihood of exposure may also be helpful in mitigating risk.

Effluent Chemistry of Closed Sulfide Mine Tailings: Influence of Ore Type

Päivi Kauppila and Marja Räisänen
Geological Survey of Finland

ABSTRACT

The seepage water quality of old sulfide mine tailings was studied from eleven closed sulfide metal mines in Finland to assess the influence of ore type on the drainage quality of tailings in the long-term. The studied sites represent a wide variety of ore types and commodities (e.g. Mo; Cu and Zn; Ni and Cu; Cu, W, As, Ag; Fe). Also the operation periods of the mines vary, from the 1750s to 1990s. Mining operations had ceased at the sites some 15–62 years ago (prior to sampling), but most of the facilities were left without any cover after mine closure. Only three of the tailings impoundments were covered with a thin layer of till or peat.

The seepage quality varied largely between the different mine sites. The pH of the seepages was between 2.8–7.3 and the total metal content (Zn + Cu + Cd + Pb + Co + Ni) between 0.004–207 mg/L. Overall, the high-acid, high-metal waters were related to Cu mine tailings, whereas the seepages from the other tailings deposits (i.e. from Ni, Fe, Mo, and Zn mines) were mostly near-neutral, low-metal containing waters. Unexpectedly, the most acidic seepage waters were found at the two sites where the tailings were covered with till after closure. One of the sites represented tailings from a Cu mine and the other from a Ni mine.

The results of the study show that there is a correlation between the tailings effluent quality and the ore type. However, other factors such as weathering period of the tailings also influence the seepage quality. These types of data contribute to the prediction of the long-term drainage quality of the new mining sites and in defining the requirements for their waste management and water treatment.

Keywords: Tailings, sulfide mining, seepage water, ore type, Finland

INTRODUCTION

Low-quality mine drainage from mine wastes is one of the major environmental issues that the mining operators struggle with. This is in particular at mines extracting base metals from sulfide-rich deposits, since the sulfide minerals oxidize once exposed to atmospheric oxygen and water. Depending on the balance between acid producing and neutralizing minerals in the waste, the drainage can be either low pH acid mine drainage ('AMD`) or non-acidic neutral mine drainage ('NMD') (Younger, 1995; Cravotta *et al.*, 1999; Pettit *et al.*, 1999; Heikkinen *et al.*, 2009). Regardless of the pH, these mining influenced waters can contain elevated to high concentrations of dissolved base and trace metals (*e.g.* Fe, Ca, Mg, Na, K, Cu, Ni, Zn) and sulfate originating from the weathering of sulfide, carbonate, oxide and silicate minerals in the waste (Pettit *et al.*, 1999; Plumlee *et al.*, 1999; Cravotta, 2008). Before opening a mine, quality of the future drainage should be estimated to assess the environmental impacts of the disposal of mine waste and to define the requirements for the waste management and water treatment techniques to prevent or minimize these impacts.

Prediction of the long-term quality of the waste effluents is a challenging task and is usually based on geochemical characterization of mine wastes using *e.g.* static and kinetic tests (White *et al.*, 1999; Sapsford *et al.*, 2008; INAP, 2009; Rousseau, 2012). Static tests provide one-time results and target to evaluate whether the waste is acid producing or not, whereas kinetic tests provide evaluation of the time dependent rates of chemical reactions in longer term. However, it has been recommended that the prediction should not be based on the tests alone, but they should be supplemented with water quality data from mine sites with similar types of geological deposits, because effluent chemistry shows ore type-specific features (Plumlee *et al.*, 1999; Lapakko, 2003; Seal & Hammarström, 2003).

In this study, preliminary results of the seepage water quality of tailings from eleven closed Finnish sulfide metal mine sites, representing six different genetic ore types, is presented to study the ore type-related effluent geochemical characteristics. At most of these sites the tailings have been uncovered since the mining operations ceased, and the tailings have had 15–62 years to weather. However, some of the tailings facilities were covered after closure with a layer of till or peat, so the influence of soil covers on the seepage water quality is also discussed. The focus of the study is in particular on the acidity and trace metal content of the seepages.

METHODOLOGY

Description of the studied sites

Seepage water samples were collected from tailings facilities of eleven closed sulfide metal mines in Finland (Figure 1), located in a temperate climate with an annual average precipitation of 600–700 mm. At all sites, the tailings were disposed above ground level into ponds constructed with earthen dams and utilizing natural depressions (*e.g.* small ponds/lakes or peatlands). The mines included Mätäsvaara Mo mine, Hammaslahti Cu-Zn mine, Laukunkangas Ni-Cu mine, Hällinmäki Cu-mine, Kotalahti Ni-Cu mine, Ylöjärvi Cu-W-As-Ag mine, Aijala Cu-Zn mine, Orijärvi Cu-Pb-Zn mine, Vihanti Zn-Cu-Pb-Ag mine, Rautuvaara Fe-Cu mine and Raajärvi Fe mine (Table 1). The ore deposit represented genetically 6 different ore types: volganogenic massive sulfide deposits, sedimentary exhalative type, porphyry copper deposits, magmatic nickel deposits, skarn and iron oxide ore types (Eilu *et al.*, 2012).

Figure 1 Locations of the studied mine sites (Contains data from the National Land Survey of Finland)

The mines operated variably from 1750s to 1990s (Puustinen, 2003, Eilu *et al.*, 2012), thus a variety of ore processing methods have been employed at the sites. Mining operations ceased at the sites some 15–62 years before the seepage water sampling (Table 1). Only three of the eleven tailings facilities (Hammaslahti, Laukunkangas, Vihanti) were covered after closure, so the tailings have been in most of the sites susceptible to oxidation. In Hammaslahti, the till cover was 35 cm thick in average (varying 10–60 cm) and it was partly covered with 10–15 cm layer of peat. Laukunkangas tailings area was covered with 50 cm till layer with 5 cm humus layer on top of it, whereas in Vihanti some 5 cm thick peat layer has been applied to revegetate the tailings facility. Covering of the sites has occurred only after some ten years after the mine closure and the end of the tailings disposal. Therefore, weathering of tailings has also initiated at these sites prior to covering.

Table 1 Commodity, ore type, operation period and amount of tailings of the studied mine sites

Mine site	Commodity	Ore deposit type[1]	Operation period[2]	Tailings (Mt)[3]
Aijala	Cu, Zn	VMS (bimodal, felsic dominated)	1949–58	2.0
Hammaslahti	Cu, Zn	Sedimentary exhalative	1972–86	5.3
Hällinmäki	Cu	VMS? (mafic)	1966–84	4.1
Kotalahti	Ni, Cu	Magmatic Ni sulfide	1959–87	9.4
Laukunkangas	Ni, Cu	Magmatic Ni-Cu-PGE	1985–94	6.6
Mätäsvaara	Mo	Porphyry (Cu, Au, Mo, W, Sn, Ag)	1903, 1910s, 1920–22, 1932–33, 1939–47	1.0
Orijärvi	Cu, Pb, Zn	VMS (bimodal, felsic dominated)	1758–1882, 1929–55	1.0
Raajärvi	Fe	Skarn (Zn-Pb-Ag, Cu, Au, Fe, W)	1964–75	2.2
Rautuvaara	Fe, Cu	Iron oxide-copper-gold	1962–88	8.0
Vihanti	Zn, Cu, Pb, Ag	VMS (bimodal, felsic dominated)	1954–92	1.4
Ylöjärvi	Cu, W, As, Ag	Close to Cu porphyry	1943–66	2.8

Sampling and analytical methods

Seepage water samples were collected from locations where water surfaces through the tailings dams. Samples were collected during early summer to midsummer (27th May to 3rd July). One seepage water sample was taken from each mine site. EC, pH, O_2, O%, and redox potential were measured in the field using a multi-parameter field meter (YSI 556 Multiprobe system), and alkalinity was determined with a Hach digital titrator with 0.1600 N or 1.600 N H_2SO_4 to an end point of 4.5. Unfiltered samples were collected for anion measurements and filtered (0.45 μm), HNO_3-acidified samples were collected for dissolved major cation and trace metal analyses. Major anions were determined with ion chromatography and major cations and trace metals with ICP-OES or ICP-MS. Duplicate samples and field blanks were taken for quality control. All the laboratory analyses were carried out at the FINAS-accredited testing laboratory of Labtium Ltd.

RESULTS AND DISCUSSION

Overall chemistry of the seepage waters and influence of the ore type

The seepage water quality varied largely between the different mine sites. The pH of the seepage waters varied between 2.8–7.3 and the total metal content (Zn, Cu, Cd, Pb, Co, Ni) between 0.004–207 mg/l (Figure 2). In general, the most abundant trace metals in the seepages were Zn, Ni, Co, and Cu and the seepages contained also high concentrations of SO_4, Ca, and Mg, which are typically released in the weathering of sulfide minerals and subsequent weathering of carbonate and silicate minerals (Figure 3).

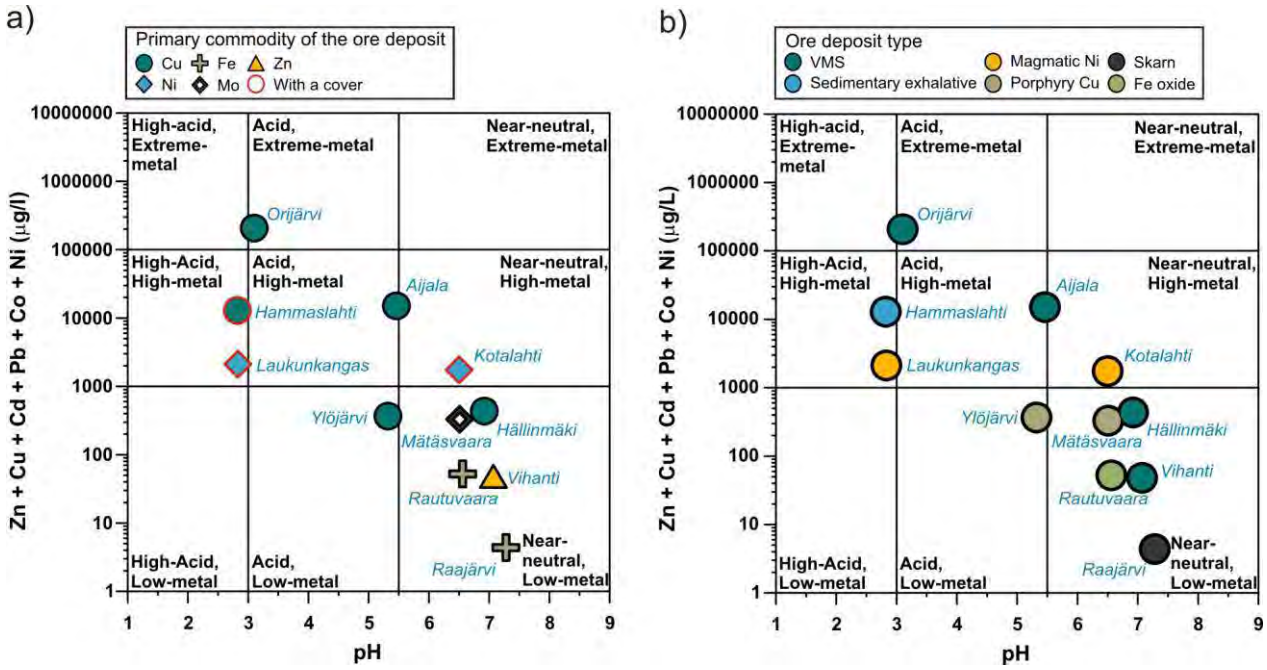

Figure 2 Ficklin diagrams (Plumlee *et al.*, 1999) of the tailings seepage waters showing the sum of dissolved heavy metals (Zn, Cu, Cd, Pb, Co, Ni) in µg/l plotted against pH value. Mine sites classified a) based on primary commodity of the ore deposit and b) based on genetic type of the ore deposit (VMS = volcanogenic massive sulfide deposit)

Based on the Ficklin diagram (Plumlee *et al.*, 1999), one third of the tailings seepages classified as high-acid/acid, high-metal waters, and half were near-neutral, low-metal drainages (Figure 2). Overall, the seepages at the sites where Cu ore had been extracted represented AMD type waters whereas the tailings effluents from most of the other types of deposits produced NMD (Figure 2). The most acidic seepage waters with highest metal contents were found at the sites where volcanogenic massive sulfide and sedimentary exhalative Cu ore types had been extracted, namely at Hammaslahti, Orijärvi and Aijala. These deposits contain typically high concentrations of sulfide minerals hosted by felsic rocks, having high acid production capacity and low neutralization capacity, and thus are prone to AMD. In contrast, the most neutral seepages with lowest metal contents were at the Raajärvi and Rautuvaara mine sites, which are iron oxide deposits containing only small amounts of sulfide minerals. However, the tailings produced in the extraction of magmatic Ni deposits (Laukunkangas and Kotalahti), porphyry deposits (Ylöjärvi and Mätäsvaara) and volcanogenic massive sulfide deposits (Vihanti, Hällinmäki, Aijala, Orijärvi) produced both AMD and NMD type seepage waters (Figure 2). These major ore type classes contain heterogeneous ore deposits, whose host rocks vary from ultramafic to felsic rocks, with varying buffering properties (Table 1). Host rocks of magmatic Ni deposits typically include ultramafic rocks with good buffering capacity, but in the Laukunkangas deposit the host rocks also contain black schists which are highly acid producing rocks (Grundström, 1985). Evidently, a more detailed classification of the ore type would likely better reveal the differences between the various ore deposits.

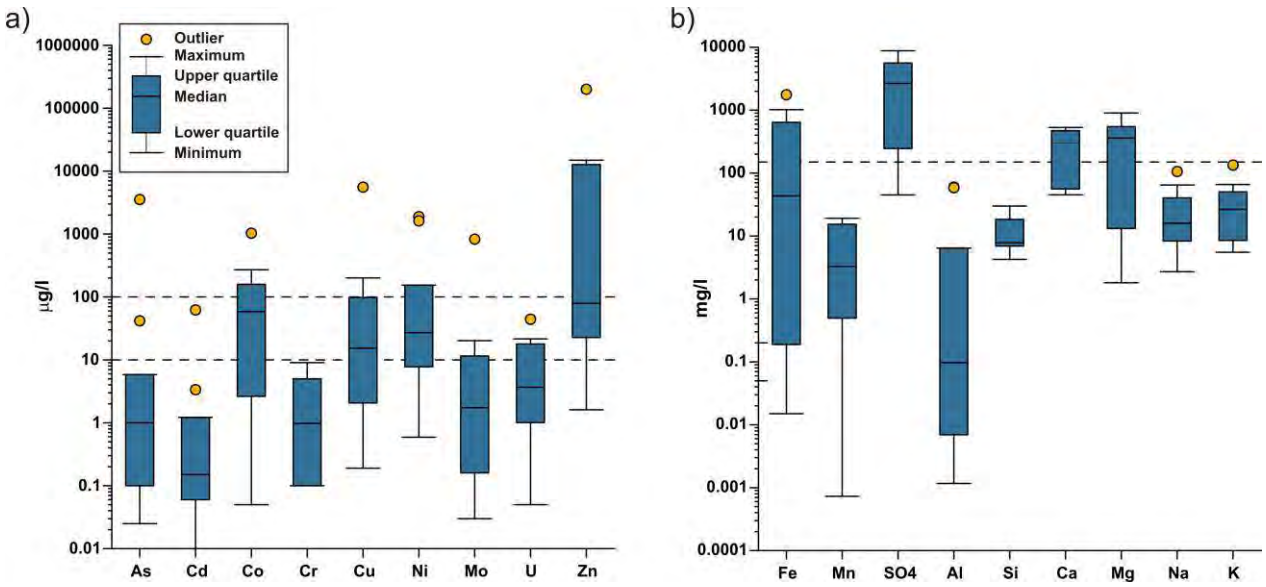

Figure 3 Box-Whisker plots for selected a) trace metal and b) major element and SO_4 contents of the tailings seepage waters

The loadings of trace metals in the seepages is a matter of the availability of the metals in the tailings (*i.e.* source of the metal) and the pH-Eh conditions controlling mineral weathering. Obviously, the tailings effluents of magmatic Ni deposits (Kotalahti and Laukunkangas) with abundant Ni sulfides in the tailings contained notably higher amounts of Ni than the other deposit types, whereas Cu concentrations were highest in the seepages of the Cu deposits (*e.g.* Orijärvi, Hällinmäki, Hammaslahti) rich in Cu sulfides (Figure 4). In addition, Zn was a typical trace metal in the seepages of the Cu deposit in which Zn occurred in exploitable amounts (Figure 4 and Table 1). However, occurrence of Zn in the seepages was also strongly linked to the pH conditions and thus in the weathering state of the tailings. For example, at the closed Vihanti Zn mine, the seepage water pH was > 7 and contained only minor amounts of Zn, even though there should be an abundant Zn source (sphalerite) in the tailings (Eilu *et al.*, 2012). The seepages of the Ylöjärvi porphyry deposit were distinct from the other seepages and had high As, U, and Co content originating from the weathering of arsenopyrite (As), uraninite (U) and presumably Co-bearing Fe-sulfides (Co). The seepages of the Fe deposits (Raajärvi and Rautuvaara) had in general very low contents of trace metals (Figure 4). The highest concentrations of Fe and SO_4 in the seepage waters occurred at the sites with the lowest pH and highest metal content, i.e. the sedimentary exhalative Cu deposit of Hammaslahti, Cu-rich VMS deposits of Orijärvi and Aijala, and the magmatic Ni deposit of Laukunkangas, indicating extensive sulfide oxidation in the tailings (Figures 2 and 4).

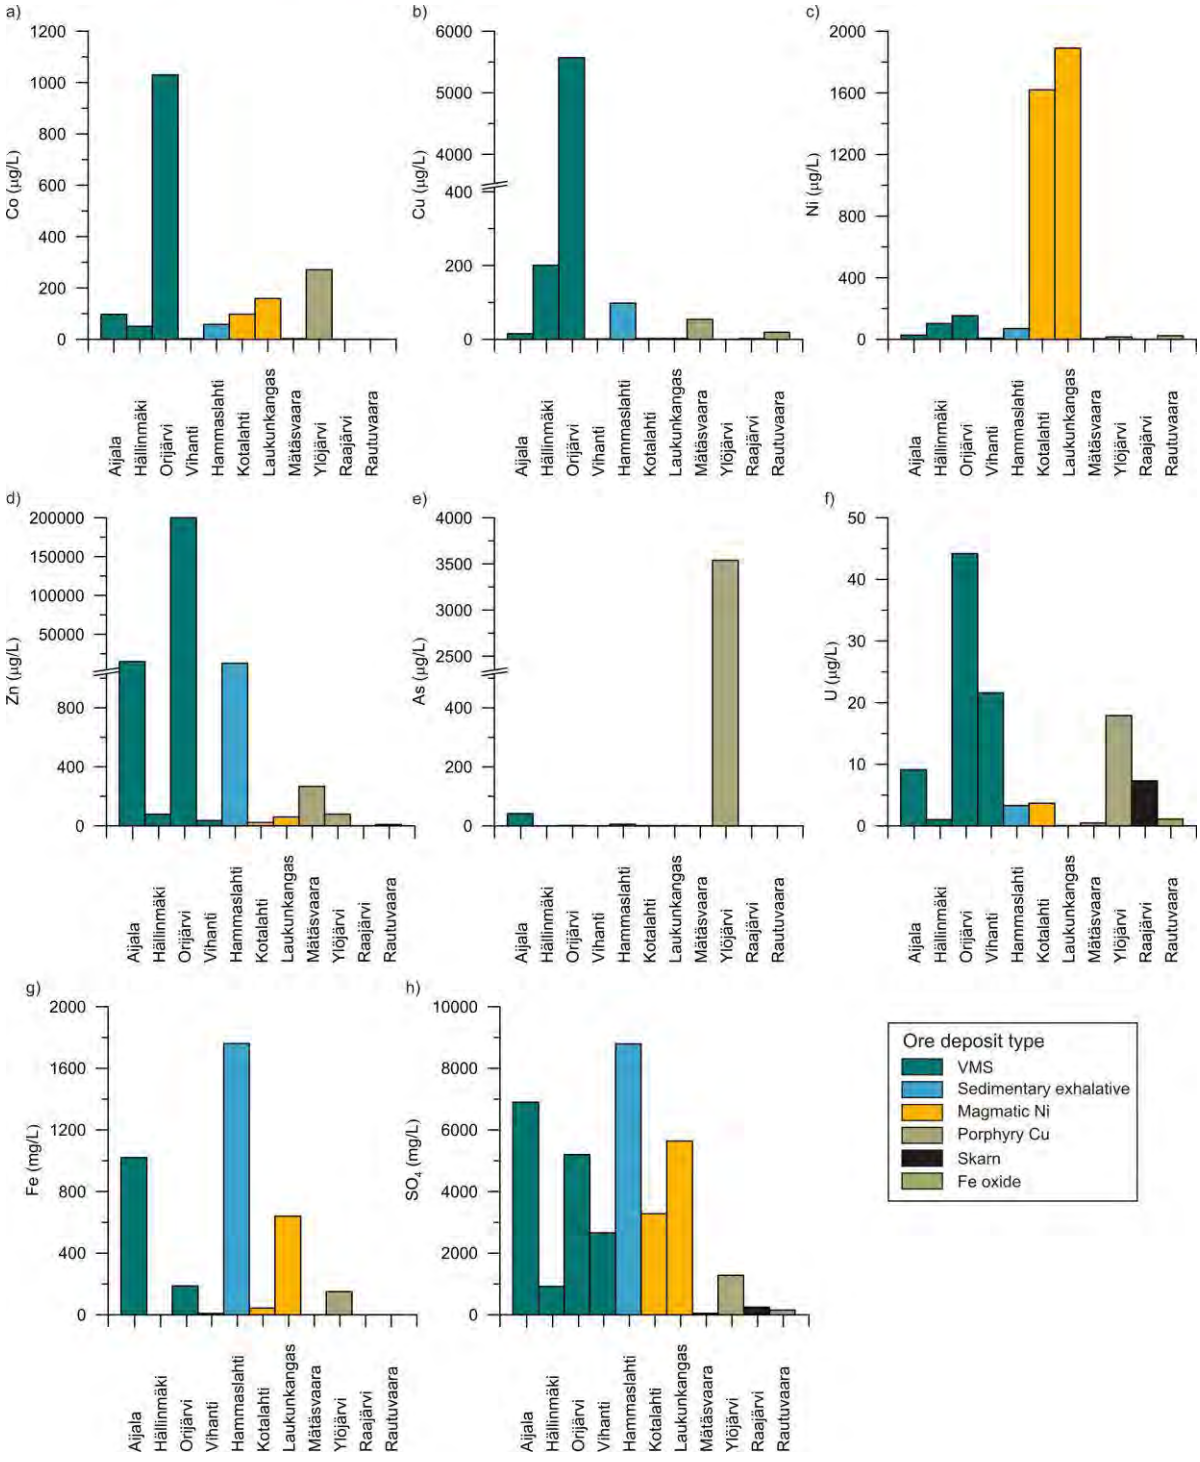

Figure 4 Concentrations of a) Co, b) Cu, c) Ni, d) Zn, e) As, f) U, g) Fe and h) SO_4 in the tailings seepage waters

The influence of the weathering period of the tailings on the drainage trace metal content was especially well seen in the seepage quality of the Orijärvi and Aijala sites. At these sites, the highest metal contents were measured and the time period after the cessation of tailings disposal was the

longest (> 40 years, Table 1). In particular, seepage waters of the Orijärvi tailings showed high concentrations of Cu, Co, Zn and U (Figure 4). High metal loadings at Orijärvi can also be related to the undeveloped processing methods of the ore leaving notable amounts of valuable metals in the tailings, since the mine operated in the early 20th century (Table 1).

Influence of the tailings covers

Covering of the tailings facility appeared to be a less important factor than the deposit type in controlling the seepage quality. Hammaslahti and Laukunkangas tailings facilities were covered in the 1990's and 2000's with less than a half a meter thick layer of till and Vihanti tailings with a 5 cm layer of peat. Despite this, the tailings facilities of the Hammaslahti and Laukunkangas generated seepages with some of the highest metal contents and lowest pH values (Figure 2). The applied cover structures were only thin soil covers that are not regarded as sufficient to prevent infiltration of rainwater into the tailings and to prevent the oxidation of sulfide minerals in the tailings (INAP 2009). Presumably the primary aim of the covers has been to prevent the dusting and to promote the spreading of vegetation. In addition, the covering of the tailings was made only after some years from the cessation of the tailings disposal. The delay in the covering of sulfide tailings contributes to the onset of sulfide oxidation and AMD production in tailings (*e.g.* Heikkinen 2009).

CONCLUSION

The tailings seepage water data collected from eleven closed mine sites in Finland, representing six different genetic ore types, showed that the ore type can be a starting point for the prediction of the future drainage quality of the tailings at new mine sites. Data indicated that especially tailings from processing of volcanogenic massive sulfide Cu deposits and sedimentary exhalative Cu deposits are susceptible to produce high-metal (*e.g.* Cu, Zn), high-acid drainage waters containing also high SO_4 and Fe concentrations. In addition, tailings effluents of certain types of magmatic Ni deposit may also be highly acidic with high metal (particularly Ni), SO_4 and Fe contents, whereas the Fe deposits seemed to be the least problematic concerning the tailings water quality. Tailings seepages from porphyry deposits may contain high levels of As, U and Co.

Covering of the tailings had little or no effect on the quality of the tailings seepage waters, because of the delay in the covering and too thin cover layers. The covers were made in the 1990's and in 2000's and apparently the primary aim was then to prevent dusting and promote the spreading of vegetation.

These types of data are valuable in defining the requirements for water treatment and tailings disposal at new mine sites. However, a larger data set and more detailed descriptions of the ore types are needed to better define the relationship between the seepage quality and the ore type. In a future study, the data set will be enhanced by collecting tailings seepage water data also from operating mine sites in Finland.

ACKNOWLEDGEMENTS

Authors are grateful to the Geological Survey of Finland for the funding of the sampling campaign and the analysis of the seepage waters.

Challenges in Prediction of Acid Rock Drainage Potential for Skarns – Use of Modified Testing

2. *Compañía Minera Milpo S.A., Peru*

ABSTRACT

The Hilarion Mining Project, located in the Peruvian Andes, is anticipating the use of thickened tailings as disposal method for the projected QuenhuaRagra tailings storage facility. A comprehensive geochemical program of tailings samples was performed to characterize them in terms of acid mine drainage (AMD) and metal leaching potentials. Two samples representative of the Zn-Ag-Pb polymetallic skarn-type deposit were used.

Skarn deposits typically pose a challenge for traditional kinetic testing programs. High neutralization potential and high sulfur contents can lead to extended testing times, as the high content of each extends the depletion times. This makes it difficult to evaluate uncertain materials or potential lag times. In this case mineralogical results indicated the presence of high concentrations of neutralization minerals and high concentrations of acid generation minerals. Acid base accounting tests confirmed high neutralization potential, together with a high acidic potential.

Humidity cell tests (HCT) were performed to confirm static test results and to determine lag time for the onset of acidic conditions. After a first stage of testing (89 and 54 cycles), the results reported circum-neutral pH conditions and low release of sulfate and metal concentrations. This result combined with depletion calculations predicting acid generation, the static tests results, and uncertainties from the net acid generating test made the AMD potential classification a challenge.

To better understand the skarn tailings geochemistry, hydrogen peroxide was used as lixiviant for the HCTs in a second stage of the testing. After a decrease in pH, both samples returned to their previous pH values; however, sulfate and metal release did react to the change. After 21 and 18 HCT cycles with hydrogen peroxide, acidic conditions were not reached.

Accelerated kinetic test provided useful information for waste management. While acidic conditions are doubtful, oxidation of sulfides will produce release of metals and sulfate.

Keywords: skarns, extended lag time, hydrogen peroxide

INTRODUCTION

The geologic characteristics of mineral deposits exert important controls on the natural environmental signatures that could result from mining and mineral processing. A good understanding of the environmental geology of mineral deposits is therefore crucial to the development of effective mining-environmental prediction, mitigation, and remediation practices (Plumlee 1999).

Skarns are coarse-grained metamorphic rocks formed when magmatic-hydrothermal fluids are expelled from the magmas and react chemically with sedimentary rocks. The skarn alteration frequently introduces calc-silicate minerals replacing carbonate-bearing rocks. The skarn ores may include massive sulfide lenses and veins occurring within and/or replacing the sedimentary host rocks (Plumlee *et al.* 1999). This type of replacement increases the acid generation capacity by increasing the content of acid-generating sulfides in rocks and may decrease the acid-neutralizing capacity by removing carbonate minerals (Plumlee 1999). However, the original host rocks frequently still retain a high carbonate content. This results in geoenvironmental model signatures of circum-neutral pH values, and low metal concentrations with a few exceptions, including copper and zinc (Plumlee *et al.* 1999).

Evaluation of a material with high contents of sulfides and high carbonate content poses a challenge for the geochemical characterization programs and the determination of the acid generation potential because an extended kinetic testing time may be required to deplete one or the other, even in an accelerated test. The long lag times to acid generating conditions or to depletion of the neutralization potential are impractical compared to other aspects of mine planning and permitting and do not allow useful decisions to be made during the design process.

The Hilarion project in Peru is a Zn-Ag-Pb skarn-type deposit hosted in a contact zone of the calcareous sedimentary sequence of the Chulec-Pariatambo-Pariahuanca Formations (early Cretaceous) and an acidic intrusive stock (likely Tertiary). The calcareous sedimentary sequence ranges from predominantly claystone in the Pariatambo formation to limestones in the Chulec formation. The intrusive rocks present in the zone are a potential source of mineralization and are characterized as dioritic, feldspar porphyry, quartz monzonitic porphyry, and granodioritic types, affected by hydrothermal alteration mainly of the kaolinite and sericite into plagioclase and chloritic in amphiboles.

Compania Minera Milpo S.A.A. (Milpo) is currently developing the Hilarion project, which is located in the Peruvian Andes at an altitude varying between 4,500 and 5,200 meters above sea level, approximately 230 kilometers north of Lima and 80 kilometers southeast of the city of Huaraz. Milpo is considering the use of thickened tailings as a disposal method in the planned tailings storage facility (TSF).

As part of the permitting efforts, Milpo and Golder developed a geochemical characterization program to assess the acid generation and metal leaching potential of tailings samples representative of the polymetallic skarn-type deposit present at the Hilarion project following standard phased geochemical programs, including static and kinetic testing. However, given the

difficulties and extended time required to evaluate materials with high carbonate and high sulfide contents, the latter was modified through the addition of an oxidizing agent for further evaluation of the materials.

This case study provides an overview of the geochemical characterization program and its results, including the challenges presented by the nature of the material investigated and the modifications applied to a standard kinetic test to better understand the geochemical behavior of the Hilarion tailings samples.

METHODOLOGY

Tailing samples from pilot scale metallurgical work were tested as a part of the geochemical characterization program. The samples represented tailings from the ore material, following all metallurgical processes, that will be mined from the skarn deposit and that are expected to be deposited in a valley fill tailings storage facility (TSF). This study evaluated the expected environmental behavior of the tailings in the TSF, after metallurgical leaching processes. The study was designed to provide information for future waste management and water management strategies for the TSF, including water management strategies for runoff water and seepage, water management strategies for the tailings pond, water balance, and recirculation requirements, and whether and when treatment might be required.

Three tailings samples were evaluated. For sample 1 and sample 2, a complete geochemical testing program, including static and kinetic testing by humidity cells, was performed following standard guidance (*e.g.*, INAP 2009, MEND 2009). The geochemical testing program for these samples is summarized in Table 1. As part of confirmatory efforts during the static testing phase, an additional sample (sample 3), was sent to the lab to perform confirmatory analyses with respect to mineralogy and with respect to oxidation potential of the sulfides (i.e., the sequential net acid generation procedure).

The focus of this study was to better understand the geochemical behavior of the samples in the long term; as such, a second phase of kinetic testing was undertaken for samples 1 and 2. This second phase of testing was a modified kinetic test as described below. Given the interest in the long-term behavior, this paper focuses on the kinetic test results; however, the results of the static testing phase are also summarized to provide the context for the interpretation of the kinetic test results.

Table 1. Summary of complete geochemical testing program

Program	Analysis	Sample 1	Sample 2	Sample 3
Static	Elemental content by acid digestion	X		
	Acid base accounting	X	X	
	Net acid generation	X	X	
	Net acid generation test effluent analysis	X	X	
	Short term leaching procedure	X	X	
	Sequential net acid generation test			X
	X-ray diffraction with Rietveld refinement	X	X	X
	Acid base accounting after humidity cell test	X	X	
Kinetic	Humidity cell test	X	X	
	Modified humidity cell tests	X	X	

The humidity cell test (HCT) method (based on ASTM 2007) was used as the kinetic test in this project. The ASTM HCT, a cyclic kinetic test, was selected primarily given its common use and regulatory acceptability. For the modified kinetic testing, the original HCTs were continued into a second phase of testing with a modified procedure. In this phase, the lixiviant was changed from deionized water to hydrogen peroxide. The second phase of testing was initiated at cycles 89 and 54 for samples 1 and 2, respectively. After the lixiviant change, the modified HCTs were continued for additional 21 and 18 cycles (to 110 and 72 cycles, respectively).

Hydrogen peroxide is commonly used as a part of the net acid generation (NAG) test developed by AMIRA (AMIRA 2002) and is intended to accelerate oxidation of sulfides and challenge the neutralization potential present in the sample. The objective of using hydrogen peroxide in this case was to attempt to reach acidic conditions predicted by the static test results and depletion calculations.

After kinetic tests were terminated acid base accounting (ABA) testing was performed on the sample remaining in the humidity cells to confirm the depletion calculations based on the HCT results and to evaluate changes to the original acid generation potential classification following kinetic testing.

Laboratory testing, with the exception of the mineralogical analysis, was performed by a commercial laboratory in Lima, Peru. The laboratory has its own quality control, and quality

assurance program and experience performing ASTM HCT method. The mineralogical analysis was performed by the University of British Columbia, Vancouver, Canada.

RESULTS

Static tests results summary.

Mineralogical results for the three samples are presented in Table 2. The results of the XRD were consistent with the general understanding of the site geology, with a polymetallic skarn type mineralization of Zn-Ag-Pb. A high concentration of calcite was determined with a range between 8.1 and 10.4% by weight. Sulfide presence was highly dominated by pyrrhotite (15.8 to 18.0% by weight), followed by lower concentrations of pyrite and sphalerite.

Results of the static testing program indicated inconsistent results for sample 01. This sample is considered to have the potential for acid generation based on standard ABA calculations (both net neutralizing potential ratio (NPR) and net neutralization potential (NNP) calculations). While the neutralization potential (NP) of the sample was high (156 kg CaCO3/t, consistent with the 10 % by weight calcite content), this sample has a high acid potential (227.5 kg $CaCO_3$/t) consistent with an elevated sulfide content (20.3% by weight sulfides, including 17.7 % by weight pyrrhotite and 1.9% by weight pyrite). In contrast, the net acid generation (NAG) test did not confirm this classification for sample 1, reporting neutral pH values after the procedure. However, the NAG test is subject to complications for samples with high sulfide contents; insufficient hydrogen peroxide may have been added to oxidize all of the sulfides present.

Results of the static testing program indicated that sample 02 is considered to have an uncertain potential for acid generation based on the NPR result (i.e., 1.8), while the NAG result reported a circum-neutral pH value. This uncertain classification is again due to the high NP (207 kg CaCO3/t, consistent with the 10.4 % by weight calcite content), this sample has a high acid potential (115 kg CaCO3/t) consistent with an elevated sulfide content determined by mineralogical analysis (18.4% by weight sulfides, including 15.8 % by weight pyrrhotite and 1.6 % by weight pyrite).

Due to the inconsistency between the NAG test and the ABA results, a sequential NAG test (AMIRA 2002) was performed over a confirmatory sample (sample 3). A three step sequential NAG test was performed over the sample. The results after the three cycles reported a pH of 2.3 and elevated metal concentrations. This test confirmed that the one step NAG test performed over the original samples was inadequate to completely oxidize all the sulfide material present and confirmed the acid generating potential of the tailings samples.

Table 2. Tailings samples mineralogical test results (% by weight)

Minerals	Formula	RE-HI10-01	RE-HI10-02	RE-HI10-04
Quartz	SiO_2	5,8	6,5	6,0
Clinochlore	$(Mg,Fe^{2+})_5Al\ (Si_3Al)O_{10}(OH)_8$	3,4	4,4	3,1

Total		100	100	100

Kinetic test results

The objectives of the kinetic test were to:

- Address the uncertainties provided by the initial static test results,
- Evaluate potential lag times to acidic conditions, and
- Evaluate the geochemical behavior of the tailings samples under acidic conditions.

The results of the HCTs would then be used in predictions of water quality and tailings behavior in the TSF during operation and after closure to assist with TSF design.

Tailings samples 1 and 2 had a first phase of the kinetic testing program in HCTs based on the standard ASTM method. However, following 89 and 54 cycles for sample 01 and 02, respectively, the HCTs had maintained neutral conditions, with pH values between 7.3 and 7.6. Metals concentrations were generally low with the exception of manganese, which is mobile at these pH values. The manganese concentrations by cycles 89 and 54 reported values between 0.28 and 1.5 mg/l.

A preliminary evaluation of the results was performed midway through the first phase of testing. Based on the ABA results, sequential NAG testing, and the high concentration of sulfide minerals, it was expected that the tests would result in acidic conditions, at least for sample 01 by this time of the HCT procedure. Additionally, forward-looking depletion calculations also indicated eventual acidic conditions. However the preliminary evaluation demonstrated that leachate from both samples reported circum-neutral pH values, a sulfate concentration around 100 mg/l, and low metal concentrations. These results indicate that not only were acidic conditions not attained, but also significant oxidation was not occurring.

At this point, it was decided to modify the HCT procedure expecting to accelerate the oxidative processes in one of the samples. Starting in cycle 54, the lixiviant for sample 02 was changed from deionized water to hydrogen peroxide, capable of accelerate the sulfides oxidation rates. Sample 02 was under this lixiviation scheme until cycle 72, when the test was terminated.

The sample 01 continued to be leached using the standard procedure for comparison until cycle 89. Based on the results reported up to that cycle, it was decided to also modify this cell and start using hydrogen peroxide as the lixiviant. The sample 01 HCT was tested until cycle 110 with hydrogen peroxide.

The results after 110 and 72 cycles (including 21 and 18 cycles using hydrogen peroxide) for samples 01 and 02, respectively, can be summarized as follow:

- Acidic conditions were not generated in any of the cells, even after the use of hydrogen peroxide as the lixiviant. The pH values for both samples ranged between 6.1 and 8.3 (Figure 1).
- After the first addition of hydrogen peroxide, pH value for sample 02 reported a decrease from 7.6 down to 6.6, but returning to pH values pre-hydrogen peroxide after 5 cycles.
- Sample 01 did not report significant changes in its leachate pH value after the change to hydrogen peroxide, keeping leachate pH values between 7.3 and 8.0 until the end of the test.
- While both samples were lixiviated using deionized water sulfate and metal concentrations remained low, reporting stable or decreasing trends.
- The addition of hydrogen peroxide in both cells resulted in a significant increase in sulfate concentrations. Both samples reported a one order of magnitude increase immediately after the first hydrogen peroxide cycle. The increase of sulfate concentration remained stable in cell 02 until terminated; while cell 01 reported a decrease in sulfate concentration after ten cycles using hydrogen peroxide, but still elevated compared to the concentrations reported when using deionized water (Figure 2).
- Metals concentration also reacted to the change in lixiviant. In both cells, similar parameters reacted to the addition of the strong oxidant. In most of the cases the increases in concentration

were above one order of magnitude. The parameters that reported increases in concentration for both samples included: barium, calcium, cadmium, cobalt, chromium, copper, magnesium, manganese, molybdenum, nickel, lead, selenium, silica, strontium, and zinc. For example, Figures 3 and 4 present the results for copper and zinc, respectively.

- After the initial peak in concentrations following the change to hydrogen peroxide, most of the parameters reported decreasing concentrations; however none of them returned to the concentrations exhibited before the change in lixiviant. Only magnesium remained stable or reporting increasing trends until the cells were terminated.

DISCUSSIONS AND CONCLUSIONS

Skarn deposits pose a challenge for geochemical characterization programs. Excessive contents of carbonates and sulfides can lead to unreasonably long depletion times even in accelerated kinetic tests, resulting in uncertainty in the final acid generation behavior of waste materials.

Pilot plant tailings samples associated with the Hilarion project had high sulfide content (18.4 to 20.3 % by weight, primarily as pyrrhotite) and high carbonate content (10 to 10.4 % by weight calcite). Static ABA and sequential NAG testing resulted in predictions of potentially acid generating to uncertain. In this type of scenarios, humidity cell tests are performed to confirm the expected behavior in the future, after oxidizing conditions are applied to the samples. Humidity cell tests are used for a number of reasons, including confirmation the acid generation potential and the release rates of metals. Unfortunately, humidity cell test duration is not definitive and will depend on the results obtained, which at the same time are dependent in the type of materials studied.

Up to 88 and 54 cycles of kinetic testing by standard humidity cells did not resolve the potential uncertainty based on the ABA results. Additionally, depletion calculations indicated that exceptionally extended testing times (up to 15 years) would have been required to resolve this issue. While it was expected that the humidity cells would reach acidic conditions, the preliminary results of the kinetic test, under standard conditions, did not provide consistency with the static test results. The change of lixiviant from deionized water to hydrogen peroxide, a strong oxidant, was

performed to accelerate the oxidation of sulfide minerals present in the samples and to reach acidic conditions.

The second stage of modified humidity cell testing provided useful information for mine design, operational planning, and closure planning. The second stage of humidity cell testing involved the use of an oxidant (hydrogen peroxide, as in the NAG test) as a lixiviant of up to 21 cycles of testing. Even after 21 and 18 cycles of leaching with the oxidant for samples 1 and 2, respectively, acidic conditions were not achieved, contrary to predictions of potentially acid generation behavior based on the ABA testing and with concentration of sulfides of up to 20.3%. However, sulfide oxidation was achieved by using the oxidant as a leachate, as shown by increases in the sulfate and metals concentrations in the leachate. Oxidation, based on sulfate generation, was greatest immediately following addition of the oxidant, and remained elevated for up to 18 cycles. For sample 1, sulfide oxidation decreased 10 cycles after the initiation of the oxidant lixiviant; however, the oxidation rates from this point through the final 110 cycles of testing (again based on sulfate release) were still elevated (4 to 5 times higher) relative to initial test conditions, indicating oxidation was still occurring despite the decrease. Even under these scenarios, available NP was sufficient to prevent development of acidic conditions.

While oxidation was occurring in the second stage of kinetic testing, significant metals and sulfate release was also observed. Increases in metals and metalloids concentrations, including Ba, Cd, Co, Cr, Cu, Mn, Mo, Ni, Pb, Se, Sr, and Zn, were observed in the second stage of kinetic testing. It is expected these metals were released by sulfide oxidation and/or micro, localized acidic zones (even if the overall tests did not result in acidic conditions). Concentrations of Cd, Mn, Mo, SO_4, Se, and Zn, several of which are expected to be mobile even at low pH values, were elevated sufficiently to pose a risk to exceeding applicable regulatory standards based on water quality modeling for the TSF. As such, design for the TSF needed to consider potential water treatment if sulfide oxidation occurs. However, a lag time to sulfide oxidation is expected based on the first stage of kinetic testing and given that the climate and design of the TSF will keep the tailings saturated, at least through operations.

While the kinetic testing may not have definitively resolved discrepancies with respect to AMD and the static testing, the expected release of metals under neutral conditions once sulfide oxidation is initiated is significant for mine, operation, and closure planning. As such, use of this modified test to further accelerate weathering reactions provided useful information with respect to the overall expected tailings behavior.

Geochemical Characteristics of Oil Sand Tailings and Bitumen Upgrading By-Products, Alberta, Canada

Bronwen Forsyth[1], Stephen Day[1] and Oladipo Omotoso[2]

1. *SRK Consulting, Canada*
2. *Suncor Energy Inc, Canada*

ABSTRACT

Few studies have characterized the metal leaching and acid rock drainage (ML/ARD) potential of tailings from oil sand production, and associated by-products from bitumen upgrading. In order to address this gap, Suncor Energy Inc. undertook sampling to characterize their various tailings and by-products using ML/ARD characterization methodologies typically applied to coal and metal mine wastes. Tailings types characterized were mature fine tailings (MFT), dried mature fine tailings (DMFT), and froth treatment tailings (FTT). Bitumen upgrading by-products characterized were coke and coke ash. Methods used included conventional acid-base accounting, net acid generation testing, X-ray diffraction, and humidity-cell testing.

The characteristics of MFT, DMFT, and FTT reflected the mineralogy of the McMurray Formation, which includes pyrite, siderite, ankerite, and various clay minerals. In contrast, the characteristics of coke are carried over from the bitumen though pyrite is not destroyed because cokers operate under reducing conditions. Coke ash is mostly composed of amorphous aluminosilicate melts, and contains readily leachable concentrations of nickel and vanadium. The application of standard ML/ARD characterization methods to oil sands is complicated by the presence of residual bitumen, which makes tailings hydrophobic and rich in organic carbon.

Keywords: oil sands, metal leaching, acid rock drainage

INTRODUCTION

Tailings management remains one of the most difficult environmental challenges for the oil sands mining sector with over 77 square kilometers of oil sands tailings ponds in Alberta (Alberta Government, 2013). Government regulations introduced in 2009 (Directive 074) require operators to dewater the tailings ponds for reclamation purposes, and to reuse the water for production. In response, recent studies have focused on developing methods to reduce water within the ponds (COSIA, 2014a; Wang *et al.*, 2014). Few studies have characterized the metal leaching and acid rock drainage (ML/ARD) potential of tailings from oil sand production, and associated by-products from bitumen upgrading, or assessed the ML/ARD implications of dewatering the saturated tailings (Kuznetsov *et al.*, 2015). Furthermore, guidance on addressing ML/ARD potential is not available within best practice guidelines for oil sands tailings management (COSIA, 2012 and 2014b). In order to address this gap, Suncor undertook sampling to characterize the ML/ARD potential of their various tailings and bitumen upgrading by-products using existing methodologies typically applied to coal and metal mine wastes.

Suncor extracts bitumen from oil sands in the Lower Cretaceous McMurray Formation of northern Alberta, Canada, which are mainly deposits of fine-grained quartzitic bituminous sands and sandstones (Flach, 1984). Bitumen is extracted from crushed oil sand ore through a process of gravity separation and flotation. The process yields bitumen, bitumen froth, fluid tailings, and coarse sand tailings. The bitumen froth contains some fine minerals and oleophilic heavy minerals (including pyrite), and is mixed with naphtha to allow further separation of bitumen from residual water and minerals in centrifuges and inclined plate settlers. The residual water and minerals in the froth stream constitute the bulk of *froth treatment tailings* (FTT). FTT is a small percentage of the tailings produced during bitumen extraction and is handled separately from the rest of the tailings stream. Fluid tailings from the primary flotation circuit are further processed in secondary flotation circuits to remove residual bitumen. Fine tailings from the flotation circuits are combined with coarse sand tailings, and transported to a sand placement area where the sand fraction deposits along shallow slopes, and the fines are transferred to a pond where they settle to form *mature fine tailings* (MFT). After a few years, MFT settles to a solids content of approximately 30 to 40 wt%. MFT are later removed from the pond, mixed with polymer and placed in thin lifts in a dedicated disposal area where they are dewatered and dried to become *dried MFT* (DMFT).

Extracted bitumen is upgraded to lighter hydrocarbon products through a process of reductive coking at approximately 450 °C. The resulting *coke* is disposed in coke pits, or utilized for heat generation and reclamation purposes. Combusted coke results in *coke ash*, which is transported to storage ponds as slurry. The ash is composed of approximately 20 % bottom and mid-ash and 80 % fly ash.

This paper details the geochemical characterization of the oil sand tailings (MFT, DMFT, and FTT) and bitumen upgrading by-products (coke and coke ash), discusses the application of standard ML/ARD characterization methodologies, and highlights some of the methodological limitations for practitioners to consider when interpreting the results.

METHODOLOGY

Sample Collection

Suncor collected 57 MFT, 12 DMFT, five FTT, eight coke, and three coke ash samples for geochemical and mineralogical analysis. MFT samples were collected from three depths at various pond locations using a suction dredge. DMFT samples were collected as grab samples directly from dedicated disposal areas. Two FTT samples were collected from the tailings line prior to discharge, and three were collected as deposited samples from 3, 5, and 20 m below the pond water line in order to capture any compositional differences as a result of tailings deposition. Coke was collected monthly as grab samples across an eight-month period. Coke ash sampling consisted of a bottom ash, fly ash, and a combined coke ash grab sample collected from an ash storage pond.

Sample Preparation and Analysis

Samples were prepared and analyzed by Maxxam Analytics in Calgary, Alberta, and Vancouver, British Columbia. Coke and coke ash samples were air-dried prior to analysis. Each tailings sample was split into two subsamples, with one fraction air-dried to remove the bulk of the water and volatile hydrocarbons, and the second fraction taken as-received for Dean Stark extraction to determine the bitumen, mineral, and water contents (Dean and Stark, 1920). The method uses hot toluene to extract hydrocarbons.

The air-dried coke and coke ash, and toluene-treated tailings were analyzed for major elements by X-ray fluorescence (XRF) spectroscopy, minor elements by four-acid digestion and inductively coupled plasma mass spectrometry (ICP-MS), and particle size by dry and wet sieving methods.

Acid-base accounting (ABA) was undertaken on coke, coke ash, and air-dried tailings. This included total sulfur (Leco), sulfur speciation (ASTM D2492-02), total carbon (Leco), total organic carbon (TOC) (Leco analysis on residue of hydrochloric acid leach), total inorganic carbon (TIC) (by difference), paste pH and electrical conductivity, and neutralization potential (Sobek *et al.*, 1978) with siderite correction (Skousen 1997).

Net acid generation (NAG) testing (EGi 2006) was undertaken on air-dried and toluene-treated tailings. The toluene-treated tailings were hydrophobic. Therefore, when the NAG reagents were first added to the samples, they were dispersed in an ultrasonic bath until streaming birefringence was observed signifying complete dispersion.

Humidity-cell tests (Price 2009) were undertaken on coke, coke ash, and air-dried tailings for a minimum duration of 20 weeks, with leachates analyzed for pH, conductivity, sulfate, acidity, alkalinity, hardness, and trace elements by ICP-MS.

Mineralogy by X-ray diffraction (XRD), with quantification by Rietveld Refinement was undertaken by the University of British Columbia on the toluene-treated tailings. Selected FTT, coke, and coke ash samples were analyzed by Laue X-ray diffraction (μ-XRD) by the Canadian Light Source Inc. at the University of Saskatchewan.

Quality Assurance

No quality issues were identified in the final data on the basis of satisfactory certified reference material recoveries, laboratory duplicates, and ion balances for leachate analyses. Analytical and data interpretation issues encountered as a result of sample hydrophobicity and organic matter content are discussed within the results.

RESULTS

Mineralogy

In MFT, DMFT, and FTT, major minerals (those greater than 10 wt%) were quartz, kaolinite, and mica. Minor minerals (1 to 10 wt%) were microcline, clinochlore, and albite. Trace minerals (those less than 1 wt%) were pyrite, siderite, calcite, ankerite, various titanium oxides, zircon, and tourmaline.

Coke was composed of refractory organic matter with no crystalline phases detected by μ-XRD. Coke ash was mostly composed of an amorphous aluminosilicate melt (69 % for bottom ash, 91 % for fly ash, 93% for combined coke ash) with crystalline phases consisting of silica (quartz and cristobalite), aluminosilicate (mullite), feldspars (microcline, and plagioclase), and titanium and aluminum oxides (pseudobrookite and hercynite, respectively). Gypsum and magnesite were also identified in the combined coke ash sample.

Acid Potential

The presence of pyrite in MFT, DMFT, and FTT indicated that it is likely to be the principal source of acidity. Total sulfur by Leco analysis was not a good measure of pyrite content due to significant sulfur concentrations being associated with the insoluble fraction (mostly organic) (Figure 1a). Sulfide determined by the ASTM D2492 method correlated well with mineralogical sulfide by XRD for DMFT and most MFT samples (Figure 1b), although the correlation was poor for FTT and three MFT samples that contained FTT. These samples were likely to have contained amorphous phases that resulted in an over-estimation of mineral sulfide by XRD due to normalization of reported mineral abundances to 100 %.

FTT had the highest sulfide content, ranging from 0.29 to 0.58 % as S. Elevated sulfide concentrations in MFT samples were associated with the presence of small amounts of FTT. Coke contained no detectable sulfide. Sulfur was inferred to be present as refractory carbonaceous matter. Coke ash contained the highest sulfate concentrations, which were present as gypsum on the basis of μ-XRD results. In fly ash, sulfate was likely to be present as iron and aluminum sulfates on the basis of contact water chemistry. Elemental sulfur was not detected but is expected based on the conditions under which the ash is formed.

Acid potential in the tailings is conventionally associated with oxidation of pyrite, whereas coke has negligible acid potential, and coke ash has acid potential associated with soluble acid sulfates and possibly elemental sulfur.

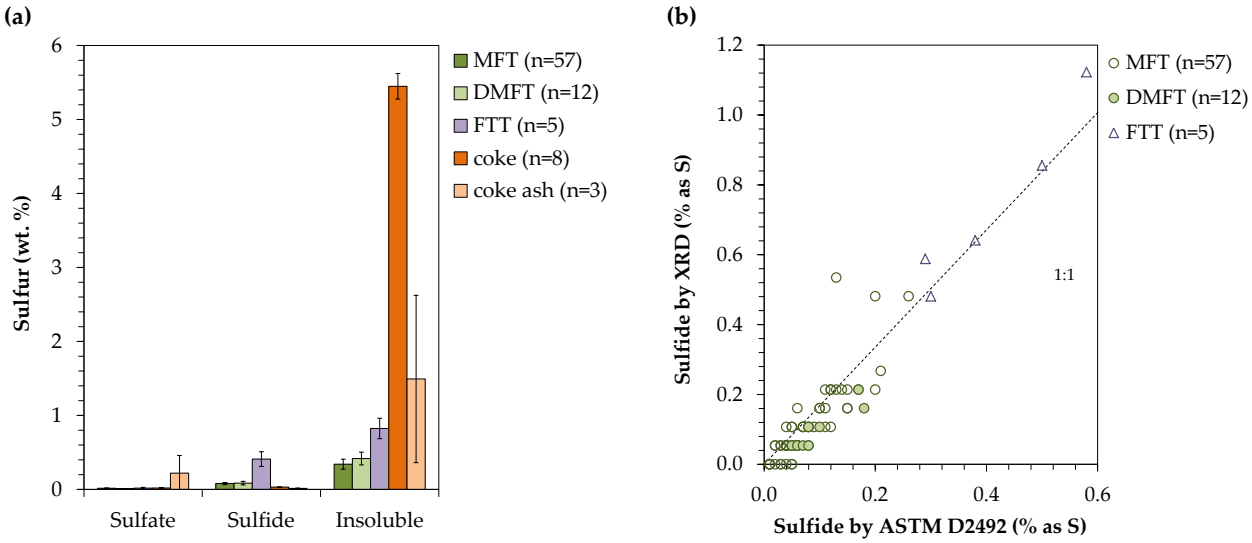

Figure 1 (a) Sulfur speciation (ASTM D2492) of oil sand tailings, coke, and coke ash presented as arithmetic average values with error bars indicating 95 % confidence intervals; and (b) comparison of sulfide concentrations in tailings as determined by ASTM D2492 and quantitative XRD

Acid Neutralization Potential

The form of neutralization potential in MFT, DMFT, and FTT was evaluated by comparing carbonate analyses, measured Sobek neutralization potentials (NPs), and carbonate neutralization potentials (CaNPs) calculated from quantitative XRD. Carbonate content was determined by difference between total carbon and residual carbon following hydrochloric acid leach. It was not correlated with carbonate content estimated from mineralogy (Figure 2a). This effect is likely attributable to the high organic carbon content and hydrophobic nature of the samples. The results of this procedure were not considered further.

XRD determinations of carbonate mineral content were used to calculate the neutralization potential associated with calcium and magnesium in calcite and ankerite (Day, 2009). Ankerite composition was assumed to be $CaFe(CO_3)_2$ for the purpose of the calculation. When compared to NP determined using the siderite-corrected method (Skousen, 1997), CaNP was correlated but generally lower (Figure 2b). Possible explanations are that the siderite-corrected NP included the influence of silicates, and that the peroxide treatment did not fully oxidize Fe^{2+} released by dissolution of siderite and ankerite. Carbonaceous matter in the samples may have competed for the hydrogen peroxide and also allowed redox to remain low. Due to these uncertainties, the mineralogical method was considered more reliable though it likely over-estimated bulk carbonate content as a result of amorphous phases in the samples.

Coke and coke ash samples had relatively low siderite-corrected NP (average 2.3 kg $CaCO_3$/t and -0.6 kg $CaCO_3$/t, respectively). Quantitative mineralogical data were not obtained. Due to the thermal process involved in converting coke to ash, carbonate minerals are not expected to be present except possibly as a result of carbonation by atmospheric CO_2 of calcium and magnesium oxides.

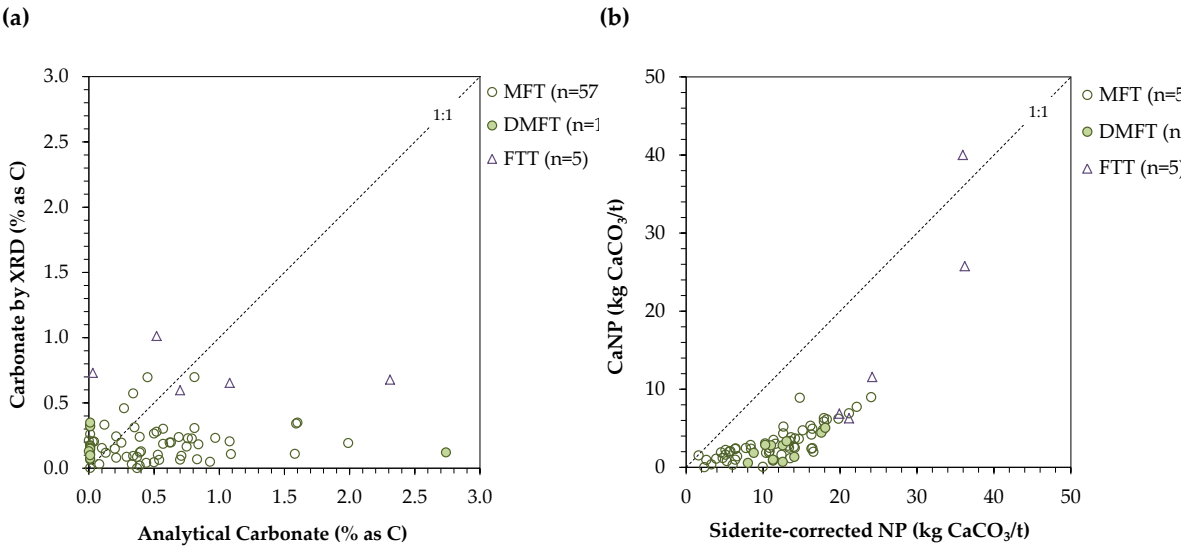

Figure 2 (a) Comparison of analytical carbonate determined as the difference between total carbon and total organic carbon, and carbonate by quantitative XRD; and (b) comparison of siderite-corrected NP and carbonate NP, whereby CaNP is calculated from calcium and magnesium-bearing carbonates

ARD Potential

ARD potential for tailings was assessed using CaNP/AP ratios. Potentially ARD-generating (PAG) tailings were defined by a CaNP/AP ratio of less than 1, whereas non-PAG tailings were defined by a CaNP/AP ratio greater than 2. CaNP/AP ratios between these limits were classified as uncertain. A value of 2 was considered to be appropriate because NP was based on Ca and Mg carbonate. Siderite-corrected NPs were not used due to their apparent tendency to over-estimate reactive carbonate NP as indicated by mineralogy. A second consideration for classification of ARD potential is that at very low sulfide content, the rate of acid generation is sufficiently slow that silicate minerals can play a role in consuming acid. For the purpose of this project, a sulfide concentration of 0.1% (acid potential 3.1 kg $CaCO_3$/t) was selected.

The majority of MFT and DMFT samples were classified as non-PAG on the basis of low sulfide content (Figure 3a). Three of the five FTT samples were classified as PAG, with variability in classification largely attributable to variable calcium and magnesium carbonate content.

In the absence of quantitative mineralogical data, ARD potential for coke and coke ash was assessed using siderite-corrected NP/AP ratios. A ratio of 3 was used to delineate uncertain and non-PAG classifications given the uncertainty in the source of NP. Coke was classified as non-PAG because it had low sulfide content (average 1.0 kg $CaCO_3$/t) and low NP (average 2.3 kg $CaCO_3$/t). Similarly, coke ash samples were low in sulfide content (average 0.4 kg $CaCO_3$/t) and NP (average -0.6 kg $CaCO_3$/t). The bottom ash and combined ash samples were non-PAG, whereas the fly ash sample was acidic (paste pH 2.8) due to the likely presence of elemental sulfur and acid sulfates.

NAG test results were compared to ARD potential classifications (Figure 3b). Samples classified as PAG by the NAG test (NAG pH < 4.5) were also classified as PAG by CaNP/AP. However, the majority of samples classified as PAG or uncertain by CaNP/AP had NAG pH greater than 4.5. The weak relationship between NAG pH and CaNP/AP may be a result of low sulfide content in the tailings, and the contribution of silicates to acid neutralization.

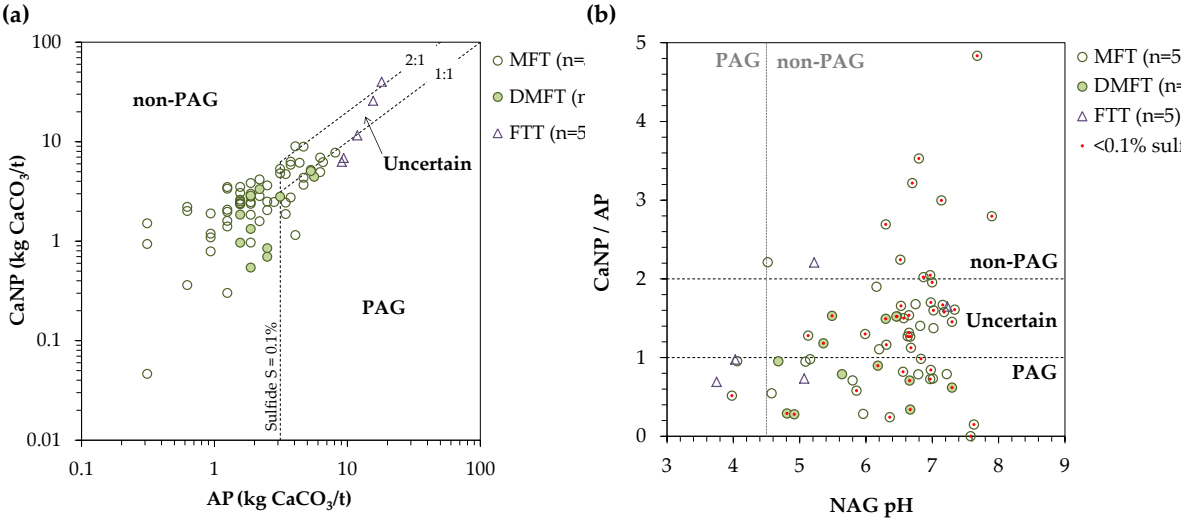

Figure 3 (a) ARD potential classifications for MFT, DMFT, and FTT; and (b) comparison of neutralization potential ratio (defined by CaNP and AP) and NAG pH

Pretreatment of the samples using the method of Dean and Stark (1920) removed bitumen prior to the NAG test. Samples pretreated to remove bitumen were characterized by greater NAG pH values than samples not subject to pretreatment (Figure 4). Sample pretreatment appears to have been effective in reducing bitumen contents and the subsequent formation of organic acids during the NAG test.

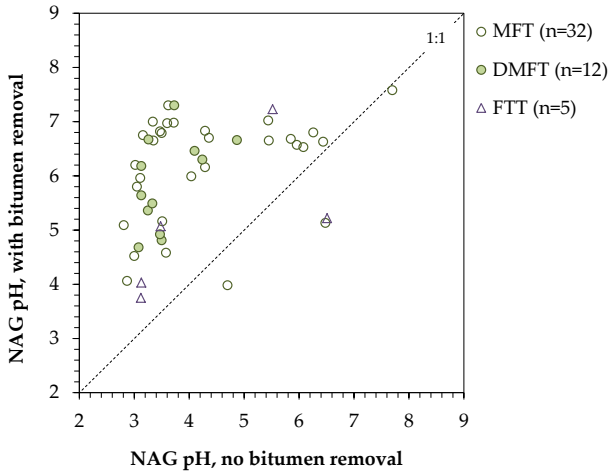

Figure 4 NAG pH before and after bitumen removal using the Dean and Stark (1920) method

Trace Element Leaching

Comparison with Global Average Values

Potential for trace element leaching was inferred by comparing concentrations in MFT, DMFT and FTT with global average values for sandstone and shale (Price 1997). The McMurray Formation is mainly sandstone but shale is locally present. As a result, tailings may have characteristics intermediate between that of sandstone and shale. Concentrations more than an order of magnitude higher than global average values were considered significant; however, potential for metal leaching needs to be considered in the context of the element-phase associations.

Relative to sandstones, cobalt, molybdenum, nickel, selenium, and uranium were enriched in MFT; cobalt and nickel were enriched in DMFT; and cobalt, molybdenum, nickel, selenium, and uranium were enriched in FTT (Table 1). These elements were not enriched relative to shale. Cobalt, molybdenum, and nickel in MFT and DMFT were correlated ($r \geq 0.78$) with insoluble sulfur and sulfide inferring an indistinguishable association with organic matter and pyrite, respectively. Cobalt ($r=0.84$) and nickel ($r=0.88$) in FTT were correlated with insoluble sulfur, whereas molybdenum ($r=0.91$) was correlated with sulfide. Uranium was correlated ($r \geq 0.96$) with titanium in all tailings implying an association with rutile, anatase, and ilmenite. These minerals are resistant to weathering and are not expected to leach uranium.

Comparison of trace concentrations in coke and coke ash with lithological average values did not yield meaningful indications of trace element leaching potential because the original minerals do not exist in these materials. The main feature of these products is the presence of percent level nickel and vanadium which occur in the organic structures of metalloporphyrins (Dechaine and Gray, 2010). Molybdenum concentrations were elevated due to the use of a Mo-based catalyst for coking.

Table 1 Element concentrations summarized as average ± 95% confidence interval

Material Type	Element Concentration (mg/kg)					
	Co	Mo	Ni	Se	U	V
MFT (n=57)	12±1.6	1.2±0.23	21±3.3	0.72±0.088	3.3±0.78	110±14
DMFT (n=12)	11±1.8	0.98±0.38	23±5.7	<0.5	3.3±1.2	99±27
FTT (n=5)	28±3.8	2.2±0.68	44±6.8	1.2±0.23	26±8	190±13
Coke (n=8)	7.2±0.49	47±2.5	370±15	n.d.	n.d.	930±41
Coke ash (n=3)	150±100	370±430	1900±600	0.63±0.26	18±13	>10000
Avg. sandstone (Price 1997)	0.3	0.2	2	0.05	0.45	20
Avg. shale (Price 1997)	19	2.6	68	0.6	3.7	130

Humidity Cells

Humidity cells are weathering tests, which provide some indication of how leaching potential correlates to concentrations in contact waters. None of the 12 tests on MFT, DMFT and FTT generated acid during the 20 weeks of testing. Tests on four PAG tailings were extended to 49 weeks, and did not generate acid. The lack of acidic conditions during the test reflects the neutralizing effects of carbonate minerals, thereby confirming their role in consuming sulfuric acid. The humidity cell tests, therefore, indicated leaching effects under neutral to slightly alkaline conditions (pH 6.3 to 8.6).

Initial humidity cell leachate chemistry was influenced by process water which is dominated by sodium, bicarbonate, and chloride. As the tests proceeded, leachate chemistry became increasingly influenced by weathering of the materials themselves including sulfate concentrations (correlated with sulfide content) and products of acid neutralization (calcium and magnesium). Increasing trends in manganese concentrations suggested that siderite was dissolving. Low leachable uranium concentrations were consistent with the expected association with chemically resistant oxides. Humidity cells on coke and coke ash generally showed leaching effects consistent with dissolution of soluble phases likely to occur in association with refractory organic matter in coke, and amorphous aluminosilicate melt in coke ash.

DISCUSSION

ML/ARD Potential of Oil Sands Processing Products

Test work performed for this study indicated that ARD potential of tailings (MFT, DMFT and FTT) is generally low because sulfide content is low relative to carbonate content. Calcite and ankerite contribute sufficient reactive neutralization potential as Ca and Mg carbonate to offset acid potential from sulfide. The exception to this general conclusion is that FTT, and DMFT and MFT containing mixed-in FTT may be classified as PAG due to the presence of pyrite. These conclusions are clearly linked to the host mineralogy of the McMurray Formation, and indicate that a site specific approach is needed to evaluate ARD potential.

Based on ABA characteristics and humidity cell test results, these oil sand tailings are expected to weather under basic conditions so that mobility of the trace constituents of pyrite (inferred to be cobalt, molybdenum, nickel, and selenium) will depend on how they speciate in waters. Cobalt and nickel are expected to have low mobility at neutral to alkaline pH, whereas the elements forming oxyanions may be more mobile. Dissolution of siderite during acid neutralization may release manganese into solution. Elements associated with carbonaceous matter (nickel and vanadium) and those associated with detrital oxides (uranium) are not expected to be mobile due to their relative stability of their hosts compared to pyrite.

Coke and coke ash contained relatively little sulfide. Coke is the most stable due to the occurrence of metals primarily hosted in refractory organic matter. Coke ash shows greater leachability due to the presence of soluble sulfate and oxide minerals.

Application of Standard ML/ARD Potential Characterization Methods

In addition to providing data on the ML/ARD potential of various oil sand tailings and bitumen upgrading by-products, this study also highlighted the challenges of applying standard methods developed for coal and metal mine wastes. One challenge was related to the hydrophobicity of the samples, which affected the application of water-based methods. For example, determining neutralization potential required the use of dispersants to break up the oil and sonification to allow the reagent to properly react with the sample. Hydrophobicity is due to the presence of bitumen in the samples, which is a source of organic carbon.

The high amounts of organic carbon relative to carbonate affected the determination of carbonate content. The use of hydrochloric acid to remove the carbonates was not effective on the basis of the poor correlation between the carbonate determinations and mineralogy. As a result, quantitative XRD may represent an alternative to the determination of carbonate mineralogy provided that measures are included to correct for the presence of amorphous matter, such as the addition of mineral standards in XRD samples.

Finally, humidity cells were used to evaluate weathering. The procedure appeared to be effective as results could be interpreted within the context of pore water leaching and mineralogical characteristics of the samples. Application of the results to site conditions requires careful consideration of sample hydrophobicity and scaling. The dominant presence of organic carbon and high moisture content of the tailings is likely to limit oxygen diffusion under field conditions.

CONCLUSIONS

The ML/ARD potential of the oil sand tailings sampled by this study and analyzed using standard ML/ARD characterization methods appears low and restricted to FTT. Metal leaching predominantly occurs under basic weathering conditions. Coke produced in the bitumen upgraders has low ARD potential but ash generated by burning coke contains soluble sulfates and oxides, some of which may be acidic. This study provides an important basis for the design of future oil sand ML/ARD characterization programs that should include careful consideration of analytical measures to address the presence of residual bitumen and associated hydrophobicity and organic carbon content.

Pyrite Oxidation Rates from Laboratory Tests on Waste Rock

Kim Lapakko[1] and Edward Trujillo[2]

1. *Minnesota Department of Natural Resources, USA*
2. *University of Utah, USA*

ABSTRACT

Fourteen samples of pyrite-bearing waste rock were characterized (particle size distribution, chemistry, mineral content, degree of pyrite liberation, extent of precipitate coating on pyrite) and subjected to dissolution testing for 52 weeks. Approximately one-kilogram samples ($0.18 \leq d < 6.25$ mm) were placed into cells similar to that described in ASTM D5744-13. The modified testing procedure was divided into three phases. First, in the leach phase, the sample was soaked with 500 mL of deionized water for one hour, after which the leachate was collected in a flask for two hours then left exposed to ambient conditions for the rest of the day. Second, a drying phase started on the second day by pumping dry air (1 L/m) into the bottom of the cell for three days. Third, after drying, the humidity cell was kept unattended with the top lid on for the remaining three days. Leachate was analyzed for pH, sulfate, a number of other solutes, and bacterial growth. Pyrite was reported to be absent from four samples, at concentrations of 0.01 to 0.1 percent in three samples, and in the range of 0.7 to 4 percent in the remaining seven samples. Rates of pyrite oxidation were determined for all samples in which pyrite was detected, using sulfate release rates during weeks 37 to 52 and the calculated exposed pyrite surface area. For samples with pyrite contents of at least 0.7 percent, the oxidation rates determined were reasonably consistent with those predicted in the literature. For this same subset, oxidation rates for samples producing acidic drainage (~3.3-3.8) were one to twelve times those for samples producing circumneutral drainage (~7.0-7.5).

Keywords: pyrite oxidation rates, kinetics, humidity cell, laboratory weathering, mine rock drainage quality prediction

INTRODUCTION

Pyrite oxidation is a major concern related to waste rock excavated during mining operations. Pyrite and other iron-bearing sulfide minerals oxidize in the presence of oxygen and water and can produce acid, as well as iron oxyhydroxides and sulfate (reaction 1). Some or all of the acid produced can be neutralized by reaction with other minerals present in the rock. The acidity of drainage from an unmitigated waste rock facility is ultimately dependent on the balance of acid-producing and acid-neutralizing reactions. If the rate of acid production exceeds the rate of acid neutralization the drainage will be acidic. Quantification of pyrite oxidation rates and the attendant acid production benefits interpretation of kinetic test data, extrapolation of laboratory data to the field, and is required to model waste-rock drainage quality based on waste-rock composition.

$$FeS_{2(s)} + 3.75O_2 + 2.5H_2O \rightleftharpoons FeOOH_{(s)} + 2SO^{-2}_{4(aq)} + 4H^{+}_{(aq)} \quad (1)$$

Monomineralic dissolution studies have been conducted to determine rates of pyrite oxidation in oxygen saturated water (Williamson and Rimstidt, 1994) and in the presence of moist air (Jerz and Rimstidt, 2004). Using a method approximating that of Option B of ASTM D5744-13e (ASTM International 2013) for weathering a suite of greenstone rock samples, Lapakko and Antonson (2006) attributed sulfate release to oxidation of pyrite in the fine fraction in which water was retained. The pyrite oxidation rates determined were in good agreement with those presented by Williamson and Rimstidt (1994) for abiotic oxidation of pyrite by oxygen.

Jerz and Rimstidt (2004) conducted laboratory experiments at 25 °C, 96.7 % relative humidity, and oxygen partial pressures of 0.21, 0.61, and 1.00 atmosphere (atm). They derived the following expression for the rate of pyrite oxidation in moist air:

$$\frac{dFeS_2}{dt} = 10^{-6.6} P^{0.5} t^{-0.5} \quad (2)$$

where, $dFeS_2/dt$ is the rate of pyrite oxidation (mol m^{-2} s^{-1}), P is the partial pressure of oxygen (atm) and t is time in seconds. They reported that the reaction rate decreased over time due to formation of a precipitate layer on the mineral surface that inhibited oxygen transport.

The present humidity-cell studies were conducted using a one-day period for rinsing and draining of the cell followed by a three-day period during which dry air was introduced to the cell. After the drying cycle samples were retained undisturbed in the cells. The conditions for pyrite oxidation were consequently much dryer than those used by Lapakko and Antonson (2006), and may simulate conditions near the boundary of waste rock piles in an arid environment. The following

sections investigate pyrite oxidation rates for 10 waste-rock samples under these conditions and compare them to rates published for monomineralic pyrite oxidation studies.

METHODS

Materials

Fourteen rock samples for humidity-cell testing were collected from waste-rock piles (7 samples), outcrops (6 samples) and scars (1 sample) at the Questa molybdenum mine in northern New Mexico (Chevron, 2005). Samples from the waste-rock piles were collected from trenches (McLemore et al., 2005), homogenized and sieved to obtain the size fraction finer than 6.35 mm (McLemore et al., 2008). Rock samples were staged crushed with 1.27- and 0.635-cm jaw crushers to obtain the -0.635 cm size fraction (McLemore et al., 2008). Due to concerns regarding flow transmission during humidity-cell testing, all samples were dry-sieved to remove the fraction finer than 0.18 mm prior to testing. Dry sieving employing 12 Tyler screens was used to determine particle size distributions of the bulk sample, the sample submitted for humidity-cell testing, and the samples following termination of the humidity-cell tests.

The resultant samples were subjected to chemical, mineralogic, and petrographic analysis (McLemore et al., 2008; 2009). Mineral Services (2008) provided descriptions of hand samples, microscopic analysis of thin sections, Rietveld x-ray diffraction analyses, and analyses by scanning electron microscopy (SEM) with energy-dispersive x-ray spectrometry (EDS). Pyrite contents used in the present paper were selected based on consideration of chemical analyses and mineralogic analyses by both New Mexico Tech and Mineral Services. Pyrite grain-size distributions (McSwiggen, 2008a) and the extent of pyrite coating were also determined (McSwiggen, 2008b).

Humidity Cell Tests

Humidity-cell testing was performed at room temperature using a modified version of ASTM D5744-13e (ASTM International, 2013) for one year. Approximately one kilogram of sample was charged to each cell. The modified testing procedure was divided into three phases, i.e., (1) leach phase, (2) drying phase and (3) stand-alone phase over a seven-day cycle. During the first day (the leach phase), 500 mL of deionized water (or synthetic water) was delivered to the cell from the separatory funnel and the sample was allowed to soak for one hour. The leachate was then collected in a flask for two hours, after which the humidity cell was left undisturbed. Leachate was analyzed (1) directly for temperature, pH, and Eh; (2) after filtration (0.45 μm) for sulfate, fluoride, and ferrous iron; and (3) after filtration and acidification (ultrapure nitric acid) for cations. The drying phase started on the second day by pumping air dried to a dew point of -40 °C (Balston model 76-10 membrane air dryer) at 1.0 liter/minute from the bottom of the cell for three days. After drying, the humidity cell was left alone for the remaining three days. Dry air flow rates, temperatures, pressure drops and humidity were measured for each cell periodically. Cell masses before and after the leach and after the dry-air portion of each weekly cycle were determined.

Samples used for the GHN-KMD-0088 cells were inoculated and analyzed for bacteria growth at weeks 5, 26, 38, 50, and 52. All leachate samples were analyzed in duplicate using MPN tests at 24 °C (Richins et al. 2008). The microbial humidity-cell inoculum was produced from rock samples from the mine that were provided for characterization and inoculum production. The inocula were produced using characterized media for enhanced growth of each general population group. The inocula were a unique composite of separately produced populations of (1) general heterotrophic species, (2) general sulfate-reducing species, (3) general *Acidithiobacillus* and *Leprotspirillum* species, (4) general acidophilic species, and (5) general *Archaea* species. The inocula contained concentrations of the five generalized population groups that mirrored the relative concentrations in the original sample.

Calculations

Pyrite grain size and liberation were determined in two steps (McSwiggen 2008a). First, the average pyrite grain size was determined for particles with diameters ranging from roughly 1 to 3 mm. The image analysis program NIH ImageJ was used to interpret backscatter electron signals collected using a JEOL 8600 Electron Probe Microanalyzer. The image analysis program identified sulfide mineral grains and determined the longest length, perimeter, and area of each grain. The "circular diameter" (diameter assuming a circular particle = 4 x particle area/particle perimeter) of each particle and total grain area present were calculated. The resultant data were sorted from smallest to largest particle area, and the percent cumulative areas for the sorted grains were calculated. The median grain diameter was defined as the circular diameter for which the percent cumulative area was 50. The probability of a sulfide grain being exposed was then calculated using the following equation:

$$P = 100 - 100[(R_1 - R_2)^2/R_1^2] \quad (3)$$

P = probability of sulfide grain being exposed,

R_1 = radius of host rock grains,

R_2 = median radius of all pyrite

Rates of pyrite oxidation were determined by dividing molar rates of sulfate release by twice the liberated pyrite surface area. Sulfate release rates were determined for periods from 6 to 9 and 37 to 52 weeks. The rate for a specific period was calculated by averaging the weekly sulfate release rates observed during the period.

The exposed pyrite surface area of a sample was determined by summing the exposed pyrite surface area in each particle size fraction, which was calculated as follows:

$$A_{py,i} = \left(\frac{\%FeS_2}{100}\right)\left(\frac{6}{\rho\, d_{gm,i}}\right)\left(\frac{M_i\, L_i\, (SR)}{100}\right) \quad (4)$$

where

$A_{py,i}$ = pyrite area in particle size fraction i, m^2,

$\%FeS_2$ = percent pyrite of sample, assumed to be constant among size fractions,

ρ = pyrite density = 5.02×10^6 g m^{-3},

$d_{gm,i}$ = geometric mean diameter of particle size fraction i, m,

M_i = mass of rock in particle size fraction i, g,

L_i = percent pyrite exposure in particle size fraction i, and

SR = surface roughness factor for pyrite estimated as 4.9, the mean of five literature values presented by Lapakko and Antonson (2006).

RESULTS

Rock Characterization

The rocks examined were collected from rock piles and outcrops at the Questa mine site and reflected characteristics of the andesitic lava and rhyolitic ignimbrite rocks at the site (Dunbar, Heizler & Sweeney, 2008). Mineralogical analyses indicated that pyrite was absent from four of the samples and this paper will focus on the remaining ten samples. Six of these samples were from rock piles and four were collected from outcrops. Six of the samples were classified as andesite and four as rhyolite, with respective QSP alteration ranges of 0 to 90 percent and 0 to 70 percent (McLemore et al. 2008).

Particle size distributions for the humidity cell samples revealed that one to five percent of the sample mass was generally finer than 0.18 mm. Samples had been dry-sieved with the intent of removing this fraction but this method was not entirely effective. In particular sample BCS-VWL-0004 had about seven percent reporting as finer than 0.18 mm. Particle size distributions for five of the samples appeared to provide a central tendency for these data. The respective ranges for percent finer than 1.7 mm and 0.5 mm for these samples were 36 to 47 percent and 14 to 17 percent. Two samples were coarser and three finer than these samples.

Major whole rock components (and typical ranges) were SiO_2 (60-70 wt. %), Al_2O_3 (13-14 wt. %), total FeO and K_2O (both 3-5 wt. %). Respective sulfide and sulfate content ranges for the samples were 0.03-2.49 wt. % and 0.04 to 0.55 wt. % (Table 1). Although carbon contents of eight of the ten samples did not exceed 0.07 percent, one value was reported as 1.58 wt. % for a sample in which wood fragments were detected (BCS-VWL-0004; Table 1). Quartz was typically the dominant mineral present (19-51 wt. %), and other major minerals were potassium feldspar (5-27 wt. %), illite-sericite (9-33 wt. %), and plagioclase (<1 – 30 wt. %) (McLemore et al. 2008).

Pyrite was the dominant sulfide mineral present, with jarosite and gypsum observed in some samples (Table 1). New Mexico Tech estimated jarosite and gypsum contents based on the sulfate content determined by chemical analysis, but the presence of these minerals was verified by petrographic examinations in six and two samples, respectively. Similarly, calcite contents were estimated assuming all carbon was present as calcite but its presence was verified in only three samples (Table 2).

Pyrite contents ranged from 0.01 to 4 wt. % (Table 1). Based on examination of 89 to 1033 pyrite grains per sample, median pyrite diameters ranged from 12 to 1100 μm (Table 1). It should be noted that the median values were selected as the 50th percentile of cumulative area, and they do not reflect the large number of very fine pyrite grains in the samples. The percentage of pyrite particles finer than 10 μm ranged from roughly 60 to 90 percent. However, with one exception, the fraction of the total pyrite surface area contributed by this fine fraction did not exceed 7.2 percent. Based on the particle size distribution, the pyrite content, and the median pyrite grain size, liberated pyrite surface areas in the samples typically ranged from about 0.02 to 0.2 m^2 (Table 1). Coatings of 6 to 7 μm thickness were reported on three of the samples. The primary chemical constituents of the coatings were FeO (74-80 wt. %), SiO_2 (9-16 wt. %), CaO (3-5 wt. %), and SO_3 (0-14 wt. %).

Humidity Cell Tests

As mentioned earlier, humidity cell testing was conducted at room temperature using compressed air, dried to zero humidity. This resulted in some cells being completely dried during the dry-air cycle. However, this did not happen consistently. Sometimes the residual water saturation would go to zero while for other weeks it would remain high. This can probably be attributed to preferential gas flow paths developing over time in the cells or a decrease in the air flow rate caused by uneven pressure distribution. Thus it is difficult to say how much moisture was present over the seven-day period for pyrite oxidation for each cell over time.

Initial pH values from five of the samples were in the range of 2.3-2.9, three ranged from 3.1-4, and the remaining two were 6.5 and 6.8. These values reasonably reflected those determined by McLemore et al. (2008) for paste pH (Figure 1). The pH reflected three trends: a neutral/basic group (pH 6.5-8.0), composed of SPR-JWM-002 and PIT-VTM-0600, a pH 5-6 group (BCS-VML-004), and an acidic group (pH 2.5-4.5) (Figure 2). The reproducibility of duplicated samples, SPR-JWM-002, GHN-KMD-0088 and GHN-JRM-0001 is demonstrated in Figure 2. Most cations and anions showed relatively high concentrations in the first few weeks of the humidity cell test, which is attributed to the initial pore water quality, the reaction of very small fines and soluble salts. Total iron concentrations generally corresponded with pH, with the lowest pH cells having the highest

iron concentrations and cells producing neutral or basic pH yielding iron concentrations at or below detection limits.

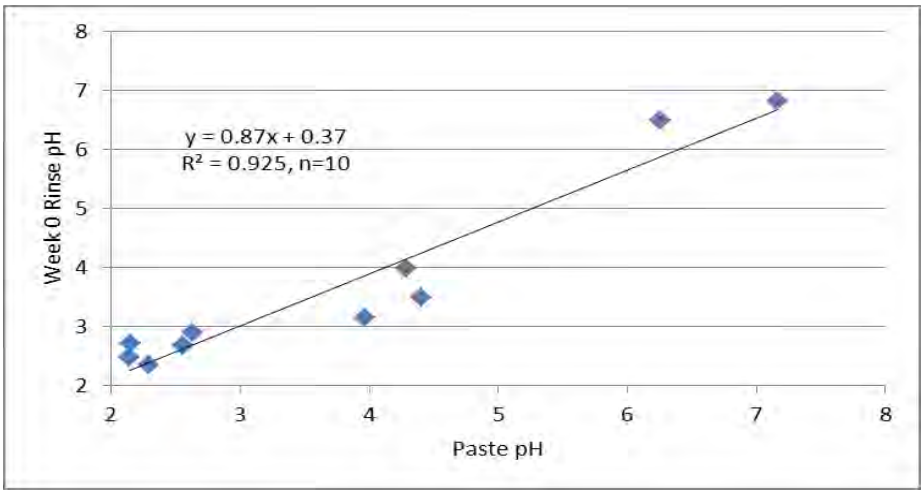

Figure 1 Effluent pH at week 0 correlated closely with paste pH.

Sulfate concentrations decreased rapidly in the initial stages of the experiment, reflecting removal of residual oxidation products generated during sample storage and preparation, as well as oxidation of highly reactive particles. In particular, such reaction could include oxidation of fine particles with high specific surface areas. Sulfate release ultimately plateaued toward the end of the period of record for most samples (Figure 2). Drainage quality for most samples was fairly stable after week 37, although release from some continued to oscillate within a constant range or decline slowly.

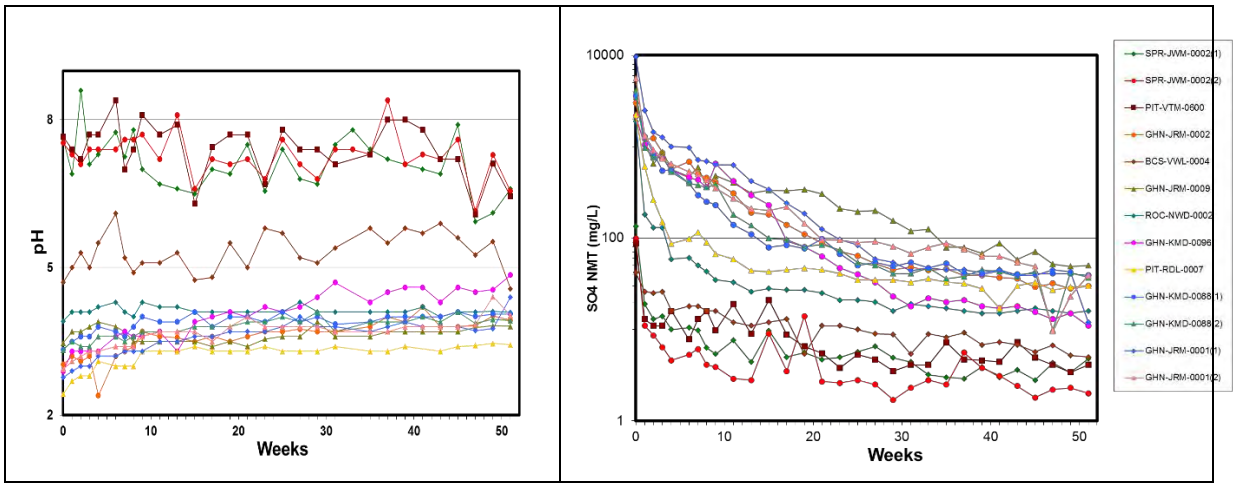

Figure 2 pH and sulfate concentration over time for all 10 samples. SPR-JWM-0002, GHN-KMD-0088 and GHN-JRM-0001 were run in duplicate.

Average sulfate release rates for weeks six through nine were calculated as an indicator of the rate of sulfate release after the initial rapid release, and the interval from week 37 to 52 was selected to represent a period of "fairly stable" sulfate release (Table 2). Ratios of the latter rate to that observed during weeks 6-9 was calculated to describe the degree to which sulfate release rates declined over the period of record. The ratios fell into two general ranges: 0.04-0.1 and 0.3-0.5 (Table 2). The lower range was associated with samples collected from trenches at the Goat Hill North rock pile. These samples were finer-grained materials that had been subjected to oxidation in the field for 30 to 35 years (McLemore et al., 2009). The remaining samples were generated from crushing larger rocks. The finer-grained Goat Hill North samples likely contained more labile sulfate generated from weathering in the field than the rock samples. The relatively rapid release of this sulfate resulted in a larger decline in sulfate release rates for the weathered samples. The trench samples also generally produced large changes in pH over this period, suggesting that the sulfate source was an acidic mineral rather than, for example, gypsum. Solid-phase analyses do not provide convincing corroboration for this suggestion (Table 1). Samples generating neutral or basic pH tended to produce low sulfate concentrations, whereas more acidic leachates generally had elevated sulfate concentrations. However, GHN-JRM-0009 consistently produced much higher sulfate concentration than the PIT-RDL-0007 despite a consistently higher pH.

Bacteriological results showed that sulfate-reducing bacteria and heterotrophic bacteria grew over time in all cells, even the ones not inoculated, however the *Acidithiobacillus* and *Leptospirillum sp*. were only detected in low numbers in a few of the cells (Richins et al. 2008). This may be due to lack of nutrients or the loss of microbes by pure water washes. Thus, it appears that *Acidithiobacillus* did not play a significant role in these humidity cells and pyrite was primarily oxidized abiotically by oxygen.

Pyrite oxidation rates were calculated for all ten samples based on the average weekly rates of sulfate release between weeks 37 and 52 and the calculated liberated pyrite surface area. Rates determined for two of the three samples in which pyrite content was reported as 0.1 percent or less were considerably higher than those for the remaining samples. The pyrite content of the latter seven samples ranged from 0.7 to 4 wt. %, and the following discussion focuses on the pyrite oxidation rates determined for these samples.

Table 2 Humidity cell data summary. Shaded values of dpy/dt indicate py ≤ 0.1 wt %.

[1] Initial rinse pH, arithmetic mean used for duplicate cells.

[2] Arithmetic mean pH, weeks 6-9.

[3] Arithmetic mean pH, weeks 37-52.

[4] Sulfate release rate, week 0, mol s^{-1} x 10^{-10}; assumes one week reaction time.

[5] Average sulfate release rate, weeks 6-9, mol s^{-1} x 10^{-10}.

[6] Average sulfate release rate, weeks 37-52, mol s^{-1} x 10^{-10}.

[7] Ratio of average sulfate release rate for weeks 37-52 to that for weeks 6-9.

[8] Average pyrite oxidation rate, weeks 37-52, mol m^{-2} s^{-1} x 10^{-10}.

The resultant oxidation rates ranged from 0.8 x 10^{-10} to 9.8 x 10^{-10} mol m^{-2} s^{-1}, with all but one value exceeding 2 x 10^{-10} mol m^{-2} s^{-1} (Table 2). The calculated rates exhibited a mild dependence on pH although this dependence must be viewed with caution. The data fall into two clusters at roughly pH 3.5 and 7.3 (Figure 3). The intent of this analysis was to aid in description of the data and not to deduce a mechanistic interpretation. It should further be noted that the two points near pH 7.3 were both generated by samples in which pyrite coatings of 6-7 μm were detected. These coating likely contributed to the lower oxidation rates observed for these samples.

The pyrite oxidation rates observed were lower than those reported for oxidation of pyrite present in greenstone samples (Lapakko and Antonson 2006) (Figure 3). Using the two linear regressions as descriptors, the Questa oxidation rates are about 30 to 60 percent of those for the greenstone samples. One factor contributing to this discrepancy is the difference in reaction conditions between the two experiments. In the greenstone experiments, no air was introduced to the humidity cells, and typically 130 to 150 mL of water was retained in the cells throughout the weekly cycle. Pyrite

oxidation in this experiment was described as occurring in the fine fraction of rock particles that were in contact with oxygen saturated water. This was consistent with the agreement of observed rates with those reported by Williamson and Rimstidt (1994).

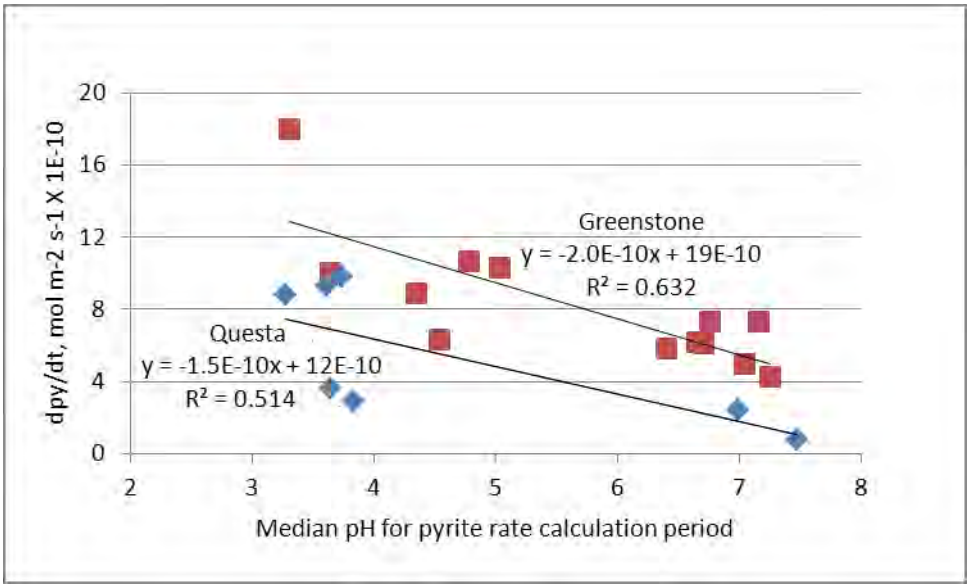

Figure 3 Pyrite oxidation rates for the Questa samples were lower than those reported for greenstone samples (Lapakko and Antonson 2006). The drier oxidation conditions of Questa samples during the weekly cycle likely contributed to the lower rates.

In contrast, the cells in the present study were subjected to three days of dry air following the day during which samples drained. During this day, oxidation likely occurred in the presence of oxygen saturated water. During the next three days water evaporated from the cell, sometimes to total dryness. Thus, during this period, oxidation could occur with pyrite grains in contact with oxygen saturated water, water saturated air as observed by Jerz and Rimstidt (2004), or with air of variable water saturation. Because it is not possible to confidently describe the precise reaction conditions, oxidation rates for several possible conditions were calculated to compare theoretical rates (i.e. Williamson and Rimstidt 1994 and Jerz and Rimstidt 2004) with those observed. The overall range of rates calculated for various time periods for abiotic oxidation by oxygen in water and oxidation in humid air was 0.3 x 10^{-10} to 7.2 x 10^{-10} mol m^{-2} s^{-1}. The observed range for the samples in this study was 0.8 x 10^{-10} to 9.8 x 10^{-10} mol m^{-2} s^{-1}, within or slightly above the theoretical range.

SUMMARY

Rates of pyrite oxidation were determined for seven waste rock samples subjected to humidity cell testing for one year based on observed rates of sulfate release and liberated pyrite surface area.

Liberated pyrite surface area was determined using pyrite content and size distributions of pyrite grains and the rock subjected to testing. The equation used for this determination yielded rates that were consistent with those reported in the literature for samples with pyrite contents between 0.7 and 4 percent. For two samples with pyrite contents near 0.1 percent, the calculated rates were one and three times those for the samples of higher pyrite content. The oxidation rate for a sample with a reported pyrite content of 0.01 percent was almost three orders of magnitude above the range for higher pyrite contents. This suggests that the method yields reasonable results for sample with pyrite contents above 0.1 percent, but for samples with lower pyrite content the method has limitations. For samples of low pyrite content the method may underestimate the liberated pyrite surface area surface area due to low pyrite concentrations or the occurrence of pyrite as very fine grains on rock surfaces. Alternatively, a highly reactive sulfide or sulfate mineral may have been present at low concentrations in these samples.

ABSTRACT

It is generally recognized that acid and metalliferous drainage (AMD) occurs as a result of oxidative dissolution of iron-containing sulfide minerals, while oxidation of sulfides containing low or no iron such as sphalerite or galena do not generally result in highly acidic drainage, but may lead to elevated concentrations of sulfate and metals., e.g. Zn, Pb. Therefore common understanding suggests that the amount of iron sulfide present in an ore deposit or mine waste plays a crucial role in determining the characteristics of the mine drainage. It is generally less appreciated that the oxidative behavior of different iron sulfide minerals varies appreciably, and the characteristics of mine drainage depends markedly on the particular iron sulfide minerals present.

In order to quantify differences in the oxidative behavior of pyrite and pyrrhotite-containing wastes, both simulated sulfidic mine wastes and actual mine tailings were leached under kinetic leach column test conditions. Synthetic mine wastes containing 5 wt% pyrite or pyrrhotite, together with 5 wt.% chlorite, 10 wt.% amazonite and 80 wt.% quartz, produced 71 % and 6 % respectively of the expected acidity based on acid base accounting during 120 weeks of leaching. Nickel mine tailings containing nearly 30 % pyrrhotite also produced much lower than expected acidity (<1 %) after 107 weeks of leaching.

Sulfur speciation analysis of both solids and the drainage demonstrate that, for both the simulated pyrrhotite mine waste and the nickel mine tailings, around 85 % of the oxidized sulfur converted to elemental sulfur, a reaction path which does not generate acidity. In contrast, for the simulated pyrite mine waste, only 2 % of the oxidized sulfur converted to elemental sulfur, with the majority oxidising through to sulfate. While elemental sulfur can further oxidize to sulfate with concomitant acid production, this reaction is very slow in the absence of oxidative bacterial catalysis. Analysis of the oxidized zone of the nickel mine tailings storage facility also demonstrated the predominant oxidation product to be elemental sulfur, suggesting that even in field conditions, pyrrhotite oxidation will likely produce significantly less acidity than is predicted by standard AMD assessment methods.

Keywords: pyrite, pyrrhotite, acid potential, elemental sulfur

INTRODUCTION

In the assessment of the acid generating potential of a mine waste material, the initial screening method usually includes acid base accounting (ABA) and, in some cases, the net acid generation (NAG) test (INAP, 2009). In its most basic form, ABA includes calculation of the acid potential (AP) of a waste usually by determining the sulfide content of the material. The use of sulfide content without further distinction between the various sulfide minerals is based on the abundance of iron sulfides, particulalry pyrite, in mine wastes. AP is then calculated from the sulfide sulfur content based on the stoichiometry of the reaction of pyrite with oxygen and water to produce one mole of sulfuric acid per mole of sulfur. It is generally regarded that other iron sulfides such as pyrrhotite, marcasite and arsenopyrite will also react simiarly to produce acid, while some sulfides such as sphalerite and galena, which can undergo oxidative dissolution to release metal ions and sulfate without iron oxyhydroxide precipitation, may not produce much if any acidity (INAP, 2009, MEND, 2009, DTIR, 2007).

Under the conditions of the accelerated oxidation NAG test (hydrogen peroxide), results from testing of various individual sulfide minerals suggest that all iron sulfides react in a similar way to pyrite, producing one mole of sulfuric acid per mole of sulfur (Stewart et al., 2003, Jennings et al., 2000). Therefore in the use of these simple screening methods for assessment of acid potential, there is generally no consideration given to different potential reaction pathways for oxidative dissolution of the various iron sulfides and the possible effects of these reaction pathways on drainage chemistry. However, a number of studies have identified that, unlike the oxidative dissolution of pyrite where sulfate is invariably the major final product of sulfide oxidation, during oxidation of pyrrhotite signficant quanities of elemental sulfur have been identified (Cruz et al., 2005, Belzile et al., 2004, Mikhlin et al., 2002, Kalinkin et al., 2000, Nicholson & Scharer, 1994). In addition to laboratory studies, investigations into weathering of pyrrhotite in site tailings storages have shown that elemental sulfur is present as a result of pyrrhotite oxidation (McGregor et al., 1998, Janzen et al., 1997).

Table 1 shows some potential overall reaction pathways for the dissolution of pyrite and pyrrhotite, ranging from oxidative dissolution to produce iron oxyhydroxide and sulfate (2 moles H^+ produced per mole S) to non-oxidative dissolution to hydrogen sulfide (2 moles H^+ consumed per mole S). It is clear from these equations, that the pathway(s) along which iron sulfide dissolution occurs will influence the amount of acidity produced (or consumed) with direct conseqence on drainage quality. It is also apparent that if oxidation of pyrrhotite proceeds only as far as elemental sulfur, then no proton acidity will be produced. If this reaction pathway becomes the dominant path for oxidative dissolution, then AP and NAG measurements will likely greatly over estimate the amount of acidity that can be expected from pyrrhotite containing waste matereials.

In order to determine and quantify the different reaction pathways of various sulfide minerals during oxidation, we have investigated the behavior of simulated mine wastes containing various sulfides including pyrite and pyrrhotite using kinetic leach column tests (AMIRA 2002). At the same time, as part of investigations into the geochemistry of tailings in the tailings storage facility (TSF) at the Savannah Nickel Mine (SNM) in the Kimberly region of Western Australia (Robertson et al. 2015), we have studied the oxidative behaviour of pyrrhotite-containing tailings both in laboratory leach columns and *in situ* in the SNM TSF. This paper details the results of these investigations, including quantification of the relative amounts of various reaction products and the subsequent acidity produced.

Table 1 Different reaction pathways for oxidative and non-oxidative dissolution of pyrite and pyrrhotite and the corresponding number of protons released per S

Product	Sulfide	Reaction	H^+ Released/S	H^+ Stored/S
Goethite & sulfate	Pyrite	$FeS_2 + 3.75O_2 + 2.5H_2O \Rightarrow FeOOH + 2SO_4^{2-} + 4H^+$	2 (100%)	0 (0%)

Goethite & jarosite	Pyrite	$FeS_2 + 3.75O_2 + 2.5H_2O + 1/3K^+ \Rightarrow 1/3KFe_3(SO_4)_2(OH)_6 + 4/3SO_4^{2-} + 3H^+$	1.5 (75%)	0.5 (25%)
	Pyrrhotite	$Fe_{(1-x)}S + 0.75(3-x)O_2 + 0.5(3-x)H_2O + 1/3(1-x)K^+ \Rightarrow 1/3(1-x)KFe_3(SO_4)_2(OH)_6 + 1/3(1+2x)SO_4^{2-} + (1+x)H^+$	1+x (55% for $Fe_{0.9}S$)	1-x (45% for $Fe_{0.9}S$)
Goethite & elemental sulfur	Pyrite	$FeS_2 + 0.75O_2 + 0.5H_2O \Rightarrow FeOOH + 2S$	0 (0%)	2 (100%)
	Pyrrhotite	$Fe_{(1-x)}S + 0.75(1-x)O_2 + 0.5(1-x)H_2O \Rightarrow (1-x)FeOOH + S$	0 (0%)	2 (100%)
Sulfide	Pyrrhotite	$Fe_{(1-x)}S + 2H^+ \Rightarrow (1-3x)Fe^{2+} + 2xFe^{3+} + H_2S$	-2 (-100%)	4 (200%)

METHODOLOGY

Kinetic leach column tests using simulated sulfidic mine wastes

To compare the oxidative behaviour of pyrite and pyrrhotite under conditions that might be comparable to the oxidative zone of a waste rock storage facility, simulated sulfidic mine wastes containing either pyrite or pyrrhotite were subjected to leaching for a period of 120 weeks. In addition to 5 wt.% sulfide, the simulated sulfidic wastes also contained 5 wt.% chlorite, 10 wt.% amazonite and 80 wt.% quartz. Leaching was conducted using the standard kinetic leach column method (AMIRA 2002).

All of the individual mineral samples used for producing the simulated sulfidic mine wastes were characterized by bulk assay and quantitative XRD analysis. The results show that pyrite and quartz were essentially pure minerals (>98%). The pyrrhotite sample contained 65 wt.% pyrrhotite, 10 wt.% pentlandite and 8 wt.% chalcopyrite. Scanning electron microscopy (SEM) analysis using energy dispersive x-ray spectroscopy (EDS) suggested an average iron content of 46.5 atomic % in the pyrrhotite, which is close to that for the iron deficient monoclinic pyrrhotite Fe_7S_8. Analysis results for the chlorite sample indicate it contained around 75% chlinoclore, with 15% quartz and 10% albite. The amazonite was an 80:20 mixture of microcline and albite.

Kinetic leach column tests using pyrrhotite tailings from SNM

Quantitative XRD analysis of the fresh tailings from SNM indicated a pyrrhotite content of 29.1%, which, if it is assumed that the sulfide content is 11.4% (Total S 11.5% - sulfate S 0.1%), is very close to the 29.3% pyrrhotite calculated from the sulfide S content assuming a formula of $Fe_{0.90}S$ for the pyrrhotite determined by EDS analysis. SEM-EDS analysis identified essentially pyrrhotite as the only sulfide, with very minor amounts of mackinawite ($(Fe, Ni)_{(1+x)}S$). No pyrite was found. XRD analysis using a high intensity, high resolution synchrotron source indicated the pyrrhotite in the fresh tailings was around 90% hexagonal, consistent with an average iron content of 47.4 atomic % ($Fe_{0.90}S$).

XRD analysis identified both anthophyllite and ferroan enstatite as magnesium bearing silicates in the tailings. SEM analysis confirmed the presence of magnesium iron silicate phases, which are likely to contribute significantly to the neutralising potential (NP) of the tailings. Inorganic carbon analysis indicated there are no carbonates in the fresh tailings (inorganic C <0.02%).

Fresh tailings collected from the SNM concentrator were placed into columns 150 mm diameter by 600 mm height. The columns were constructed in four segments, each segment containing liquid and solids sampling points. The tailings were placed into the columns as slurries in process water as received. Approximately 15 kg of tailings (dry weight) were packed into each column. After allowing the bed to consolidate, water was allowed to drain from the columns. The consolidated tailings bed had a porosity of close to 0.40, similar to that estimated for the tailings in the SNM TSF.

KLC tests were run with tailings at 50 and 75 % average saturation. However, after allowing Column 1 (target 50 % saturation) to drain under gravity for four months the average degree of saturation of the tailings bed had not dropped below 75 %, presumably due to the high suction pressure of this material. Following the first flush, Column 1 was allowed to drain until no further water was collected. Vacuum was then applied to the column until sufficient water was removed to give an average degree of saturation of 50%. After about six months of operation, it was found that small volumes of water were required to be added to Column 2 to maintain 75% average saturation.

Flushing of the tailings was achieved by adding 3 L of deionized water to the columns and allowing the flush water to remain in the column for 24 h prior to draining. Water was collected in clean plastic-lined foil bags so that air was excluded during collection. pH and oxidation-reduction potential (ORP) measurements were made at each of the liquid sampling points (top, middle and bottom segments) for each column immediately prior to collection of the flush water. Flushes were conducted at weeks 16, 26, 39, 52, 65, 78, 91 and 107. Solids were sampled from each segment following flushes at weeks 26, 52, 78 and 107. Approximately 10 g of wet solids were removed from each sampling point by inserting a hollow tube through the entire width of the column. The samples were weighed and then dried under vacuum at 50°C prior to analysis.

Characterization of sulfur species in tailings from SNM

Core samples from TSF1 at SNM were collected using a drilling rig fitted with an auger bit in which the core was collected in 40 mm diameter tubes, each of 700 mm length. Using this method, the cores had very limited exposure to air during sampling and no drilling water was used so pore water was not diluted during sampling. Samples from the drill holes were bagged immediately in air tight plastic bags and transported to the metallurgical laboratory on site as collected.

Measurements including pore water pH, Eh and dissolved oxygen (DO) were made in a glove bag under an argon atmosphere. Remaining pore water was filtered and appropriately preserved and then transported to our laboratories in Adelaide. The remaining core samples were frozen and transported to Adelaide without thawing. Samples were stored frozen until they were analysed when they were thawed and a portion dried under vacuum at 50°C.

Analysis of column leachates and solids, and tailings storage facility pore waters and solids

Samples of simulated sulfidic mine waste, fresh tailings and TSF core samples from SNM were characterized using standard static test procedures (NP, total S, chromium reducible sulfur (S_{CR}), NAG) in addition to mineralogical analysis by quantitative XRD and SEM-EDS analyses. Sulfur speciation analysis was conducted on both fresh tailings and on samples of weathered tailings from

the kinetic leach column tests and on core samples collected from the SNM TSF. Sulfur speciation analysis was also conducted on solids removed from the kinetic leach column tests conducted on simulated sulfidic mine wastes after 120 weeks of leaching.

NP and NAG analyses were conducted according to the methods described in the AMIRA ARD Test Handbook (AMIRA 2002). S_{CR} analysis was conducted using the method of Sullivan et al. (2004). Sulfur speciation analyses were carried out using the methods of Li et al. (2007) and Stewart et al. (2009). Because of the high concentration of pyrrhotite in the SNM tailings samples, it is likely that pyrolysis of the tailings does not result in complete removal of the pyrrhotite (Li et al., 2007). Therefore a portion of the pyrrhotite would report as HCl extractable sulfur which also includes insoluble sulfates such as jarosite. Consequently HCl extractions were not conducted and estimates of jarosite content were not made. Determination of elemental sulfur was achieved by extraction of the solids with acetone followed by analysis of the extract by liquid chromatography (McGuire and Hamers, 2000).

RESULTS AND DISCUSSION

Kinetic leach column tests using simulated sulfidic mine wastes

During KLC testing of the simulated sulfidic mine wastes containing pyrite and pyrrhotite, coloration of the pyrrhotite waste suggested significant oxidation had taken place, but acidity measured in leachates was surprisingly low in comparison to the expected acidity based on either ABA or NAG tests (Table 2). In an attempt to understand the lower than expected leachate acidity, sulfur mass balance was undertaken to determine reaction pathways of sulfide oxidative dissolution. Sulfur mass balance included sulfur species contained in leachates, sulfur in acetone extracts of solids (elemental sulfur) and sulfur species in 1M KCl extracts of the solids (soluble sulfates, e.g. gypsum, melanterite, etc.).

Based on sulfur mass balance undertaken at 120 weeks of leaching, less than 20 % of pyrite and more than 70 % of pyrrhotite had undergone oxidation, consistent with the visual evidence that suggested substantial oxidation of the simulated pyrrhotite waste and in line with previous studies, which suggest pyrrhotite oxidation rates one to two orders of magnitude higher than for pyrite (Belzile et al., 2004). Correction of expected acidities based on the amount sulfide oxidized, gave much closer agreement with measured acidity for the simulated pyrite waste, but the measured acidity was still significantly lower than that expected from oxidation of the simulated pyrrhotite waste if oxidation was assumed to proceed to goethite and sulfate (Table 2). However, the sulfur mass balance indicated that the dominant (85 %) sulfur oxidation product in the case of the simulated pyrrhotite waste was not sulfate but elemental sulfur (Table 2), a reaction which will not produce acidity (Table 1). Further correction of the expected acidity to take into account oxidative dissolution to elemental sulfur, shows much closer agreement with the measured acidity for the simulated pyrrhotite waste.

Further analysis of leachate solutions and 1M KCl extracts of the solids were undertaken to determine the processes that may lie behind the difference in measured and expected acidity, even after reaction to elemental sulfur is taken into account. The results of these analyses are shown in Figure 1. The figure shows the titrated acidity (released acidity) together with stored acidity measured by titration of the KCl extract. It also shows released and stored alkalinity, which were calculated from concentrations of Ca, Mg and Na in leachates and KCl extracts respectively,

assuming the presence of these ions results from neutralising reactions. When stored and released acidities and alkalinities are combined, their sum is in good agreement with the expected acidities (Fig. 1). The results demonstrate that for the pyrite waste, the majority of acidity is released, with minor stored acidity and limited neutralization provided by chlorite in the simulated waste. In the case of the simulated pyrrhotite waste, the proportion of expected acidity which was released under KLC conditions was much less, with more stored acidity and some neutralising by chlorite (Jambor et al., 2007).

Table 2 Comparison of expected and measured acidity in leachates after 120 weeks of KLC testing conducted on simulated sulfidic wastes containing either pyrite or pyrrhotite

Sulfide	AP (kg $CaCO_3$/t)	NAG (kg $CaCO_3$/t)	Titrated leachate acidity (kg $CaCO_3$/t)	Total sulfide oxidized (%)	Expected acidity (kg $CaCO_3$/t)	Relative amount oxidized to S^o (%)	Expected acidity S^o excluded (kg $CaCO_3$/t)
Pyrite	84	65	10	17	14	2.0	14
Pyrrhotite	50	32	2.0	73	37	85	5.6

Kinetic leach column tests using pyrrhotite tailings from SNM

Similar to observations made during KLC tests of simulated pyrrhotite waste, visual inspection of the SNM tailings during column leach testing suggested extensive oxidation, but acidities measured in leachates remained low (Table 3) and in the case of the tailings leached at an average saturation of 75 %, almost non-existent (Table 4). With a pyrrhotite content of around 30%, these tailings were predicted to be strongly acid producing. Sulfur mass balance analysis indicated around 40% of the pyrrhotite had undergone oxidation during two years of leaching at 50 % average saturation and around 10% was oxidized during two years of leaching at 75 % average saturation (Tables 3 and 4), suggesting both columns should have produced substantial acidity if oxidation had proceeded to sulfate (Table 1). However, as for the simulated pyrrhotite waste, sulfur analysis demonstrated that the major pathway for pyrrhotite oxidation during leaching of the SNM tailings was via oxidation

to elemental sulfur, with around 90 % of oxidized sulfur in the tailings leached at 50 % saturation and around 80 % of oxidized sulfur in the tailings leached at 75 % saturation, reacting to produce elemental sulfur and no acidity (Tables 3 and 4). When this non-acid producing reaction pathway is taken into account, expected and measured acidities are much closer, although there was still significantly less measured acidity than expected, especially for the column leached at 75 % saturation.

Table 3 Comparison of expected and measured acidity in leachates during 107 weeks of leaching of SNM tailings with and average saturation of 50%

Leaching time (weeks)	AP (kg $CaCO_3$/t)	NAG (kg $CaCO_3$/t)	Titrated leachate acidity (kg $CaCO_3$/t)	Total sulfide oxidized (%)	Expected acidity (kg $CaCO_3$/t)	Relative amount oxidized to S^o (%)	Expected acidity S^o excluded (kg $CaCO_3$/t)
26	356	213	0.03	7.6	27	91	2.5
52			5.2	25	87	88	11
78			7.4	44	155	90	16
107			9.3	39	139	88	17

Table 4 Comparison of expected and measured acidity in leachates during 107 weeks of leaching of SNM tailings with and average saturation of 75%

Leaching time (weeks)	AP (kg $CaCO_3$/t)	NAG (kg $CaCO_3$/t)	Titrated leachate acidity (kg $CaCO_3$/t)	Total sulfide oxidized (%)	Expected acidity (kg $CaCO_3$/t)	Relative amount oxidized to S^o (%)	Expected acidity S^o excluded (kg $CaCO_3$/t)
26	356	213	0	2.0	7.1	80	1.4
52			0.02	7.9	28	79	5.9
78			0.03	10	36	79	7.7
107			0.05	9.5	34	73	9.2

The results of a similar analysis of stored and released acidity and alkalinity in leached SNM tailings to that conducted for the simulated sulfidic wastes are shown in Figure 2. Again, when stored and released alkalinity (neutralized acidity) are summed together with stored and released acidity, there is good agreement with the expected acidity based on the total amount of sulfide oxidized and the percentage of reaction leading to elemental sulfur. In some cases, the expected acidity is not entirely accounted for by the measured neutralization and stored and released acidity. These small differences are likely due to stored acidity in jarosite which was not quantified, but was detected during XRD analysis of the leached tailings.

Figure 2 shows that acidity released during oxidation of pyrrhotite in the SNM tailings comprized only a very small fraction of the total acidity generated and that the majority of the acidity has been neutralized, although at 50% saturation, there is also a significant fraction of stored acidity. Analysis of leachates and KCl extracts indicate that most of this neutralization comes from

magnesium bearing minerals, possibly enstatite. The results suggest that if the tailings can be maintained at near or above 75% saturation, then pyrrhotite oxidation is likely to be sufficiently slowed to allow the small amount of acidity generated from oxidation through to sulfate (Table 1), to be neutralized by reactive silicates present in the tailings. Under these conditions, released acidity is likely to be less than 1% of that predicted by ABA or NAG tests.

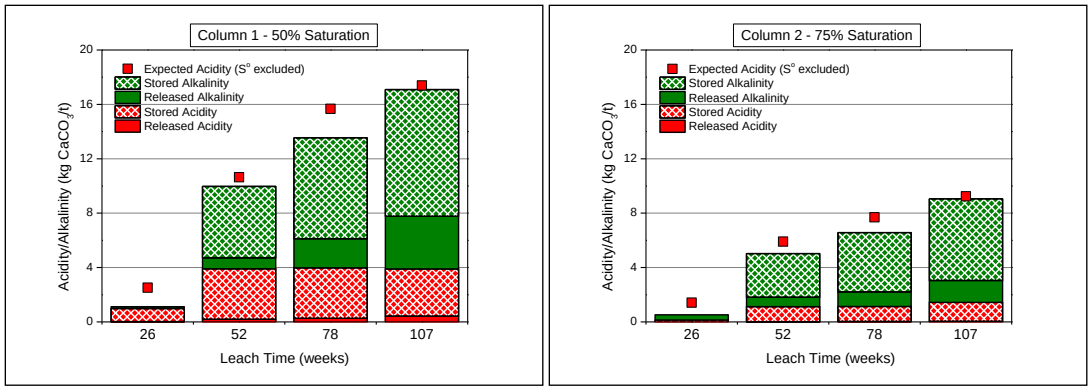

Figure 2 Acidity and alkalinity measured in leachates (released) and in KCl extracts of solids (stored), during 107 weeks of leaching of SNM tailings at an average saturation of 50% (left) and an average saturation of 75% (right)

Characterization of sulfur species in tailings from SNM

As a part of the study of geochemical reactions which occur during weathering of the SNM tailings, core samples were taken from several locations at the TSF. Core samples were taken through the full depth of the tailings deposited in the TSF and represented tailings deposited over about a five year period. Surface tailings, which had formed a hardpan, represented material deposited during the previous 1.5–2.5 years. Sulfur speciation analysis was undertaken on the core samples. The results of these analyses are show in Figure 3.

For each core sample taken, in the oxidized hardpan layer, elemental sulfur was the dominant sulfur species present with only minor sulfide (pyrrhotite) remaining. It was not possible to determine with any accuracy the relative proportion of oxidation of pyrrhotite to elemental sulfur vs oxidation to sulfate, as the amount of sulfate produced could not be determined since it is not quantitatively retained within the hardpan. Nevertheless, an estimate of the relative amounts of oxidation to elemental sulfur and sulfate could be made based on the results of sulfur speciation. For example, if in the Geochem 4 hardpan sample it is assumed that the original sulfide sulfur content is similar to the sulfide sulfur content of the tailings immediately below the hardpan, then sulfide sulfur decreased from 9.2 to 1.0 %. At the same time the elemental sulfur content increased from 0.1 to 7.1 %. This equates to an 86 % conversion of sulfide sulfur to elemental sulfur, suggesting that oxidation to elemental sulfur is the dominant reaction pathway for oxidation of pyrrhotite in the TSF hardpan.

These results suggest that under the conditions prevailing in the TSF, further oxidation of elemental sulfur is very slow in comparison to pyrrhotite oxidation, and that therefore the acidity generated by pyrrhotite oxidation will be substantially less than that predicted from ABA and NAG tests. This

was confirmed by results of tailings pore water analysis and ground water monitoring around the TSF, which showed elevated concentrations of sulfate, Ca and Mg, but neutral pH and no acidity, results consistent with the laboratory-based leaching tests conducted on SNM tailings.

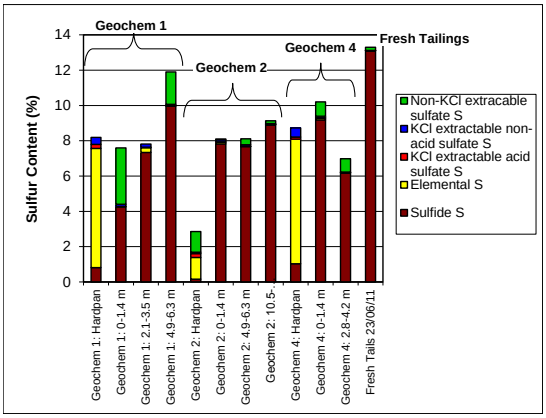

Figure 3 Results of sulfur speciation analysis of core samples taken from the SNM TSF

CONCLUSIONS

Oxidation of iron sulfides is recognized as being the cause of AMD, but generally no distinction is made between different iron sulfides in prediction of acid potential. Despite the fact that it has long been recognized that oxidation of pyrrhotite produces elemental sulfur as well as sulfate, with the former reaction generating no net acidity, there appears to have been no previous studies which have quantified the contribution of reaction to elemental sulfur to the overall oxidation of pyrrhotite. In this study, oxidation of simulated sulfide mine wastes containing pyrite or pyrrhotite under kinetic leach column tests conditions, demonstrated that oxidation of pyrite was dominated by the reaction to produce sulfuric acid (98 %), while pyrrhotite oxidation primarily (85 %) produced elemental sulfur and consequently significantly less acidity (~5 %) than would be expected based on AP calculations or NAG testing.

Similar results were obtained during column leaching of mine tailings containing around 30% pyrrhotite. About 90 % of oxidized sulfur in the tailings leached at 50 % saturation and around 80 % of oxidized sulfur in the tailings leached at 75 % saturation, reacted to produce elemental sulfur and no acidity. Consequently measured acidities were around 6 % of the predicted acidity in the tailings leached at 50 % saturation and less than 0.2 % of the predicted acidity in the tailings leached at 75 % saturation. The very low acidity from the tailings leached at 75% saturation was not only due to oxidation principally occurring via production of elemental sulfur, but also because the majority of acidity produced by the alternative oxidation pathway to sulfuric acid was neutralized by magnesium silicates also present in the tailings.

While further oxidation of elemental sulfur to produce sulfate and acid may occur, especially in the presence of bacterial catalysis, analysis of the oxidized zone of the tailings in the mine TSF suggests that, similar to laboratory column leach tests, *in situ* oxidation of pyrrhotite led to elemental sulfur as the main product. The results from the TSF suggest that further oxidation of elemental sulfur with natural bacterial populations is relatively slow in conditions at SNM. These results indicate that tailings and mine waste rocks where the major iron sulfide is pyrrhotite, are likely to produce

signficantly less acid than those containing pyrite. The results of this study further suggest that if pyrrhotite oxidation can be sufficiently slowed, for example by maintaining adequate levels of saturation in tailings, then silicates present in many mine wastes may be reactive enough to neutralize most, if not all, of the acidity produced. In short, complete assessment of the acid potential of a mine waste material will include not only the amounts, but also the identities of any iron sulfides present.

ACKNOWLEDGEMENTS

Funding from a Linkage Grant from the Australian Research Council and sponsors of the AMIRA P933A project (BHP Billiton Iron Ore, Savage River Rehabilitation Project, Hidden Valley Services PNG, Rio Tinto, Teck Metals) in supporting the investigations of simulated sulfidic mine wastes is gratefully acknowledged. The authors also acknowledge the assistance and funding by Panoramic Resources Limited for the work conducted on pyrrhotite tailings.

ABSTRACT

The acid-forming potential of ore and waste can be calculated based on a detailed knowledge of mineralogy, especially sulphide and carbonate contents. However, most mineralogical techniques (e.g., semi-quantitative X-ray diffraction (qXRD), scanning electron microscopy/energy dispersive spectroscopy (SEM/EDS) point counting) are too expensive for routine application. Mineralogy can be calculated from assay data using linear programming (simplex method) which is a mature method with application to real world quantities that cannot be negative. In order to apply this method, a table of mineral compositions is required for all the significant minerals in the study area. Unlike least squares methods, the mineral list can exceed the number of elements included in the assay data. Several carbonate compositions with a range of neutralising potential can be included. To use the linear programming method, a calibration must be established based on known compositions. This calibration can be based on qXRD or SEM/EDS point counting methods.

Not all types of assay data are sufficient for calculating mineralogy reliably. The best assay data comes from X-ray fluorescence analysis of major elements, including "loss on ignition" (LOI). Adding measured C content to this analysis provides a robust data set for calculating sulphide and carbonate contents of rocks. The mineralogy can be calculated without measured C, if LOI and SiO_2 are included in the analysis. However, typical mine databases contain multi-element assays based on a four-acid digestion method. In this case SiO_2 is not analysed and there is no "LOI" or total C. With typical four acid digestion data it is not possible to estimate the original carbonate content even when the mineralogy is simple. In rocks with complex mineralogy, mixed carbonates and/or multiple sulphides, qXRD and full chemical analyses are required to calculated acid rock drainage potential from mineralogy.

Keywords: calculated mineralogy, linear programming, ARD, carbonate

INTRODUCTION

In mining operations, the rock mineralogy is a key parameter controlling the acid generation/neutralisation potential (Paktunc, 1999). An efficient measurement of mineral abundance in waste samples is the key to understanding large scale acid rock drainage (ARD) potential. This can be done via calculated mineralogy and there are a number of methods that can be used to determine modal mineralogy from chemical assay. Two of these methods with potential application in the minerals industry are discussed here. These methods have been applied to two data sets, one with a simple mineralogy and a second data set from rocks with multiple sulphide and carbonate minerals.

METHODOLOGY

There has been a long history of calculating mineralogy from assay data. An early version was Bryan et al. (1969) which was improved on by Le Maitre (1981) and a more recent version was published by Paktunc (1998, 2001). All of these programs are based on simple least squares models and thus suffer from two serious limitations: 1) The nature of least squares models requires the number of minerals to be less than the number of elements in the analyses, and 2) the methods used do not enforce non-negativity constraints, so often the calculated mineralogy is impossible. The standard method for calculating a least squares model with non-negative constraints was published by Lawson and Hanson (1995). However, this method can now be readily carried out using the non-linear minimization routine included in the "Solver" tool within EXCEL®; an easily accessible version of this was presented by Herrmann and Berry (2002).

There is an additional problem with simple least squares minimisation methods, in that these methods assume that the errors on all input data are the same in absolute terms. For example, the absolute errors on SiO_2 and CO_2 values are considered to be the same. In practice, the relative errors are similar so that high abundance elements such as SiO_2 are over fitted and low abundance elements such as S and CO_2 are under fitted. A better result is obtained if the fit errors are weighted by the measurement errors (Press et al., 1986). This is especially important when merging data with very different errors such as quantitative Xray diffraction (qXRD) and assay data. Berry et al. (2011) addressed these problems and suggested two solutions suitable for calculation of mineralogy applicable to mine wastes: weighted least squares and Linear Programming.

There are many choices involved in selecting the most suitable assay data set for a mining environment. We have carried out a full major element analysis (including Ba and Cu) by X-ray fluorescence (XRF) with associated measurement of "loss on ignition" (LOI). H_2O+ and CO_2 were measured using a Flash Elemental Analyser. No organic C was observed so all C is assumed to be in carbonate. Quantitative XRD results were obtained using SiroQuant™ ver3.0 using the Rietveld method which is a standardless, full pattern approach to semi-quantitative phase analysis.

In most cases mine assays do not included any estimate of the volatile components. In addition it is now common for multi-element data to be four-acid digestions where SiO_2 is not analysed. To show how the absence of these components in the analyses affects the accuracy of the calculation, the mineralogy was calculated from several different subsets of this data.

All results reported here are based on 50 samples. For the linear programming, a separate group of 50 samples was used as a training set. No samples from the training set were included in the test data. The mineralogy of the training set was estimated using the weighted least squares method and all available analytical data.

Weighted least squares to combine assay and qXRD results

The assay data alone do not include enough constraints to calculate complex mineralogy. One way to overcome this problem is by measuring the mineralogy by qXRD. The qXRD results provide many additional constraints that can be used in calculated mineralogy and the calculation can include all major minerals. In the examples reported here, we calculated the abundance of 26 distinct mineral compositions with 34 constraints. Berry et al. (2011) applied this technique using the "NNLS" (non-negative least squares) subroutine of Lawson and Hanson (1995). Here we have used the non-linear "Solver" routine in EXCEL®. All calculated mineral abundances were limited in the Solver routine to be ≥0 (non-negative constraint) and ≤100% (as required by closure constraints on modal abundance).

For the assay results the measurement error was estimated as 3% relative plus 0.05% absolute. The errors for the qXRD results are based on repetitions of samples, error estimates reported in the literature and consideration of the fit errors achieved. For qXRD results the errors were set at 6% relative plus 0.5% absolute. At this weighting the problem can be stated as finding a modal mineralogy consistent with the chemical analysis which is as close as possible to the qXRD results. All samples in this study could be adequately explained (chi-squared probability of valid fit greater than 25%) based on these error estimates.

Linear programming and the Simplex Method

The second method of calculating the modal mineralogy from chemical analyses suggested by Berry et al. (2011) was linear programming using the Simplex method (Press et al., 1986). For the results reported here, the calculations were carried out using the linear routine in "Solver" with EXCEL®. This method requires a training set to calibrate the objective functions required. It can calculate mineral modes from an extended mineral list and additional linear constraints can be added as required. In this method, as in the weighted least square method, calculated mineral abundances were limited to ≥0 and ≤100%. For some minerals additional upper limits to abundance were enforced. A list of 45 distinct mineral compositions was included in the calculation.

Experimental Data

Experiment A: Simple assemblage

An evaluation program has been run on samples from a Cu porphyry deposit with a relatively simple mineralogy where carbonate is dominated by calcite and the significant sulfides are pyrite and chalcopyrite. Extensive mineral liberation analyzer (MLA) measurements failed to detect dolomite, ankerite or siderite above detection levels.

For these samples the mineralogy was calculated by:

a) weighted least squares using qXRD, major elements, total C and H_2O+
b) linear programming using major elements, total C and H_2O+
c) linear programming using major elements and LOI
d) linear programming using major elements except SiO_2

For experiment A the weighted least squares results were used to calculate the preferred "best" values for acid generating potential (AP) and neutralising potential (NP).

Experiment B: Complex assemblage

In the second experiment, the deposit type was IOCG (iron oxide-copper-gold) and the mineralogy relevant to ARD is more complex. Calcite, siderite, dolomite and ankerite were detected at significant and highly variable levels. Sulphides include significant chalcocite, bornite and chalcopyrite as well as pyrite which was at relatively low levels (i.e., typically less than 1%). In many ways this represents a worst case scenario for calculating ARD potential from assay data. The only significant sulphate was barite so problems with estimating other sulphates were not tested. Because of the mineralogical complexity, the mineralogy of all samples was measured using a SEM/EDS point count method (20,000 points) on grain mounts (Fandrich et al., 2007).

For these samples the mineralogy was estimated by:

a) SEM/EDS point counting
b) weighted least squares using qXRD, major elements and LOI
c) linear programming using major elements and LOI
d) linear programming using major elements except SiO_2

The linear programming estimates of the carbonate minerals, in experiment B, were calculated as end-member compositions for calcite, dolomite and siderite. Since the preferred estimate of acid neutralising capacity from intermediate carbonates is a linear sum of the cations (Paktunc, 1999), no attempt was made to estimate the actual proportion of ankerite in these analyses. For experiment B the SEM/EDS point count data were used to calculate the preferred "best" values for AP and NP.

Since the application of interest here is prediction of ARD, the results will be discussed in terms of AP and NP. No pyrrhotite was detected in these samples so AP is primarily due to pyrite. Thus the AP was calculated simply, as suggested by Paktunc (1999):

$$AP = 16.33 * X_{pyrite} \quad \text{in kg sulfuric acid equivalent per tonne}$$

The NP was calculated using the factors listed in Table 1.

Table 1 Estimates of NP from the literature (Skousen et al., 1997, Jambor et al., 2003, 2006, 2007, Hammarstrom et al., 2003). Siderite NP is for end-member siderite based on non-oxidisable cations as recommended by Paktunc (1999). All sulphides, tourmaline, fluorite, titanite and barite are assumed to have an NP of 0.

mineral	NP (calcite eq Kgms/t)	mineral	NP (calcite eq Kgms/t)
amphibole	3	K feldspar	1
ankerite	970	magnetite	2
apatite	8	muscovite	1
biotite	4	plagioclase	1
calcite	1000	pyroxene	5
chlorite	6	quartz	0
dolomite	1086	rhodochrosite	870
epidote	1	rutile	0
hematite	2	siderite	0
kaolinite	0		

RESULTS AND DISCUSSION

Experiment A: Simple assemblage

The abundance of calcite totally controls the NP results in experiment A. In this environment any method that considers the CO_2 content will produce an accurate assessment of the NP (Fig. 1). Where there is only a general indication of the volatile content, in this case a measure of LOI, the carbonate content can still be inferred but in these experiments the estimate is about 20% (relative) too high (Fig. 2). Using only the commonly available limited assay data, with no SiO_2 or LOI, the estimate is poor (Fig. 3) but still perhaps of some value as a general indication of which rock packages have acid neutralising potential.

The AP for the samples in experiment A is totally controlled by pyrite and with this simple mineralogy S analyses (with correction for barite and chalcopyrite) provide an excellent estimate of the pyrite content. Thus all the analytical methods tested give the same AP (Figs. 4, 5, 6). In this case even the simple four-acid analytical data commonly available in mine databases provides an excellent indication of AP.

RMS difference 7.5.

Experiment B: Complex assemblage

There are three different estimates of calculated mineralogy for the complex case. Using weighted least squares to combine qXRD and full major element assays by XRF gives an un-biased but not very accurate measure of NP. This can be seen by comparing the result with the more reliable SEM/EDS point counting method (Fig. 7). Using only analyses with LOI it is very difficult to balance the hydrous and carbonate minerals. In this example (Fig. 8), the NP was over-estimated by ~20 $CaCO_3$ eq kg/t at relatively low carbonate contents. With typical limited assay data (Fig. 9) the overestimate of the NP value was closer to ~30 $CaCO_3$ eq kg/t. These values suggest that, for the complex case in these experiments, the combined qXRD-assay method is required to adequately estimate NP. It is possible that a full assay (i.e. XRF + LOI) with CO_2 analysis would be sufficient but that was not tested on these rocks.

The qXRD analysis was strongly affected by the high X-ray fluorescence background in these high Fe rocks despite the use of a Co X-ray tube. The XRD laboratory noted that there was interference from an intense hematite XRD peak onto one of the main peaks of pyrite and they predicted that many of the low pyrite contents reported were too high. The combined qXRD-assay results inherit this bias to high pyrite estimates (Fig. 10). The comparison with the AP values determined from mineralogy based on SEM/EDS point counting suggests the pyrite content is overestimated by about 0.5%. This bias is seen as AP values that are about 10 kg H_2SO_4/t too high (Fig. 11) using the qXRD-assay estimates of mineralogy.

Using the assay data with LOI alone the AP values are generally too low (Fig. 12). With S allocated to four sulphides it is difficult to correctly predict the mixture on a routine basis. Most samples are close to the correct value but there are two outliers where the AP estimate is 20 kg H_2SO_4/t too low. The estimate based on a limited assay (Fig. 13) gives a similar result. While these methods are less robust than the qXRD-assay method they are not affected by the qXRD interference and have smaller average errors in AP value.

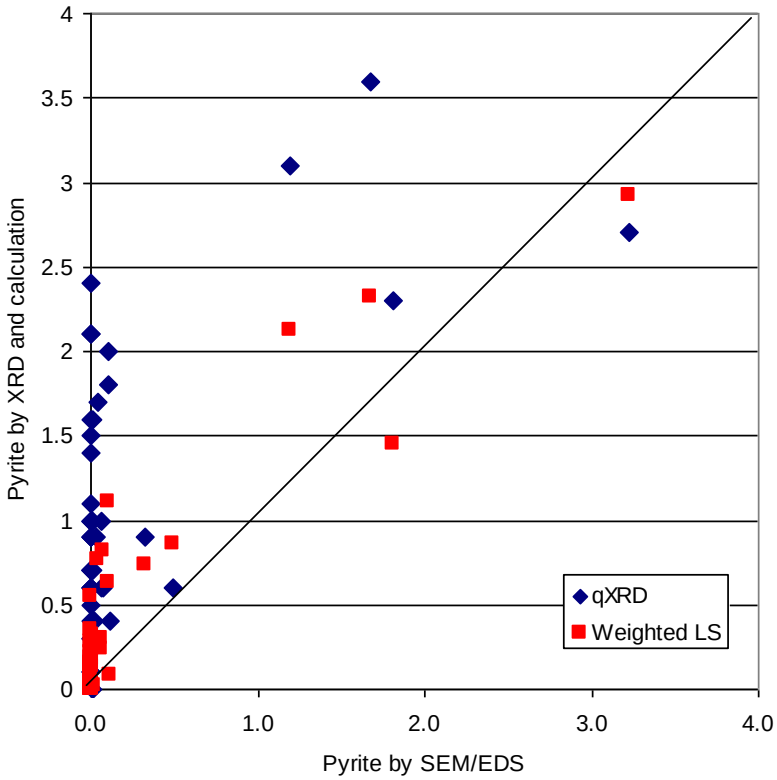

Figure 10. Comparison of pyrite estimates from qXRD alone (blue diamonds) and after merging qXRD with assay data using a weighted least squares method (red squares), with the more accurate estimate using SEM/EDS point counting.

CONCLUSION

Mineral grade calculated from assay data has potential to provide a low cost prediction of ARD potential, albeit, provided care is taken in the calibration and in selection of suitable assay characteristics. Quantitative (q)XRD is a robust method for identifying the major minerals in a sample. However the precision is poor and especially so at abundances less than 5%. Combining assay data with qXRD results leads to a substantially improved estimate of the mineralogy. Where there is an adequate training set of samples with "known" mineralogy, it is possible to estimate the mineralogy from assay data alone using linear programming.

In waste rocks with simple mineralogy it is possible to predict the ARD potential of rocks based on major element analyses where at least LOI is measured. However if the only available analysis are from four-acid assay data (no Si, no LOI) the NP cannot be accurately predicted and therefore the net acid production potential cannot be quantified.

Where the mineralogy is complex, with multiple S-bearing phases and/or mixed carbonates, ARD potential can be predicted from samples which have both qXRD and assay data. If only major element analyses with LOI are available the calculation of AP and NP are inaccurate and with only four-acid data no realistic estimate of ARD potential is possible.

ACKNOWLEDGEMENTS

Some of the C and H_2O+ analyses used in this paper were carried out at the Central Science Laboratory, University of Tasmania. The qXRD results were provided by Stafford Mcknight, University of Ballarat. Support for the data collection in this report was provided by AMIRA P843.

ABSTRACT

Secondary minerals and other weathering products (for example, secondary sulfates, carbonates, oxides, and amorphous coatings) can serve as an important control on the concentration of trace metals in mine-impacted water. This becomes particularly true for mine features like waste rock stockpiles with engineered covers that are designed to minimize water flux, thereby increasing the likelihood that constituents released during mineral weathering are going to be retained within the feature. Standard methods designed to characterize constituent release rates (i.e., humidity cell tests) do not provide information on secondary mineral controls under mine site conditions due to the high water:rock ratio employed in these tests. Other types of tests that use less water may provide empirical evidence for weathering product-related controls, but, because they lack information on control mechanism or weathering product identities, it can be a challenge to extend the results to mine site conditions. Here, we report on the results of an ongoing study into controls exerted by weathering products on trace metal mobility from a magmatic sulfide Cu-Ni-PGE deposit within the Duluth Complex, located in Minnesota, USA. Key aspects of this study include: (1) utilization of weathered samples collected from outcrops on site as proxies for potential future oxidized waste rock; and (2) application of complementary analytical techniques, from both commercial and university labs, selected to achieve the chemical sensitivity and high-spatial resolution necessary to characterize secondary minerals in weathered rocks (including, but not limited to, X-ray diffraction, electron-microprobe analysis, and chemical analysis following sequential extraction). Results of this work are being used to refine the conceptual model for the mobility of trace metals that would be released during weathering of potential future waste rock.

Keywords: secondary minerals, metal attenuation, scanning electron microscope, X-ray diffraction, mineral characterization

INTRODUCTION

The Duluth Complex, Minnesota, USA, is a large composite mafic intrusion emplaced during a failed mid-continental rifting event that occurred in the region approximately 1.1 billion years ago and has been identified as one of the world's largest Cu-Ni-PGE resources (Miller et al., 2002). Multiple magmatic sulfide Cu-Ni-PGE deposits in the Duluth Complex are currently the subjects of ongoing mineral exploration, mine planning, and environmental review. While there is likely to be variability in the chemistry of mine-impacted waters from different potential future mines in the Duluth Complex, similarities in mineralogy, geology, and regional characteristics throughout the complex suggest that the following aspects of a site geochemical model may be typical for Duluth Complex deposits:

- The region has a wet, continental climate with abundant valuable water resources. Any potential future mine would likely be required to utilize engineered systems that minimize contact water as part of the mine water and waste rock management plans, for example, utilization of advanced stockpile cover systems, where appropriate.

- Oxidation of sulfide minerals is a potential source of acidity, sulfate, iron, and other metals (Lappako & Antonson, 2012; Lappako, Olson, & Antonson, 2013; Lappako, 1993). Within Duluth Complex magmatic deposits, sulfur content, as well as the sulfide mineralogy, show wide variability (Ripley & Alawi, 1986). The typical sulfide mineral assemblage includes pyrrhotite ($Fe_{(1-x)}S$), chalcopyrite ($CuFeS_2$), cubanite ($CuFe_2S_3$), and pentlandite ($(Fe,Ni)_9S_8$). Sulfide minerals may contain trace metals in addition to those indicated by the mineral formula. Whereas a larger suite of metals may be environmentally relevant for Duluth Complex rocks, this study is focused on Cu, Ni, Co, and Zn.

- Carbonate minerals are generally absent or at low concentrations in Duluth Complex rocks; instead, neutralization potential is supplied by dissolution of silicate minerals (Lappako et al., 2013). The silicate mineralogy for Duluth Complex rocks is dominated by anorthite-rich plagioclase feldspar, olivine, and pyroxene (Miller et. al 2002), of which, anorthite-rich plagioclase and olivine may provide significant neutralization potential. For rocks of sufficiently low sulfide content, this neutralization mechanism may be adequate to maintain circum-neutral conditions (Day & Kennedy, in press; Miller et al., 2010).

Ultimately, metal concentrations in mine-impacted water will reflect combined effect of constituent release from sulfide minerals, as well as, attenuation during weathering from mechanisms such as precipitation of secondary phases, sorption onto solid phase surfaces, and co-precipitation. In this context, the term "secondary phases" refers to minerals and other solid phases that form as a result of rock weathering after being exposed at the surface. Evidence for metal attenuation by ferric (oxy)hydroxides and related iron-rich secondary phases has been widely reported in the literature (for example, Carbone et al., 2012; Alpers et. al. 1994; Jambor & Dutrizac, 1998). With respect to Duluth Complex rocks, metal attenuation has been inferred for field leach piles with acidic pH (Kelsey et al., 1996). However, the role of attenuation by secondary phases would likely be more

significant for systems with low-sulfide waste rock where drainage maintains circum-neutral pH (Smith et al., 2013), because many of these attenuation mechanisms are pH dependent. Whereas extensive characterization has been performed on constituent release rates from Duluth Complex rock (Lappako, Olson & Antonson, 2013), relatively little work has characterized the relevant attenuation mechanisms, in particular, under circum-neutral conditions.

The following work aims to characterize weathering products and related attenuation mechanisms that could be active in mine-impacted drainage at a potential future Duluth Complex mine. Characterizing weathering products can be challenging due to the poor crystallinity and micro- to nanometer-scale size of features (e.g. thin surface coatings). To overcome some of these limitations, an assortment of high-resolution techniques, including scanning electron microscopy (SEM) methods, x-ray diffraction (XRD), and chemical sequential extraction were used, employing resources at both university and commercial labs.

METHODOLOGY

Low-sulfur waste rock piles of Duluth Complex rock are not available; therefore, weathered rock from exposures (both natural outcrops and historical railroad cuts) of Duluth Complex were collected and used as analogues for waste rock that may be produced by a potential future project. This approach has some limitations, for example, differences in time scales between natural weathering and mining, difference in surfaces, and poorly constrained drainage chemistry. Opportunistic sampling was conducted at six locations to capture the variety of visual alteration. Samples included both rock with visible weathered rinds as well as, white crusts (Figure 1). Of the six sampling locations, one captured rock from a meta-sedimentary rock that underlies the Duluth Complex. This paper focus on the Duluth Complex samples from the remaining five sampling locations. At each location, a grab sample (small clasts typically less than 1-2 inches, about 1 kg) and separate hand samples (about 1 kg) were collected.

Figure 1 Left image shows example of a field sampling location where Duluth Complex rock was exposed during construction of a railroad. Right image shows "white crust" observed at the site.

Secondary Mineral Characterization Techniques

Rietveld X-Ray Diffraction

Rietveld X-ray diffraction (XRD) was performed at the University of British Columbia. Grab samples were ground (< 10 μm) under ethanol in a vibratory McCrone Micronizing Mill for 7 minutes. Step-scan X-ray powder-diffraction data were collected over a range 3-80° 2θ with CoKα radiation on a Bruker D8 Advance Bragg-Brentano diffractometer equipped with an Fe monochromator foil, 0.6 mm (0.3°) divergence slit, incident- and diffracted-beam Soller slits and a LynxEye-XE detector. The long fine-focus Co X-ray tube was operated at 35 kV and 40 mA, using a take-off angle of 6°. The detection limit for this method is about 0.5 percent.

Qualitative powder X-Ray Diffraction

To supplement Rietveld XRD on whole rock samples, coatings on hand samples were isolated for additional analysis by XRD. Samples were viewed under a binocular microscope to identify visually distinct weathered areas. Alteration coatings were then scraped with a stainless steel pick onto a plastic weigh boat. While viewing the granular scrapings under a binocular microscope, material that appeared as primary mineral grains (i.e. unweathered materials) was removed. Samples were ground with an agate mortar and pestle and mounted on zero-background plates. Using a Phillips XPert MPD diffractometer at the University of Minnesota-Duluth with CuKα radiation source, each sample was scanned between 5° and 65° 2θ at a scan rate of 0.05 deg./min. X-rays were refined with a graphite monochromator, 1° divergence slit, incident and diffracted Stoller slits, a 10 mm mask and collected with a point scintillator detector. The X-ray tube was operated at 40 kV and 40 mA. The long collection time gave sufficient counts to match patterns from the database for some secondary phases. Diffraction data were processed with X-Pert HighScore software and compared to mineral patterns in the International Centre for Diffraction Data (ICDD) database.

Scanning Electron Microscopy

The morphology and semi-quantitative coating chemistry were characterized using a SEM. Preparation included crushing (< 1 mm), mounting in epoxy, polishing, and carbon coating (15 nm). A JEOL JSM-6590LV scanning electron microscope, combined with an INCA X-ACT energy dispersive spectroscopy system (EDS) and complementary software, was operated at the University of Minnesota-Duluth. Operating conditions were optimized independently for imaging in backscattered mode and EDS mode; moderate accelerating voltage (15 kV) produced optimal results. EDS calibration was performed on metallic Cu and is considered semi-quantitative. Additional work was performed on a JEOL 8600 Electron Microprobe operated in EDS mode by McSwiggen & Associates, a commercial lab in St. Anthony, Minnesota. The procedure was standardless, and therefore semi-quantitative.

Chemical Sequential Extraction

A sequential extraction procedure was chosen based on a hypothesis that metals of interest could be divided into six solid phases or groupings. Groupings coincide with relative environmental stability mineral classes. One gram of pulverized material was used as the starting mass for each sample. The chemical extraction was analyzed by ICP-OES.

Table 1 Abbreviated sequential extraction procedure.

Extraction Step	Extraction Target Phase	Associated Mineral Groups	Method Reference
1	Water soluble	• Sulfate salts	Dold 2003
2	Weakly acid soluble (pH 5)	• Carbonates • Adsorption to primary and secondary Fe oxides, kaolinite and montmorillonite. • Apatite	Tessier et al. 1979
3	Weakly reducible	• Al-hydroxides • Poorly crystalline Fe-oxide/ (oxy)hydroxides	Chao and Zhou 1983
4	Strongly reducible	• Goethite • Primary Fe-oxides • Ilmenite	Chao and Zhou 1983
5	Oxidizable	• Sulfides • Pyrrhotite • Chalcopyrite	Chao and Sanzolone 1977 in Leinz et al. 2000
6	Residual	• Various silicates	

RESULTS AND DISCUSSION

X-Ray Diffraction

XRD with Reitveld analysis on powdered bulk rock samples confirmed a primary mineral assemblage consistent with typical Duluth Complex lithologies. Samples were largely composed of the primary minerals: plagioclase feldspar, olivine, pyroxene, and ilmenite. For most samples, sulfide minerals were likely below the detection limit (about 0.5 %), although chalcopyrite was detected in one sample. Results from bulk XRD did not yield secondary iron-oxide mineral identifications. This may be due to low mineral abundance and/or iron-rich coatings that were amorphous or poorly crystalline. There were isolated occurrences of the efflorescent sulfate salts alunogen and epsomite, as well as, the silicate weathering products, kaolinite and montmorillonite. Several phyllosilicate minerals (biotite, actinolite, clinochlore) were identified that may have resulted from late-stage processes associated with the igneous intrusion, such as deuteric alteration of primary silicates.

The powder XRD on the hand sample coatings provided evidence for additional weathering products. Diffraction of iron-rich material generally did not produce diffraction patterns that

allowed phase identification, suggesting the rind material structure is very poorly crystalline to amorphous. However, in one case, poorly crystalline goethite was identified and appeared to be a product of sulfide- mineral replacement (Figure 2). The presence of goethite (FeOOH) may indicate crystalline transformation of iron oxide-rich coatings (Guo & Barnard, 2013 and references therein) or *in situ* formation due to the lower pH micro-domain proximal to the primary sulfide grain undergoing alteration as suggested by Jambor, 2003. An additional efflorescent sulfate salt was identified in one sample as rozenite ($Fe(SO_4)\bullet 4(H_2O)$) (Figure 3).

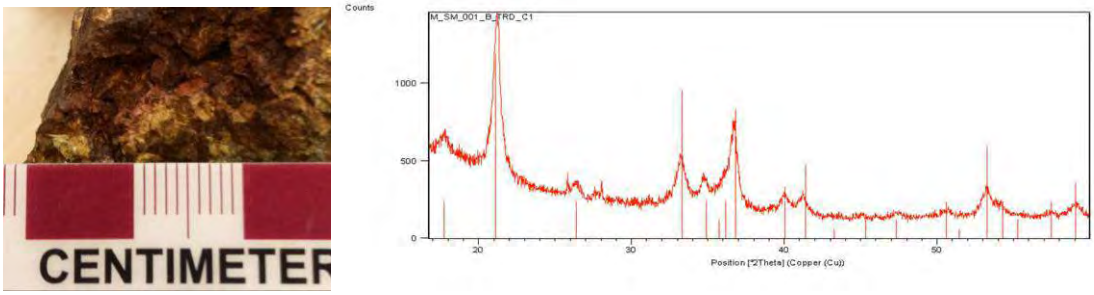

Figure 2 Hand sample showing rust-colored sulfide-replacement texture (left). XRD pattern of pictured material with the matched pattern (vertical lines) from ICDD database for goethite (ID card 000080097) (right).

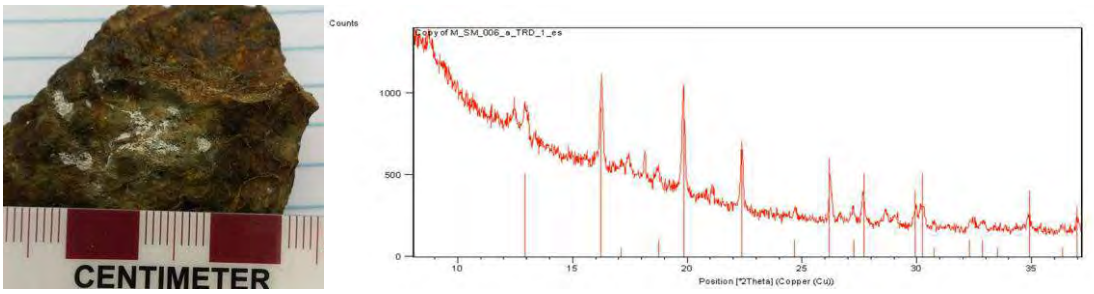

Figure 3 Hand sample showing visible weathering (left). Diffraction pattern of the white precipitate from this sample along with the pattern (vertical lines) from ICDD database for rozenite (ID card 000160699) (right).

Electron Microscope Analysis

Secondary mineral occurrences observed using back-scattered electron (BSE) images include: along fractures/ grain boundaries; as sulfide replacement; and on the exposed surfaces of mineralized rock. Chemical composition data gathered with energy dispersive spectroscopy (SEM-EDS) performed at University of Minnesota Duluth indicate the coatings commonly contain iron and silica as major components and variable amounts of aluminum, sulfur, and metals (e.g. copper) as minor elements (Table 2). BSE images and associated chemical composition suggests variations in solution chemistry (cyclic chemical compositions) during deposition of these features.

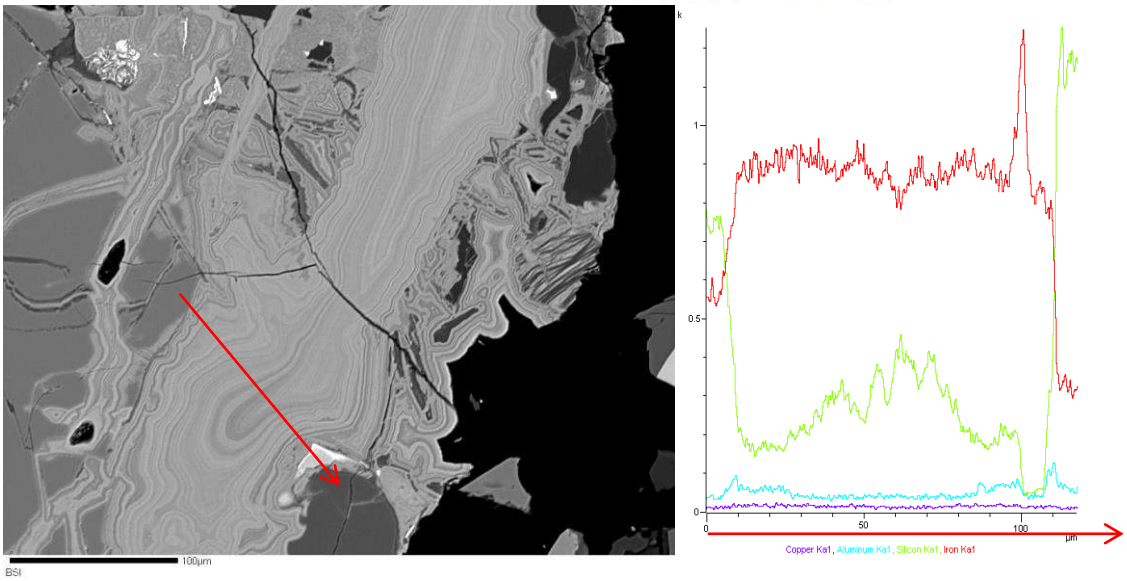

Figure 3 BSE image and location of cross-section line scan of an iron-rich coating (left). Relative chemical abundance plot Fe (red) and Si (green) Al (blue) and Cu (purple) showing variation across iron rich rind (right).

Table 2 Typical range of composition for iron rich coatings, oxygen not reported.

Element	Range of values* observed (weight percent)
Fe	45-66
Si	4-10
Al	1-2
S	0-5
Cu	0-3

* Semi-quantitative values.

Additional energy dispersive spectroscopy (EDS) analyses, performed by McSwiggen & Associates, indicated that the iron oxide-rich layers can contain up to 6 wt% CuO. These compositions were determined using a standardless technique, and therefore were semi-quantitative. Consistent with the analyses performed at the University of Minnesota Duluth, the amount of copper contained within the iron oxide-rich layers is highly variable. For some samples, the copper content was below the detection limit of the instrument under the operating conditions described (approximately 0.1 wt.%). On-going investigations are working to resolve certainty related to Cu speciation, association, and the upper limit of trace metal concentration.

The SEM analysis indicates that the width of individual layers within the layered iron oxide-rich features ranges from approximately < 1-3 µm. Spatial resolution for the EDS analysis is on the order

of 1 μm at 15 kV. Therefore, individual EDS analyses are likely sampling multiple layers, especially when layers are not oriented parallel to the electron beam. Our analyses likely represent a composite composition of several rind layers. If this is the case, it can be expected that true variability in the chemical composition of individual layers is greater than what is suggested by EDS data. Furthermore, these techniques cannot assess the form of the Cu, for example sorbed species on Fe oxide and/or fine-grained Cu secondary minerals.

Sequential Extraction

Results from sequential extraction confirm SEM observations of trace metals associated with iron oxide-rich layers. Iron oxides are expected to report within the reducible fractions. Results from sequential extraction indicate that these fractions can contain significant copper, nickel (Table 3). Similar trends for Co and Zn were also observed. For each of these elements, up to approximately half of the total amount of that element was associated with the reducible fractions.

Table 3 Sequential extraction results for **c**opper and nickel.

Extraction (mg/kg)	**Water soluble**		**Weakly acid soluble**		**Reducible***		**Oxidizable**		**Residual**	
	Cu	Ni	Cu	Ni	Cu	Ni	Cu	Ni	Cu	Ni

** SM4a contained white crusts (see Figure 1, right)

CONCLUSION

Collectively, the mineral characterization techniques employed provide evidence for attenuation of constituents released during weathering of Duluth Complex rock by means of: (1) silicate mineral alteration to clays (kaolinite, montmorillonite); (2) precipitation of sulfate salts (epsomite, alunogen, rozenite); and (3) formation of iron-oxide rich layers which also contain variable amounts of trace metals, silicon, and aluminum. Assuming that the iron-oxide layers behave similarly to hydrous ferric oxide, the degree to which iron oxide layers will attenuate copper, nickel, zinc, and cobalt from mine-impacted water will be a function of drainage pH, total iron content, trace metal content, and reactive surface area (Dzombak & Morel, 1990). Micro-scale heterogeneity may indicate the presence of micro-geochemical environments and/or temporal fluctuations in water chemistry.

ACKNOWLEDGEMENTS

We would like to thank Andrew Thrift of Teck American Inc. for supporting this work. We also thank Dr. Jim Miller for facilitating industry support for this work through the Precambrian Research Center (PRC). Dr. Bryan Bandli at UMD provided excellent guidance for both XRD and SEM analyses. Bronwen Forsyth (SRK) designed the sequential extraction procedure and related data processing/interpretation. University of British Columbia (QXRD), Vancouver Petrographics (thin sections), and McSwiggen and Associates (microprobe) provided essential data and products. We would also like to thank two anonymous reviewers for comments that resulted in a number of improvements to this manuscript.

ABSTRACT

The determination of the neutralization potential (NP) and acid potential (AP) of environmentally reactive material is a crucial step in the characterization and prediction of acid rock drainage (ARD) and metal leaching (ML) in mine waste for environmental planning. The calculations performed from laboratory tests (static testing) make assumptions regarding acidification and neutralization potential without mineralogical information. The role of mineralogy in ML/ARD is significant and mineralogical characterization can be used to check assumptions or enhance the prediction of water quality.

Mineral Liberation Analyzer (MLA), a scanning electron microscopy-based software program, can provide highly detailed information regarding the abundance, variability, chemistry, and physical characteristics of various acid producing and acid neutralizing minerals. Mineralogical information was determined for several mining projects in Canada using MLA and AP and NP were calculated from modal mineralogy. These results were compared to the results of static testing. Automated mineral analysis is suitable for mining projects with unusual circumstances, such as cases where detailed characterization of acid-neutralizing and acid-generating phases is called for or where concentrations of key mineral phases are below detection limits of other mineralogical characterization techniques such as XRD. Notably, the energy dispersive X-ray spectroscopy associated with MLA is ideal for the identification and quantification of iron and manganese bearing carbonates such as siderite and ankerite, which are measured as carbonates in static tests of NP but can contribute acidity from iron and manganese when dissolved. In addition, there are many other factors that control ML/ARD that can be analysed using automated mineral analysis, including mineral associations, exposure of minerals, and grain size.

Keywords: automated mineralogy; acid base accounting

INTRODUCTION

Automated quantitative mineralogy is a powerful tool that allows us to answer questions regarding mineralogical controls on the behavior of mining-related waste in the environment. Mineral Liberation Analyzer (MLA), an SEM-based mineralogical software program, and its sister software QEMSCAN have traditionally been used by the metallurgical industry for characterizing ore and mill feed. Tailings, waste rock, polished rock thin sections, mining impacted soils, and other sediments can be analyzed using MLA to determine the relative abundance of minerals in mine waste to better understand the processes that formed them and their fate. MLA has been applied to whole rock thin sections of waste rock to develop a mineralogical ARD index by Parbhakar-Fox et al. (2011), to assess the levels of base metals in mining-impacted estuarine sediments in Cornwall by Pirrie et al. (2003), and to identify mineralogical products important to weathering processes from waste rock at the Antamina Mine in Chile (Blaskovich, 2013).

In our research program, we have applied SEM-MLA to the following mine waste problems: (1) determination of acid potential and neutralization potential of mine tailings, with results that compare favorably with static testing, (2) comparison of the modal mineralogy of mine-impacted stream sediments based on SEM-MLA, bulk-XRD, and X-ray absorption spectroscopy, (3) prediction the fate of Hg, As, Cd and other elements in tailings from a complex, oxidized orebody (4) calculation of the relative proportions of anthropogenic and natural As-bearing grains in lake sediments and (5) explanation of variations in Pb bioaccessibility in tailings samples. This paper focuses on the first application.

Laboratory static tests for AP and NP are not mineralogically based and do not take into account the variability in chemical content of various acid-producing and acid-neutralizing minerals. Mineralogy plays a significant role in the neutralization of ARD and mineralogical characterization is recommended as part of every drainage chemistry prediction program to check assumptions made by laboratory tests (Price, 2009). The most important acid neutralizing minerals are in the carbonate group, which react readily and freely. Some silicate minerals such as olivine and wollastonite provide neutralization (Jambor et al., 2002) but with very slow reaction rates. It is expected that the onset of ARD precedes the reaction rates of neutralizing silicates (Jambor et al., 2002) and most researchers recommend the use of neutralization potential derived from carbonates such as calcite and dolomite, excluding iron and manganese carbonates (Jambor, 2000; Price, 2009).

The presence of iron and manganese carbonates such as siderite [$FeCO_3$], rhodochrosite ([nCO_3] and ferroan dolomite [$Ca(Fe,Mg)(CO_3)_2$, Fe>Mg] complicates neutralization potential, because the alkalinity produced by the dissolution of the carbonates is offset by the acidity contributed by iron and manganese oxidation and hydrolysis (Frostad, Price & Bent, 2003; Price, 2009). At present, the industry standard is static laboratory tests to determine sulfur species and neutralization potential, and kinetic laboratory tests where material is leached over a period of time to analyze reaction rates and metal loads. These tests utilize crushed samples and do not take mineralogical factors explicitly into account.

Automated mineralogy provides a way to look at the mineralogical and physical factors that control metal leaching and acid rock drainage. For these studies, modal mineralogy was obtained from MLA, an automated, quantitative SEM-EDS based mineralogical software program. MLA works on particle thin sections and determines modal mineralogy while collecting sample images and allowing for the analysis of sample texture and particle size. These results were expressed in

terms of AP and NP, and then compared with conventional laboratory determinations of these parameters. This approach was applied to tailings from three unique sites: a massive sulfide ore that does not produce acid drainage, a syenite-hosted rare earth element (REE) deposit with very low sulfide content, and a massive sulfide ore that is known to produce ARD.

Investigated Sites

New Calumet

The former New Calumet Mine is located on Ile du Grand Calumet in Quebec, Canada, approximately 90 km northwest of Ottawa, Ontario. The New Calumet deposit consists of massive sulfide lenses and disseminated sulfides associated with cordierite-anthophyllite-bearing gneisses that have been metamorphosed from hydrothermally altered rocks (Corriveau et al. 2007). The ore consists mainly of sphalerite and galena with smaller amounts of pyrrhotite, silver, gold, chalcopyrite, and tetrahedrite. Gangue minerals are quartz, calcite, amphibole, pyroxene, biotite, orthoclase, plagioclase (anorthite and albite), titanite, goethite, and spinel (Williams, 1992).

From 1943 to 1968, 3.8 million tonnes of Pb-Zn ore grading 5.8% Zn, 1.6% Pb, 65 g/tonne Ag, and 0.4 g/tonne Au were extracted using flotation processing (Bishop, 1987). Approximately 2.5 million tonnes of tailings remain exposed on site in multiple locations: the Gobi Desert (GD), Mount Sinai (MS), and the Beaver Pond (BV). To date, remediation has been limited to re-vegetation in some areas.

The pH of drainage from the three New Calumet tailings deposits remains neutral to alkaline based on testing from the 1960s to present day (Doonkervort, 2007; Praharaj & Fortin, 2008; Dongas, 2013). However, Jaggard (2012) noted the occurrence of anglesite [$PbSO_4$], a mineral stable under acidic conditions, in the fine (<20 μm) fraction. This suggests the presence of an acidic environment, even if only on a small scale or in certain environments within the tailings.

Nechalacho

The unmined Nechalacho rare earth element deposit is situated at Thor Lake, approximately 100 km east of Yellowknife, Northwest Territories, Canada. The deposit is hosted within a hydrothermally altered layered nepheline-sodalite syenite in the peralkaline Blatchford Lake complex. The main REE ore minerals are zircon, fergusonite, allanite, monazite, bastnäsite, and synchysite/parisite. Gangue minerals are largely K-feldspar, albite, biotite, quartz, and magnetite (Sheard et al., 2012). Sulfides are uncommon in the deposit, representing < 0.01 % of the mineralogy (Purdy, 2014), most commonly occurring as pyrite, although sphalerite, galena, molybdenite, and chalcopyrite have also been reported in trace quantities (Pinckston & Smith, 1995; Purdy, 2014; Sheard et al., 2012). Carbonate minerals are also not abundant in the deposit, typically comprising about one to two percent of the rock, and include ankerite, siderite-magnesite, calcite, dolomite, bastnäsite, and synchysite/parisite (Purdy, 2014). It remains unclear how much neutralization potential is contributed by bastnäsite and synchysite/parisite.

Geco

Geco is a former Cu-Zn-Ag-Au massive sulfide producer located near Manitouwadge, roughly 250 km east of Thunder Bay, Ontario. The deposit is situated within the Manitouwadge greenstone belt,

locally hosted in quartz-feldspar-biotite ± hornblende gneisses and quartz-sillimanite ± muscovite schists (Petersen, 1986). The ore mineralogy comprises chiefly of pyrite, pyrrhotite, sphalerite, and chalcopyrite, with minor galena, and marcasite. Gangue minerals are largely quartz, plagioclase, K-feldspar, muscovite and amphibole (Jamieson, Shaw & Clark, 1995), although other minerals have been documented in the deposit (Petersen, 1986). Carbonate minerals occur only in trace amounts and acid drainage from tailings has been documented (Jamieson, Shaw & Clark, 1995).

METHODS

Tailings samples from New Calumet Mine were prepared as thin sections for MLA by Vancouver Petrographics in Langley, BC, Canada. Samples were impregnated with set epoxy, mounted to glass slides, and ground to 30-50 μm thickness. Thin sections are doubly-polished and liftable, and mounted onto glass using Krazy Glue™. Water and heat were not used during preparation of thin sections, to avoid any chemical alteration of the samples. Kerosene was used when fluids were necessary.

Tailings from the Nechalacho deposit and Geco Mine were prepared at Queen's University, Kingston, Ontario, Canada. The Geco samples were sieved into three size fractions (< 125 μm, 63-125 μm, and < 63 μm), and the Nechalacho samples were left unsieved due to their fine grind size (80 % passing at 38 μm). All samples were mixed 2:1 with graphite to decrease particle density and particle agglomeration before being mixed with epoxy in a plastic vial lightly coated with petroleum jelly. The mixture was stirred thoroughly to ensure the entire sample was suspended in the epoxy and then placed in an ultrasonic bath for 10 minutes to reduce particle agglomeration. Samples from the Geco Mine were left as epoxy mounts and polished, whereas the samples from the Nechalacho deposit were cut vertically and mounted as thin sections before being polished. Water was used in the sample preparation of both the Nechalacho and Geco samples as dissolution of secondary phases was not identified as a concern.

Samples were carbon coated and analyzed under high vacuum at Queen's University on a Quanta 650 FEG-E-SEM with FEI's MLA software.

MLA Methods

MLA requires optimization of several project specific parameters, such as operating voltage, magnification, spot size, brightness and contrast. FEI recommends calibrating brightness and contrast on the brightest (highest atomic number) mineralogical phase in the sample to achieve the best range of gray scale coloring in back scatter electron view for particle distinguishing.

An important part of using Mineral Liberation Analyzer is the creation of an accurate and complete Mineral Reference Library that is used to classify the minerals in a sample or sample suite (Fandrich et al., 2007). The Mineral Reference Library is made up of mineral names or chemical composition groupings with associated EDS spectra. Each EDS spectra collected in an MLA run is compared to the Mineral Reference Library and assigned a classification (mineral name or chemical composition grouping) based on the EDS spectra it matches most closely. An accurate mineral reference library is critical, as multiple mineral types contribute to acid generation and acid neutralization.

Static Testing – Acid Base Accounting

All of the samples collected from New Calumet and Geco, and one mixed sample of mixed tailings from Nechalacho were subjected to static tests at a commercial laboratory. The analyses included paste pH, total inorganic carbon, sulfur speciation, determination of AP and NP, method modified after Sobek and CO_3-NP(Price, 2009).

RESULTS AND DISCUSSION

Determination of Neutralization Potential

Table 1 compares the NP calculated by SEM-MLA based on the modal amounts of carbonate minerals with the NP measured using chemical tests (total inorganic carbon or CO_3-NP, and the modified Sobek test). Calculating the neutralization potential of material from modal mineralogy via MLA allows for the consideration of Fe and Mn carbonates (Frostad, Price & Brent, 2003; Paktunc, 1999). For the Calumet samples, the ferroan dolomite grains contain an average iron mole % of 3.9%, and for the Nechalacho samples, the ankerite grains contain an average iron mole % of 16.24% (Buckwalter-Davis, 2013; Purdy, 2014). The total NP was calculated according to Frostad, Price & Bent (2003) from two components. $CaCO_3$-NP takes into account the modal mineralogy of calcite and dolomite and subtracts the contribution from iron (Equation 1) and $FeCO_3$-NP takes into account ferroan dolomite/ankerite and siderite and removes the contribution from iron (Equation 2).

$$\mathrm{CaCO_3 - NP}\left(\frac{\mathrm{kg\ CaCO_3}}{\mathrm{t}}\right) = \left\{\mathrm{calcite\ wt\ \% + dolomite\ wt\ \% + \left(ferroan\ dolomite\ wt.\ \% \times \left(1 - \left(\frac{Fe\ mole\%}{100}\right)\right)\right)}\right\} \times 10 \quad (1)$$

$$\mathbf{FeCO_3 - NP}\left(\frac{\mathbf{kg\ CaCO_3}}{\mathbf{t}}\right) = \frac{\left(\mathbf{(ferroan\ dolomite\ wt.\ \% \times Fe\ mole\%) + siderite\ wt.\ \%}\right)}{\mathbf{115.86^{*} \times 100.09^{\#} \times 10}} \quad (2)$$

*115.86 = molecular weight of $FeCO_3$

#100.09 = molecular weight of $CaCO_3$

The NP values calculated from MLA are broadly similar to those measured by CO_3-NP (static test) for all three mine sites. The CO_3-NP value, based on total inorganic carbonate, is generally considered to be a more relevant static test than the modified Sobek, which can overestimate NP by including non-carbonate neutralizing minerals that are unlikely to actually react in the field (Price, 2009). Studies to measure the neutralization potential of common rock-forming minerals and common rock types and compare it to NP calculated from modal mineralogy have been done by Jambor et al. (2002); Jambor, Dutrizac & Raudsepp (2006); and Jambor, Dutrizac & Raudsepp (2007). Non-carbonate minerals (with estimated NPs) that may contribute to NP in a minor way in a modified Sobek test include plagioclase, chlorite, enstatite, anthophyllite, muscovite, and orthoclase (Jambor et al., 2002; 2006). The Nechalacho ore minerals bastnäsite and synchysite-parisite are fluorocarbonates with possible neutralization potential; however they were not included in the calculation as their contribution to NP remains uncertain.

Acid Potential

Acid potential can be calculated from modal mineralogy by calculating the sulfur content of acid-generating minerals. Static testing uses a determination of the amount of sulfur in the sample to calculate acid potential. The total sulfur results from static testing compare well to the total sulfur assay determined by MLA (Table 2). Sulfide sulfur from static testing was calculated by subtracting the sulfate sulfur content from the total sulfur measurement. This is a recommended indirect method for estimating sulfide sulfur where organic sulfur is not present (Price, 2009).

AP from modal mineralogy was calculated in two ways: with pyrite and pyrrhotite and arsenopyrite only (Py+Po+As) and with all the sulfides that have the potential to oxidize (sulf). Table 3 shows that MLA-calculated AP is generally similar to AP determined by laboratory-measured %S.

Neutralization Potential Ratio

Acid base accounting involves taking the results of static testing, including paste pH, sulfur species, and neutralization determination, to make estimations as to the potential for metal leaching and acid rock drainage. The neutralization potential ratio (NPR) evaluates NP/AP. For this analysis, two NPR calculations are compared in Table 4. NPR (static testing) is calculated from AP(static testing) and the NP calculated from modal mineralogy, and NPR(MLA) is calculated from the AP and NP calculated from modal mineralogy. Samples are considered potentially net acid generating (PAG) if the NPR < 1, non-PAG if NPR > 2 and uncertain if NP/AP is between 1 and 2 (Price, 2009). Three of the samples from New Calumet are potentially acid-generating based on these criteria, one non-acid-generating, and two uncertain. Subsequent MLA analysis on five additional samples from Mt. Sinai (MS) confirmed NPRs near zero for all samples (Dongas 2013). The Nechalacho tailings all have high NPR and are thus non-PAG, whereas the Geco tailings have very low NPR and are classified as PAG.

CONCLUSIONS

Our results have shown that the NP and AP calculated from SEM-MLA results compare well with the results of static tests for three different mine sites, and the calculated NPR places the samples in the same category with respect to potential acid generation as the static testing.

NP and AP calculated from modal mineralogy provide several advantages over laboratory tests, notably the explicit consideration of Fe and Mn carbonates, and the identification and quantification of important acid-generating or acid neutralizing minerals that may be found in smaller amounts and with greater chemical accuracy than could be detected by other quantitative techniques such as XRD.

Particle size and liberation were not analyzed here, as they are not comparable between thin section analysis using MLA and static testing. MLA works on intact samples and preserves sample texture and particle size. Static testing utilizes subsamples crushed to <74 micrometers or <120 micrometers (depending on laboratory) and the crushing and grinding creates new particles and surfaces (Price, 2009). However, preliminary assessment of the degree of liberation of sulfide minerals in the New Calumet samples suggest that after 50 years of exposure, most of the remaining sulfide grains are very small (<50 micrometers) and locked within silicate grains, and likely unavailable to contribute to AP even in samples crushed for static testing. This would explain the persistently pH-neutral drainage at this site despite the NPR value between 0 and 1 for most samples.

ABSTRACT

A range of techniques are available for the removal of sulfate ions from mine waters and industrial effluents. A number of processes involve the removal of sulfate as ettringite, a calcium aluminium sulfate ($Ca_6Al_2(SO_4)_3(OH)_{12}{\cdot}26H_2O$) at elevated pH (11.5 – 13). Various process configurations have been proposed using lime and a source of aluminium to react with the sulfate in the process feed. This paper presents a study of the effect of the source of aluminium (when mixed with lime and synthetic sodium sulfate rich effluent) on the physicochemical properties of the resultant ettringite sludge and on the propensity of the precipitate, when recirculated, to form high density sludge (HDS). The study demonstrates that sodium aluminate ($NaAlO_2$), aluminium chloride ($AlCl_3$), aluminium nitrate ($Al(NO_3)_3$) and polyaluminium chloride (PAC) all form ettringite and remove sulfate, with $AlCl_3$ being the most successful during 'single-pass' treatment. Furthermore, synthetic $Al(OH)_3$ was demonstrated to be unreactive and the study also confirms the results of earlier literature that crystalline gibbsite does not form etttringite. The continuous trial with $NaAlO_2$ suggests that recirculation of sludge does improve the reaction kinetics of ettringite precipitation with lower residual sulfate concentrations being reached in similar residence time in the reaction tank when influent water is contacted with recirculated sludge. Different aluminium sources play a key role in determining the resultant sludge volume with $NaAlO_2$ forming a voluminous sludge and $AlCl_3$-derived etttringite forming a denser single-pass sludge. Both reagents show only a slight tendency to form HDS upon recirculation. Microscopy images show differences in the precipitate morphology between Al sources and recycled precipitates. These results highlight the importance of understanding how reagent choice influences the properties of the resultant sludge properties, with the commensurate implications for process design, when applying the ettringite precipitation process for the removal of sulfate from effluents.

Keywords: Sulfate removal; high density sludge (HDS); sodium aluminate

INTRODUCTION

Elevated concentrations of the sulfate ion ($SO_4^{2-}{}_{(aq)}$) occur in water bodies impacted by acid mine drainage (AMD). The sulfate results from oxidation of the sulfur moeity of pyrite,. Elevated sulfate concentrations are also common in other industrial effluents from smelting operations, pulp and paper mills, textile mills and tanneries (Galiana-Aleixandre et al. 2005; GBC 2000). Sulfate in itself is not toxic to humans. The taste threshold depends on the form in which the sulfate is present, but generally lies between 250 mg/L and 1000 mg/L. No health related issues have been reported or fully proven to be the result of any sulfate concentration and in terms of water quality standards no target have been set by WHO although their recommendation lies at 250 mg/L due to taste (WHO 2011). At concentrations greater than about 500 mg/L sulfate becomes a concern if the water contacts concrete infrastructure because it can cause deterioration of concrete, this can restrict disposal of sulfate-rich effluent to sewers.

The treatment of sulfate has for a long time been of secondary importance in water treatment due to the relatively low toxicity of sulfate compared to other contaminants. However, in the recent years environmental regulators have become more concerned with high sulfate concentrations in effluents especially when it is a key contributor to high total dissolved solids which are becoming a target of more stringent regulation. According to the International Network for Acid Prevention (INAP) it is therefore likely more demanding regulations will appear in the future (Lorax 2003). A number of treatment approaches for treating sulfate rich water have been variously reviewed in the literature (e.g. Bowell, 2004; Lorax, 2003). Some methods, in particularly those used for AMD, are developed to also clean water from metals and reduce the acidity. The existing methods can be broken down into four types (Lorax 2003) (i) Chemical treatment with mineral precipitation (ii) Membranes (iii) Ion exchange and (iv) Biological treatment. Note that ultimately membrane processes result in a concentrated sulfate brine which will require precipitation or crystallisation to produce a solid for final disposal. Biological processes generally rely on conversion by reduction to H_2S and either removed as metal sulphide or zero valent sulphur. Chemical treatments involve precipitation of the insoluble/sparingly soluble sulfate salts including gypsum, ettringite, barium sulfate (e.g. Bosman et al. 1990).), and jarosite. The Lorax(2003) report highlights ettringite precipitation processes as being particularly promising.The reaction occurs at elevated pH and involves reaction of dissolved sulfate with a source of aluminium (Al) and calcium (Ca) such that ettringite ($Ca_6Al_2(SO_4)_3(OH)_{12}\bullet 26H_2O$) precipitates. This paper concerns the ettringite precipitates that form during water treatmentfor the removal of sulfate.

Properties of ettingite precipitates

Ettringite can refer to both the mineral and the ettringite crystal structure (Tishmack and Burns 2004; Damons and Petersen 2002). The distinguishable features of the ettringite crystal structure are parallel columns comprising Ca^{2+}, Al^{3+} and OH^- structured units of $[Ca_6Al_2(OH)_{12}\cdot 24H_2O]^{6+}$. Between the columns channels are formed where water is present as well as sulfate ions which balance out the structural charge (Johnson, 2004; Damons and Petersen 2002). The mineral can exchange some of its ions without adverse structural change (Damons and Petersen 2002). The actual water content of ettringite can change (24-32 moles per mole of ettringite) and a change in water content does

have an impact on the XRD peaks. (Tishmack and Burns 2004). Most research on ettringite is in conjunction with concrete where it is a common constituent phase. Much literature is focused on secondary ettringite formation which can be problematic due to growth and expansion of the mineral which causes cracking. A comprehensive study by Cody et al. (2004) investigated how the nucleation and growth of the ettringite crystals were affected by different chemicals. The findings from the study showed that different precipitate morphologies were found and were dependent on the type and amount of additives.

Although there are some publications covering the effectiveness of different reagents in removing sulfate by ettringite precipitation (e.g. Janneck et al, 2012), there is an absence of studies looking at the influence on the resultant sludge. This study came about after inital continuous trials of an ettringite precipitation process (detailed below) resulted in excessive volumes of precipitate, as compared to other mine water sludges that the authors are familiar with. This paper thus aimed to examine (i) the influence of aluminium source on the properties of the resultant sludge and (ii) to examine whether recirculation of the sludge leads to a densification of the final sludge. Sludge recirculation is well established in the High Density Sludge (HDS) process used commonly for the removal of metals from AMD (add reference). Recirculation of the sludge results in denser HDS (in terms of m/v) than single-pass sludge with better settling rates, dewaterability and reduced resistance to filtration which equates to better process economics (Coulton et al 2004). Among the published ettringite based sulfate removal processes, those of Outotec and Veolia incorporate sludge recirculation. Note that sludge recirculation is included in the SAVMIN process but only after regeneration of the sludge to active $Al(OH)_3$ so this process is not comparable with that presented here.

METHODOLOGY

Initial Continuous Trial of Sodium Aluminate

The initial experiment began with a continuous pilot plant trial using sodium aluminate ($NaAlO_2$), based upon early trials showing that $NaAlO_2$ was a suitable source of soluble aluminium for ettringite precipitation. The pilot plant was supplied by G.U.N.T. Gerätebau GmbH. A photograph of the plant in use with $NaAlO_2$ and lime and a close-up of the ettringite precipitates can be seen in Figures 1 and 2. The plant consists essentially of a raw water tank, a reactor tank followed by a flocculation/coagulation train with up-and-over weirs, followed by a lamella clarifier. Reagents are dosed from reagent containers with feed pumps. Manual setting of the lime flow to the reactor tank was performed with regular pH measurements with a portable instrument. A sludge recirculation pump was installed and for most of the work up to two lime slurry feed pumps were installed. All chemical analyses were performed using the portable Hach Spectrophotometer following standard procedures (add reference).

The plant was configured to add lime and $NaAlO_2$ concurrently into the cylindrical precipitation vessel, where recirculated sludge was also added. Raw water feed rate was fixed initially at 10 litres per hour, giving a nominal residence time in the vessel of 1 hour excluding the influence of the thickened sludge re-circulation. Lime was added as a 5% m/v suspension to maintain the pH at the required value in the precipitation tank (pH > 11.5) and $NaAlO_2$ was dosed as a solution at 5 % m/v based on the stoichiometric amount of Al required. Anionic flocculant (NA 120 L) was dosed as an aqueous solution at a concentration of 0.005 % m/v to give a dosage between 1.3 and 2.6 mg/l of

dry polymer. Recirculation of sludge was achieved with the peristaltic pump (yellow in colour on Figure 1).

Figure 1. Photograph of plant in operation showing the ettringite precipitate in the clarifier and the external sludge recirculation pump in the foreground

Figure 2. Close-up of the clarifier with subdued lighting showing ettringite precipitates and clear overflow

Batch testing of different aluminium sources

The batch experiments treated a sodium sulfate solution by addition of stoichiometric quantities of aluminium (in various forms) and a 10 % stoichiometric excess of lime. The solution was kept at SO_4 = 1500 mg/L to avoid precipitation of gypsum. The chemicals used were 2.22 % m/v Na_2SO_4 solution, 5% m/v $Ca(OH)_2$ slurry, and the aluminium sources trialed were as follows: 25 % $AlCl_3.6H_2O$, $NaAlO_2$, polyaluminium chloride (10% m/v), 22 % (m/v) $Al(NO_3)_3{\cdot}9H_2O$, aluminium hydroxide powder and synthesised aluminium hydroxide. The synthesised aluminium hydroxide was produced by neutralising 250 ml of a 2 % m/v $AlCl_3$ solution with NaOH. This resulted in a gel which was filtered, rinsed and dried.

Batch tests were carried out as follows: 100 ml of the Na_2SO_4 feed solution was added to a beaker placed on a magnetic stirrer. Reactions were started by introduction of 4 ml of the $Ca(OH)_2$ slurry. This was followed by aluminium addition (in which ever form). Immediately afterwards an additional 1.1 ml of the $Ca(OH)_2$ was added to the beaker. The suspension was allowed to stir for a total of 15 minutes. The suspension was then placed in a settling cylinder and the sludge allowed to settle for 15 minutes and then sludge volume recorded. This was the end point for 'single pass' experiments. For all non-final cycle (i.e. where the sludge was to be recycled) experiments, at the end of settling the supernatant was carefully decanted off and the sludge returned to the reaction beaker. 100 ml of Na_2SO_4 feed solution was added to the sludge in the reaction beaker and the next cycle begun. The experiments were thereafter repeated according to this procedure for between 1

and 12 cycles for $AlCl_3$ and 6 cycles for $NaAlO_2$. To obtain images of the precipitate morphology 0.5 ml of suspension was removed during the 14th minute of the final cycle for recycled sludge experiments. The sample was spread across a petri dish and immediately oven-dried at 35°C prior to imaging under an optical microscope. At the end of all experiments solids were recovered by filtration, oven-dried at 35°C (for 24 hours) and weighed.

RESULTS AND DISCUSSION

Continuous pilot plant trial with sodium aluminate

Operation in this mode proved to be extremely challenging and in hindsight it would have been prudent to perform bench-scale batch tests (as was done for the remainder of the study) to determine whether sludge recirculation lead to densification of the ettringite sludge. It soon became impractical to return the thickened sludge to the precipitation tank using the peristaltic pump alone. For that reason it became necessary to employ a laborious method of filtering the sludge in a large Buchner funnel arrangement and return solids as a much thicker paste than was possible using the plant thickener. Nevertheless it was possible to keep running for about three weeks, treating about 800 litres of raw water containing up to 2350 mg/l of sulfate.

Figure 3 depicts the reduction in sulfate concentrations achieved throughout the pilot plant operation with $NaAlO_2$ as the source of Al and shows that a substantial improvement in removal efficiency took place as plant operation proceeded. In order to explain this trend it is necessary to consider the variations in other parameters that took place. Of particular note are the changes in aluminium dosages and rise in solids concentration in the reactor as time progressed. The pH in the precipitation reactor was slowly increased over time but was always above the target value of about 11.5 for ettringite precipitation. The improved sulfate removal cannot be attributed directly to the increase in aluminate dosage that occurred at Day 8. $NaAlO_2$ dose was increased from 0.17 l/h to 0.34 l/h after day 8 and then reduced to 0.25 l/h for days 15–25. It is more valid to examine the influence of stoichiometric amounts of Al present in the reactor. Up to Day 8 the removal of sulfate ion was approximately 10,000 mg/h. The Al addition rate was 2.8 g/h, thus representing an approximate stoichiometric excess of 50 %. Between Days 8 and 15 the removal of sulfate ion increased to about 20,000 mg/h whilst the excess of Al stayed at about 50 %. After Day 15 it was possible to add Al at approximately stoichiometric amounts and achieve removals of sulfate of up to 22,000 mg/h. It is concluded that the improved performance in terms of increase in the sulfate removal kinetics (implied by lower sulfate concentrations for the residence time) is the result of adding recycled solids to the precipitation vessel. It is interesting to note that very little improvement in sulfate removal efficiency occurred after the solids concentration exceed about 2 % m/v (i.e. 20 g/l).

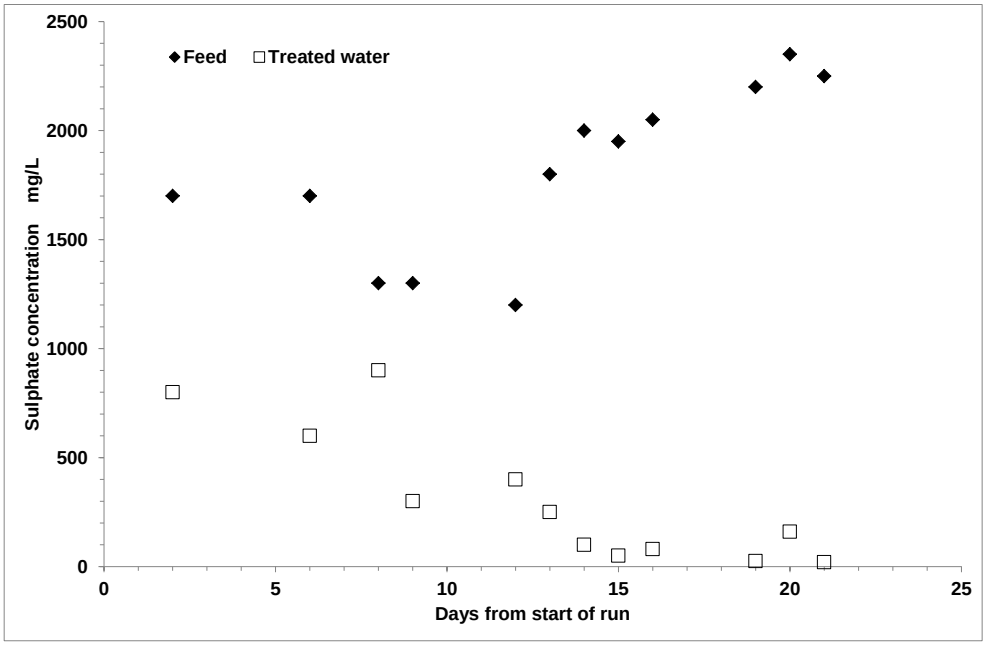

Fig 3. Variation in sulfate concentrations during pilot plant operation. pH > 11.5, Al dose variable (see text).

Batch trials with different aluminium reagents

In all cases where an obvious reaction occurred, the resultant precipitated solid was determined to be ettringite through XRD analyses. Furthermore ICP-OES on digested precipitates demonstrated the Ca, S, Al ratio expected for ettringite.

Initial Sludge Volumes

Table 1 shows the results of the single-pass ettringite precipitation experiments with various reagents providing the source of aluminium. Several important observations are as follows: In agreement with literature $Al(OH)_3$ powder is found to be largely unreactive, synthetic $Al(OH)_3$ was also found to be unreactive. $AlCl_3$ forms the least voluminous single pass sludge, and removes sulfate to the lowest residual level. The use of $NaAlO_2$ results in the most voluminous sludge (80 ml per 100 ml of influent treated) and relatively poor sulphate removal.

Propensity for sludge to densify during recycling

Figure 4 shows the effect of recycling the ettringite sludge on the resultant sludge volume where $NaAlO_2$ or $AlCl_3$ has been used as the Al source for ettringite precipitation. The 'predicted' sludge volumes are based on projections of sludge volume accumulating at the same volume that the single-pass sludge precipitated, and assuming incompressibility of the sludges. It can be seen that the initial trend of relatively high precipitant volume is observed to continue over 6 cycles for the

$NaAlO_2$ based sludge (in fact, the experiment had to be abandoned after 6 cycles due to impracticality of recycling the sludge). However, there is some evidence of sludge densification due to recycling of the sludge compared to projections based on single pass sludge volumes. Similarly, it can be again seen that $AlCl_3$ forms a much lower volume precipitate and that recycling of this precipitate leads to a slight densification over the volume of sludge expected from projection of the single-pass sludge volumes. However, beyond 9 cycles no further benefit is observed. These data indicate that sludge recycling confers some small benefits in terms of sludge densification as well as improved reaction kinetics.

Table 1 Mean residual sulfate and settled sludge volumes for different aluminium sources when precipitating ettringite from solutions with initial sulfate concentration = 1467 mg/L

Reagent	Number of experimental repeats	Mean Residual sulfate concentration (mg/L± stdv)	Settled sludge volume* (mL per 100ml of influent)
$NaAlO_2$	3	525 (± 19.2)	80 (± 17)
$AlCl_3$	4	365 (±193)	16 (± 2)
$Al(NO_3)_3{\cdot}9H_2O$	2	383	28
PAC	3	639 (±263)	22 (±2)
$Al(OH)_3$powder	1	1269	94
$Al(OH)_3$ synthetic	1	1464	95

*In 15 mins of settling time

Morphological characteristic of ettringite sludge

The optical microscopy reveals that the morphology of the ettringite precipitates varies for different Al source and also by recycling of the sludge. Figure 5 (a) and (b) show the $NaAlO_2$ single-pass and 6x recycled sludge. It can be seen that both the single pass sludge and the recycled sludge do not show the classical needle-like morphology of ettringite, but rather that small spherical particles dominate, this is particularly clear for the recycled sludge. Interestingly Cody et al. (2004) observed that large amounts of Na (added as NaCl) leads to the formation of spheres of ettringite precipitate rather than needles. Figure 5 (c) and (d) shows the $AlCl_3$ single-pass and 12x recycled sludge. The single-pass sludge demonstrates amorphous masses of crystals whereas the 12x recycled sludge shows that this early morphoogy has changed to a prounounced needle-like morphology (with needles of up to 100 μm) more typical of pure ettringite. It is clear that during recycling the precipitates have changed its morphology, whether this is due to ageing or through crystal growth is not known.

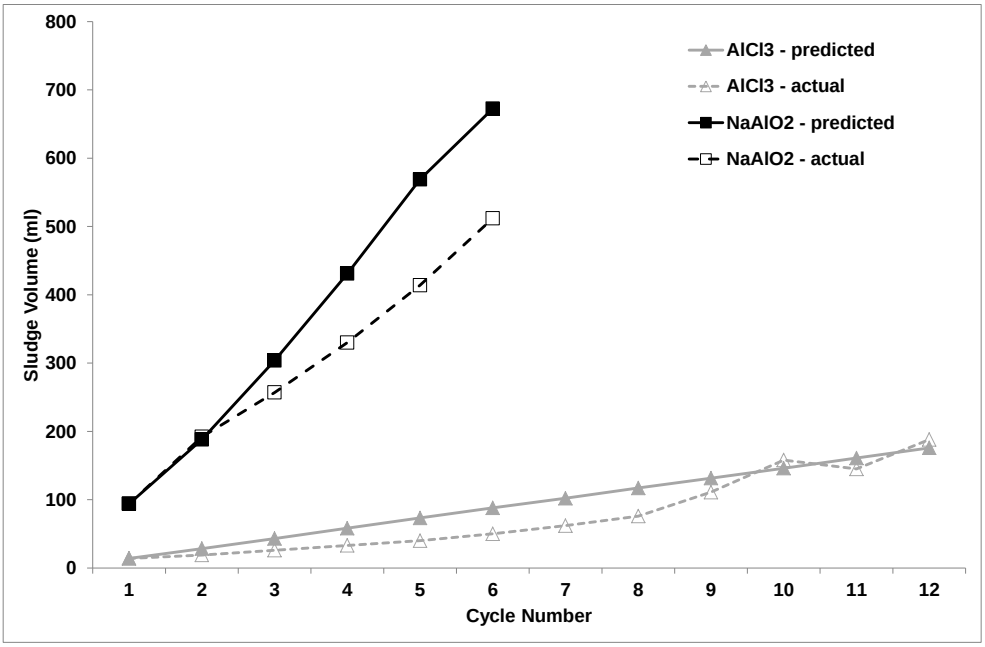

Fig 4. Effect of sludge recycling on volume of ettringite precipitation. Predicted volumes are based on projection of the single-pass sludge volume (corrected for measured sulfate removal)

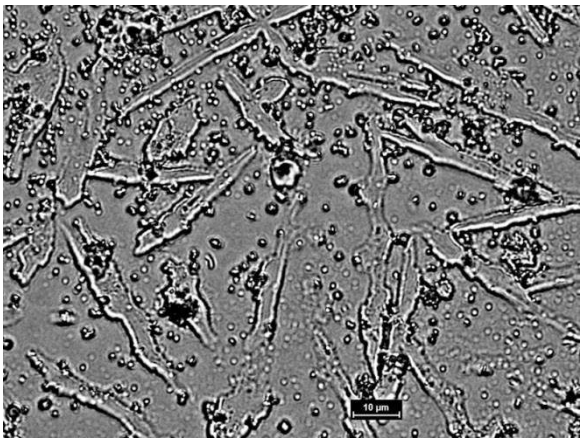
Cody et al. (2004) describe how (i) nucleation of ettringite may becompletely inhibited and another less stable mineral suchas calcium aluminate monosulfate forms, (ii) how nucleation gel/colloid can form or nucleation (iii) or crystal growth can be inhibited and can affect growth in numerous ways depending on which crystal planes are poisoned by foreign ions. This study along with Cody et al. (2004) indicates that ettringite precipitates seem to be sensistive to the aqueous environment from which they form and that this can have profound effects on the nature of the sludge formed.

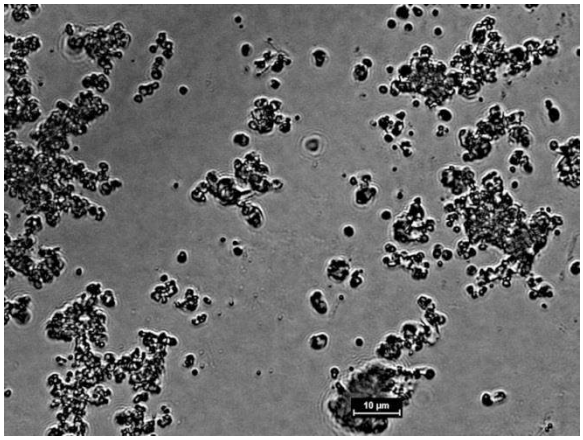
CONCLUSIONS

The following conclusions are drawn from this study:

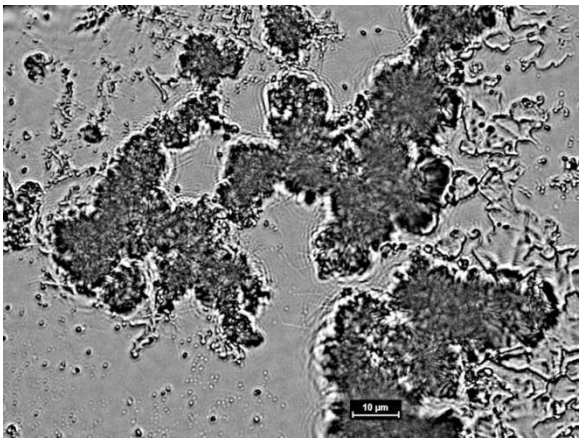
- Sodium aluminate produced a voluminous ettringite sludge during both continous operation and batch testing relative to aluminium chloride
- Using aluminium chloride as the aluminium source leads to the lowest residual sulfate levels in single-pass operation.
- Recirculation of the sodium aluminate based sludges yielded improvements in sulfate removal, which in the context of the continuous operation equates to better removal process kinetics



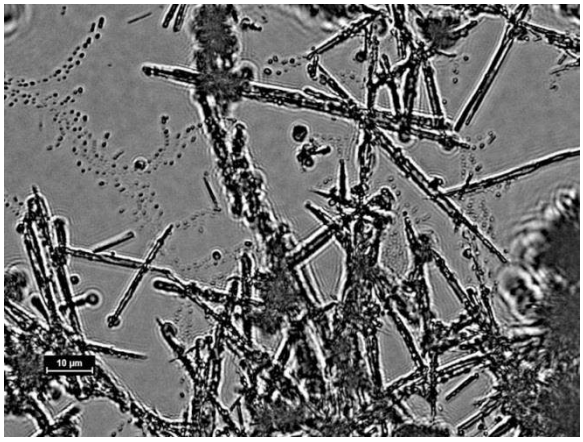
(a) $NaAlO_2$ single-pass sludge, 100 x magnification



(b) $NaAlO_2$ 6 x recycled sludge, 100 x magnification



(c) $AlCl_3$ single-pass sludge, 100 x magnification



(d) $AlCl_3$ 12 x recycled sludge, 100 x magnification

Fig 5. Optical mineralogy of air dried ettringite sludge.

- Recirculation of the sodium aluminate and aluminium chloride based sludges showed that the sludges have the propensity to slightly densify on recycling
- Morphological differences were observed between precipitates formed from different reagents and when recycled
- The choice of Al-bearing reagent will influence the morphology of the precipipate formed during the ettringite precipitation process, crucially these microscopic morphological changes correlate with macroscopic sludge characteristics.

ABSTRACT

Savannah Nickel Mine is an underground mine located in the Kimberley region of Western Australia and is owned and operated by Panoramic Resources Limited (Panoramic). The open cut mine commenced in 2005 and rapidly progressed to an underground operation. Tailings generated from processing ore are stored at an above-ground valley fill Tailings Storage Facility (TSF). The initial mine approval was based upon a number of studies, which incorporated preliminary geochemical data, and included a requirement to tranfer the tailings from the TSF to the open cut void at the end of mine life. Recent exploration success has demonstrated that the open cut void has insufficient storage capacity to store the volume of tailings predicted to be generated over the life of mine.

Over the past decade, a substantial body of geochemical and mineralogical information has demonstrated that the geochemical behaviour of the tailings in the TSF is much more benign than initially predicted. Despite containing almost 30% pyrrhotite, the tailings generate only a fraction of the acidity predicted by classical static geochemical test techniques, and the rate of acidity generation is more than compensated by the inherent non-carbonate acid neutralizing capacity available from specific silicate minerals within the tailings matrix. These studies have shown that leaving the tailings in situ at mine closure and using a cover system will produce a sustainable environmental outcome, and the mine operator has recently received regulatory approval to increase the storage capacity of the TSF and implement this closure strategy.

The mine operator now has a very good understanding of the geochemistry of the tailings, although geochemical, mineralogical and a broad range of other related studies are continuing, moving towards mine closure.

Keywords: Tailings, Pyrrhotite, Geochemistry, Mineralogy, Mine Closure

INTRODUCTION

In order for mining companies to obtain approval and finance for mining and mineral processing projects, a broad range of technical studies need to be completed, including the geochemical and mineralogical assessment of mine waste materials. These studies should commence during exploration and ultimately continue throughout the various phases of the life of the operation through to closure. Successful completion of these studies can lead to the development and implementation of appropriate environmental management strategies, which can significantly reduce the risk of the development of Acid Rock Drainage (ARD) and Metal Leaching (ML).

Acquisition of timely geochemical and mineralogical information on the characteristics of waste materials can be used to develop innovative design solutions, limit the potential for environmental impacts, and promote sustainable closure (Miller, 2014). During the mine planning and regulatory approvals stage, there may be a limited amount of information available on the long-term geochemical behaviour of waste materials. This can lead to the development of impractical mine waste management solutions and prescriptive approval conditions, which may not result in the best environmental outcome. Some flexibility should remain during the mine operational phase to improve mine waste management strategies, based on additional knowledge and experience gained during the mine life.

Geochemical and Mineralogical Studies

Whilst technical guidelines for the geochemical and mineralogical assessment of mine and mineral process waste materials have been developed in Australia (DITR, 2007) and internationally (INAP, 2009), it is important to consider the individual characteristics of sites and waste material types when selecting the best test methods to use. Classical geochemical characterisation techniques can sometimes produce inconclusive and unexpected results. In such cases, further study using more specialised geochemical and mineralogical tests can be warranted, particularly where some uncertainty remains over the long-term geochemical behaviour of waste materials.

The information acquired from geochemical and mineralogical tests on mine waste materials can assist with predicting the level of environmental risk and potential impacts. However, due to scale-up and other factors such as the heterogeneity of the mine waste materials and the redox conditions experienced by mine waste materials in the field, simplistic direct comparison of leachate chemistry with existing water quality guidelines should be treated with caution. Where uncertainty exists, modelling is often used to assess the complex behaviour of mine waste materials and potential impacts from mine waste storage facilities (Mayer *et al*., 2003).

Focus of Paper

This paper presents a case study from Savannah Nickel Mine located in the Kimberley region of Western Australia, which illustrates the benefits of ongoing geochemical and mineralogical characterisation and assessment studies on mine tailings materials throughout mine life and in planning for closure. These studies form an integral part of broader operational and closure planning studies completed for the site Tailings Storage Facility (TSF), such as geotechnical

stability, cover design, geomorphology, solute transport modelling, ecotoxicology and ecological assessment of downstream aquatic fauna.

Classical geochemical classification techniques completed at the mine planning stage of the project produced results that were not replicated in the field and led to regulatory conditions of consent, which not produce the most effective long-term environmental outcome at the site. Geochemical, mineralogical and other related studies completed over the past ten years show that leaving the tailings *in situ* at mine closure and using a store and release cover system will produce a more sustainable environmental outcome. Whilst some researchers have had some success with reactive alkaline cover systems, the use of such a cover system is not required st this site (Quispe *et al*., 2013) The mine operator has now received regulatory approval to increase the capacity of the TSF and implement this closure strategy.

CASE STUDY

Project Background

Savannah Nickel Mine is owned by Panoramic Resources Limited (Panoramic) and is located in a semi-arid to sub-tropical part of Australia with an average annual rainfall of approximately 557 mm (ranges from 280 to 1,310 mm) and an average annual evaporation of approximately 3,200 mm. Most rainfall occurs in the hot summer months between December and March.

Commencing in 2005 as an open pit operation, the mine is now an underground operation, and tailings are currently disposed of as a cement-based backfill underground or stored at an above-ground valley fill TSF. The original mine approval required the mine operator to remove the tailings from the TSF back into the underground workings and open pit at the end of mine life. Approximately six million tonnes of tailings had been placed at the TSF by the end of 2014.

Additional mineral resources were identified at the project resulting in an extension of the mine life and a requirement for additional capacity to accommodate additional tailings generated from mineral processing. In 2007, Panoramic began assessing options for the long-term management of tailings at the operation to match revised life of mine ore reserve estimates. The preferred option was to increase the capacity of the TSF in a series of embankment raises and leave the tailings *in situ* at mine closure before covering with a suitable cover system. The high evaporation to rainfall rate at the site (over 5:1) essentially precludes the use of a permanent water cover system for the tailings.

Geochemical information presented in the original approvals documentation (Notice of Intent) in 2002 predicted that the tailings would be Potentially Acid Forming (PAF) and could pose a significant long-term risk to the environment from potential seepage of ARD and ML. However in 2008, an independent peer review found that removing tailings from the TSF and returning them to the open pit was unlikely to produce the best environmental outcome at closure. A broad range of technical studies were recommended to assess the tailings at the TSF and the merits of vairous mine closure options. These studies included geochemistry, mineralogy, surface water and groundwater hydrology, cover design, geomorphology, solute transport modelling, ecotoxicology and ecological assessment of downstream aquatic fauna. A network of surface and groundwater monitoring infrastructure was already in place at the site.

The additional technical studies outlined above were commissioned in 2008 and completed in 2013, and included consultation with relevant stakeholders, including State Government agencies. Site

visits and risk workshops were held to communicate the ongoing findings of the technical studies and demonstrate a transparent process for seeking approval for the preferred operational and post-closure tailings storage option. In 2013, Panoramic received approval from the WA State Government to increase the capacity of the existing TSF and implement the preferred long-term tailings storage option at closure. Panoramic has continued to fund long-term geochemical and mineralogical studies on tailings, and some of the latest findings are included in this paper.

RESULTS AND DISCUSSION

Tailings Characteristics

Geochemical studies completed on a simulated tailings sample in 2002 concluded that pyrite was present as the main sulfide species and classified the tailings as PAF. Subsequent geochemical and mineralogical studies completed over the past ten years have found that 'actual' tailings generated at the project and deposited in the TSF contain pyrrhotite rather than pyrite and react in a very different way to that originally assumed in 2002. Whilst the 'actual' tailings are still classified as PAF using static geochemical classification methods, the bulk tailings continue to generate very little acidity, and contain sufficient neutralising capacity to produce circumneutral pH leachate with excess alkalinity and low metal concentrations (Robertson *et al*, 2012). At the TSF surface, the tailings form a trafficable hardpan surface about 3 cm thick and the oxidation front has not progressed below the hardpan layer. Below the surface hardpan, the tailings remain relatively fresh/unoxidised and do not generate acid conditions after a storage period of up to ten years (Robertson *et al.*, 2012) as evidenced by:

- The visual appearance of the tailings at the TSF,
- *In situ* geochemical and mineralogical data for tailings in and below the hardpan surface;
- The findings of a "tailings-at-depth" geochemical assessment down to 20m;
- Water quality seepage data at the downstream Water Storage Facility;
- Groundwater monitoring data downstream of the TSF; and
- Geochemical and mineralogical studies completed over the past ten years.

Water quality monitoring downstream of the TSF indicates that seepage water is typically pH-neutral, with excess alkalinity and elevated conductivity, mostly attributable to dissolved sulfate, calcium and magnesium, whereas the concentration of dissolved iron is low. The elevated sulfate is attributable to a number of factors including the oxidation of near-surface tailings stored in the TSF (*i.e*. hardpan formation) and recycling of sulfate rich water from dewatering of the water storage facility seepage and underground workings at the mine.

Geochemical and mineralogical studies of *in situ* bulk tailings at the TSF demonstrate that below the hardpan surface, bulk tailings remain pH neutral (due to the neutralizing capacity of magnesium silicates) are slightly brackish, and containing low concentrations of trace metals suggesting limited oxygen diffusion into the bulk tailing material (possibly through a combination of surface hardpan formation, elevated tailings saturation levels, and maintenance of reducing/anoxic conditions at depth in the TSF). The results of ongoing kinetic leach column (KLC) studies on tailings over the past seven year mirror these findings. A key finding is that under anoxic conditions, the tailings pore water contains very low concentrations of soluble reduced iron and sulfate sulfur species

indicating limited potential for any latent acidity in TSF seepage. However, this does not entirely explain the geochemical behaviour of the *in situ* bulk tailing materials at the TSF. A significant amount of elemental sulfur was also found to be present in both the bulk tailings at depth and the oxidised hardpan, which suggests that alternative pyrrhotite reaction mechanisms are occurring in the bulk tailings.

Tailings Hardpan

The relatively benign geochemical nature of the tailings solids at the TSF is unusual as this material can contain up to 30 wt. % pyrrhotite. A review of the available literature over the past 15 years suggests that pyrrhotite is less well studied that pyrite, but is commonly associated with nickel sulfide deposits (Schippers *et al.*, 2007, Heikkinen and Räisänen, 2008; Robertson *et al.*, 2012).

The rate of pyrrhotite oxidation slows when a hardpan layer is present on tailings under both dry and saturated cover conditions (Gilbert *et al*., 2003). McGregor and Blowes (2002) suggested that a TSF hardpan layer could act as a hydraulic and diffusive barrier against the migration of rainfall infiltration and oxygen. The authors presented a case study for uncovered pyrrhotite tailings at a TSF in Canada (Fault Lake), and highlighted that the hardpan layer had grown to 20 cm and the oxidation front had migrated only an additional 18 cm after 25 years of exposure to atmospheric conditions. Further numerical simulations of the Fault Lake tailings concluded that, over a time period of 1,000 years, only the top three metres of tailings would become oxidised (Romano *et al.*, 2006), which aligns with earlier tailing modelling work which indicated that the overall rate of oxidation of the near surface tailings was eventually controlled by the diffusion of oxygen into the tailings mass rather than by the reaction kinetics in the tailing (Elberling *et al.*, 1994). No information on water quality was presented in either of these references. These references illustrate the characteristics of a tailings surface hardpan and clarify the expected rate of progression of the oxidation front into the bulk tailings material over time.

At Savannah Nickel Mine TSF, the tailings form a surface hardpan, which also appears to limit oxygen diffusion or at least maintain a high level of saturation in the bulk tailings and generally retains the bulk tailings in a mostly reducing/anoxic environment. This has been confirmed by recent work completed on the tailings (Schumann *et al*, 2015), which indicates a slow and comparable rate of progression of the hardpan layer and oxidation front into the tailings (1cm per year if tailings are maintained above 75 % saturation). Another attribute of the tailings is that they contain significant amounts of potentially acid-neutralising gangue silicate minerals (*e.g*. enstatite), which can provide both short- and long-term neutralisation of acid generated through pyrrhotite oxidation (Ciccarelli *et al*, 2008).

Soil-atmosphere modelling results associated with the proposed final cover design for the TSF prepared by O'Kane Consultants demonstrate that a saturation level of 75 % in the tailings below the cover material is likely at depths of 5m or greater below the tailing-cover interface (Panoramic, 2012). At shallower depths in the tailings profile, a reduced level of saturation is expected, although at a depth of 1 m, a saturation level in the range 62 to 68% is still likely. This modelling takes no account of the surface hardpan maintaining higher levels of saturation in the bulk tailings. Hence the predicted level of saturation, together with the surface hardpan, will serve to significantly slow the pyrrhotite oxidation rate at the TSF to a rate that is likely to be matched by the silicate dissolution rate within the bulk tailings.

Reaction Pathways

In order to explain the relatively benign nature of the project tailings, the reaction mechanisms of pyrrhotite should be considered. The dissolution behaviour of pyrrhotite is less studied than that of pyrite; however a number of studies from both laboratory and field investigations have been published (*e.g.* Nicholson and Scharer, 1994; Thomas *et al*., 1998, 2000; and Belize *et al*., 2004). Pyrrhotite can follow a number of reaction pathways that can be acid forming or non-acid forming (Thomas *et al*., 2001). The non-acid forming reaction pathway involves the generation of goethite and elemental sulfur. Another potential pathway for pyrrhotite oxidation is where iron is converted to goethite and in this situation sulfur is fully oxidised to produce sulfuric acid. The two main reaction pathways which are considered to potentially operate within the tailings are provided below.

Reaction Pathway 1

$$Fe_{(1-x)}S + 3(1-x)/4O_2 + (1-x)/2H_2O \rightarrow (1-x)FeOOH + S^0 \quad [1]$$

Pyrrhotite + Oxygen + Water → Goethite + Elemental Sulfur

Reaction Pathway 2

$$Fe_{(1-x}S + 3(3-x)/4O_2 + (3-x)/2H_2O \rightarrow (1-x)FeOOH + H_2SO_4 \quad [2]$$

Pyrrhotite + Oxygen + Water → Goethite + Sulfuric Acid

Both acid forming and non-acid forming reactions could be occurring in the tailings at the TSF. However, the KLC test results, "tailings at depth" assessment, and seepage and groundwater quality observations downstream of the TSF suggest that, although pyrrhotite may be acid generating to some extent in the hardpan tailing material, it is generally non-acid forming or acid neutral in the bulk tailing material. The presence of elemental sulfur in the bulk tailings hardpan and at depth, and the lack of oxygen below the tailing hardpan surface (dissolved oxygen was measured in the tailing porewater during a drilling and sampling program at the TSF) suggests that a non-acid forming pathway is likely to be favoured. It is noted that no reduced sulfur species (such as sulfite) were found in the bulk tailings pore water at depth and iron concentrations were very low suggesting that the potential for latent acidity to occur in seepage from the TSF is low.

Any acid generated according to an acid generating reaction pathway in the tailings is likely to be neutralised by alkalinity from residual lime from the tailings and/or from mineral dissolution reactions. Recent mineralogical assessment work has established that the tailings contain enstatite, a magnesium silicate with a dissolution rate comparable to the measured oxidation rate of pyrrhotite in near saturated tailings and which provides a source of alkalinity at a rate comparable to the acid generation rate from pyrrhotite oxidation. This results in pH neutral drainage with excess alkalinity and low levels of dissolved metals as well as elevated salinity from sulfate, calcium and magnesium. These results are consistent with observations reported in the literature regarding other pyrrhotite-bearing tailings wastes (Schumann *et al.*, 2015).

KLC Tests

Long-term KLC tests have been operated for bulk (25 kg) tailings samples from the project over the past seven years to investigate the likely quality of seepage from tailings stored at the TSF. When operated under anoxic, saturated conditions the leachate chemistry closely resembles that of groundwater monitoring data for seepage from the TSF (*i.e.* pH neutral, excess alkalinity and low concentrations of trace metals). The KLC data has been used in other study components (*e.g.* post-closure TSF seepage modelling and potential groundwater impacts), to facilitate prediction of the likely quality of any long-term TSF seepage and potential for environmental impact.

More recently, three KLC tests have been established to determine the oxidative dissolution behaviour of pyrrhotite in the tailings as a function of water content and in the absence of additional alkalinity inputs **(Figure 1**). The three KLC tests have been operated with average levels of saturation of 50 **%**, 75 **%** and 100 % to investigate what geochemical processes are likely to occur in the tailings stored in the TSF in the post-operational period, during which saturation levels and alkalinity inputs may be less than those which currently occur during operations.

The tailings used in the more recent KLC tests were fully characterised prior to commencement of the tests. The pyrrhotite content of the tailings is around 29 wt. %, and no pyrite was found. The tailings contain no carbonate minerals, but contain magnesium silicates such as enstatite and anthophyllite, which are likely to provide some neutralising capacity. After eighteen months "weathering" of the tailings under KLC test conditions, the following conclusions can be drawn:

For fully saturated conditions –

- Leachates from the column are pH neutral with no acidity;
- Leachates are composed essentially of calcium and sulfate with most metals being non-detectable;
- There is little evidence of pyrrhotite oxidation (approximately 6 % estimated oxidation);
- The main geochemical process occurring in the tailings under fully saturated conditions is dissolution of gypsum which is present in the tailings as a precipitated phase when the tailings are deposited in the TSF.

At 75 % saturation –

- Leachate pH dropped to around pH 4.5 after eighteen months with low levels of acidity;
- Leachates are composed essentially of calcium, magnesium and sulfate with low levels of metals;
- Around 15 % of the pyrrhotite in the tailings has undergone oxidative dissolution;
- The main geochemical processes occurring in the tailings at approximately 75 % saturation are oxidative dissolution of pyrrhotite to produce goethite and elemental sulfur as the major reaction (64 %) and goethite and sulfate as the minor reaction pathway (36 %). Less than 2 % of the oxidised sulfur is leached from the column as soluble sulfate; the majority of sulfate remaining within the tailings as partially soluble sulfates (e.g. gypsum, epsomite, melanterite) or less soluble salts such as jarosite or schwertmannite. Dissolution of magnesium silicates (enstatite and anthopyllite) is also occurring.

Figure 1 KLC test setup.

At 50 % saturation –

- Leachate pH dropped to around pH 4 after eighteen months with acidity around 10 times higher than that in leachate from the tailings weathered at 75% saturation;
- Leachates are composed essentially of magnesium, iron, calcium and sulfate with the concentrations of other metals being low;
- Around 57 % of the pyrrhotite in the tailings has undergone oxidative dissolution over the 18 months of leaching;
- The main geochemical process occurring in the tailings at approximately 50 % saturation are essentially the same as those occurring at 75 % saturation, except that the rates are increased in the tailings with lower water content.

These results confirm that even under unsaturated conditions, the dominant reaction pathway for pyrrhotite oxidative dissolution in tailings produces elemental sulfur which, in the absence of further oxidation, is a non-acid producing reaction (Robertson *et al*, 2012). Of the pyrrhotite, which is fully oxidised to sulfate, the majority appears to precipitate as poorly soluble sulfate salts which contain stored acidity. This stored acidity in compounds such as jarosite is likely to redissolve at a sufficiently slow rate such that dissolution of magnesium silicates in the tailings will match that of acid production eliminating or greatly reducing acidity.

The low amount of acidity generated during weathering of the tailings can clearly be seen from the data shown in **Table 1**. Even under conditions of 50% saturation where nearly 60% of the pyrrhotite in the tailings has oxidised, the acidity measured in leachate is only 0.2% of the expected acidity based on ABA analysis. Therefore it is likely that even if fully saturated conditions cannot be maintained post operation, oxidation of pyrrhotite will result in a significantly reduced acidity load than is predicted by classical static geochemical tests.

Table 1 Measured versus expected acidity during eighteen months of tailings KLC testing

Saturation (%)	Amount pyrrhotite oxidised (%)	Expected acidity[A] (kg H_2SO_4/t)	Measured acidity (kg H_2SO_4/t)	Measured acidity as a percentage of expected acidity
50	57	145	0.34	0.23
75	16	41	0.039	0.10
100	6	15	0.035	0.23

A. Expected acidity calculated by multiplying the measured net acid producing potential (NAPP) (255 kg H_2SO_4/t) by the percentage of pyrrhotite oxidised.

The results of these KLC tests also demonstrate that there is an inverse correlation between the moisture content of the tailings and the rate of pyrrhotite oxidation, indicative of oxygen diffusion as the rate controlling process. These results suggest that at saturation levels likely to occur in the TSF following closure, the oxidation rate of pyrrhotite is likely to be sufficiently slow to be matched by the dissolution rate of magnesium silicates in these tailings resulting in pH neutral or low acidity leachate. Further testing is continuing to verify whether this situation is maintained.

CONCLUSIONS

A case study has been used to illustrate the complexity of the geochemical and mineralogical processes associated with tailings material at a nickel mining operation in Australia. Whilst detailed and targeted geochemical studies in the early stages of mine feasibility and planning can provide important information of the characteristics of mine waste materials, this paper illustrates that ongoing study and flexibility are required throughout the life of mine to ensure that the most appropriate operational and closure options are developed and implemented for tailings storage.

The results of this case study indicate that there is now a very good understanding of the geochemistry and mineralogy of tailings material at the mining operation based on a number of studies by recognised experts and peer reviews, where field evidence at the TSF matches predicted geochemical behaviour over time. The downward movement of the surface hardpan and oxidation

front into the bulk tailings at the TSF is very slow and predicted to remain so even without a cover system in place. The final cover design for the TSF predicts a high level of saturation in the bulk tailings below the cover material, but does not take into account the positive effects of the surface hardpan on maintaining the elevated tailings saturation level. Mineralogical and kinetic geochemical studies show that the rate of pyrrhotite oxidation and acid generation in the tailings is likely to be matched by the magnesium silicate dissolution rate. At the TSF, this results in pH neutral drainage with excess alkalinity and low levels of dissolved metals as well as elevated salinity from sulfate, calcium and magnesium. Further testing is continuing to confirm that this situation is maintained in the longer term.

ACKNOWLEDGEMENTS

The project was primarily undertaken by RGS Environmental Pty Ltd and Levay & Co. Environmental Services at the University of South Australia. The authors acknowledge the assistance and funding of the project by Panoramic Resources Limited over the past eight years.

Waste Rock Modelling to Improve ARD Prediction and Project Economics: A Case Study

Emily Luscz and Terre Lane
Global Resource Engineering, USA

ABSTRACT

Treatment of mine water impacted by acid rock drainage (ARD) can be a significant cost item for mining projects. Accurate predictions of potentially acid generating (PAG) waste and associated metals are important for estimating project economics, for detailed mine planning, and for developing waste rock management plans to protect downstream water quality. In this study, the methods used to predict ARD are described for an open pit mining project in southern Peru with waste rock containing significant sulfide mineralization. In conjunction with a geochemical testing program, two approaches were used to characterize potentially acid generating waste for the project. The first approach predicted PAG waste based on rock type, and utilized a conservative management strategy to handle all mineralized rock types as PAG, regardless of the variability within each rock type. The second approach used additional waste rock samples and geostatistical evaluation to construct an ARD block model that included an estimate of acid generating potential and contained metals. This allowed for scheduling of waste rock to minimize special handling of PAG materials with an associated reduction in handling cost. The results showed that while the first approach relied on less data, the second approach resulted in cost savings for the project. In addition, relying on rock type alone resulted in some potentially non-acid generating waste being classified as PAG. This case study illustrates the value of geospatial modeling of acid-generation potential to support project planning. The improved economics for the project compensated for the additional cost of the second approach.

Keywords: Acid rock drainage prediction, mine waste geochemistry, block modeling

INTRODUCTION

The Corani project is a proposed silver-lead-zinc project owned by Bear Creek Mining Company (BCMC) and is located in a high-altitude region of southern Peru. Initial feasibility work completed in 2010/2011 projected that the open pit would produce 256 million tonnes of waste rock over an 18-year mine life with waste rock being placed in several dump locations and as pit-backfill. A significant portion of the waste rock will contain sulfide mineralization, and as a result, mitigation of potential acid rock drainage from the waste facilities is a concern for the project. Additionally, naturally-occurring ARD, from weathering of exposed sulfide-bearing formations, and ARD, from historic mining, impact the project area.

Accurate prediction of geochemical risk is important for any project facing potential ARD risk and has implications for project economics, permitting, mine planning and environmental management. Guidelines for testing procedures and the approach to geochemical characterization are given in the Global Acid Rock Drainage (GARD) Guide (INAP, 2009) and several ASTM standards (i.e. ASTM E1915-11 (2011) and ASTM D5744-07e1, (2007)), but the amount of data collected and how this data is integrated into the mine plan and economic model varies between projects and depends on the stage of the project, the type and level of geochemical risk and the regulations and permitting requirements for the project.

In order to better understand the ARD potential of the proposed project and to develop a program for managing ARD at the project, a preliminary geochemical characterization was completed as part of the feasibility work (Dorey & Breckenridge, 2013). This program included static tests, LECO Furnace total sulfur and total carbon assays, and on-site kinetic cell tests. This was combined with geologic and metallurgical characterization of lithologies and material types. The conclusions from this work included the following:

- The geochemistry of the project will be dominated by certain mineralization types; in particular, mineralized lithic tuff with fine black sulphides (FBS) and mineralized tuff with pyrite and marcasite (PM).
- Whole rock analysis indicated that several metals of environmental and processing concern exist at high levels; synthetic precipitation leaching procedure testing suggested that many of these metals are readily leachable.
- The kinetic tests showed that many waste types were acid generating though the behaviour among certain mineralization types was mixed.

Following this work, additional samples were collected for geochemical testing. In total, static testing was completed on over 400 samples with an additional 200 samples analyzed by LECO Furnace.

Two different approaches were used to assess the geochemical risk of the project. The first approach (*Method 1*) predicted potentially acid generating (PAG) waste based on rock type and utilized a conservative management strategy to handle all mineralized rock types as PAG, regardless of the variability within each rock type. Given the availability of additional samples and optimization work being completed for the project, the second approach (*Method 2*) used an ARD block model that included an estimate of acid generating potential and contained metals. The methods used to calculate the amount of PAG material for the project are described below.

METHODOLOGY

Method 1

The initial geochemical testing program revealed that much of the mineralized material could be considered PAG. Consequently, a conservative approach was used to estimate the amount of PAG material generated by the project. It was assumed that all mineralized tuff material would have acid-generating potential and would be managed using encapsulation. Based on this assumption, all blocks classified as mineralized tuff in the resource model were also classified as PAG. This allows a straight-forward approach to predicting total PAG waste, but does not allow the variability of acid-generation potential to be considered.

The annual PAG and NAG quantities were reported from the mine plan in order to stage the design of the waste storage facilities. The design included selective management of PAG waste, including encapsulation within inert waste and engineered cover zones. The calculations confirmed that enough non-acid generating (NAG) material would be available to line and cover the waste rock storage facilities, and in addition, to provide enough NAG material for construction of the tailings dam and for road construction.

Method 2

Following the collection of the additional geochemical samples, an ARD block model was developed to refine the PAG volume estimate as well as to allow the PAG production schedule to be estimated in conjunction with detailed mine planning. The ability to schedule PAG waste strategically as part of the planning process can allow waste handling and placement scenarios to be optimized. Waste with the highest PAG potential is ideally placed in the central portion of the encapsulation zones where oxygen permeation and precipitation infiltration are less important. In addition it may be possible to mine high ARD potential zones during the dry season and low ARD potential zones during the wet season, minimizing ARD risk from active placement areas. Method 2 also results in a reduction in the predicted total quantity of PAG material that must be managed, and increases the quantity of NAG material available for use as a construction material.

TECHBASE was used for data compilation and analysis of the geochemical data. TECHBASE is a database management program that includes capabilities for statistical analysis, spatial modelling and generating advanced graphics. The geochemical data, drillhole collars and survey data were loaded into the database along with the project block model.

Since samples varied in length, samples were composited into intervals with a minimum length of 1 and a maximum length of 8 meters. Once the geochemical samples were composited, composited intervals were assigned a lithology and geometallurgical type from the block model. This was accomplished by using nearest neighbour to assign lithology values from the block model to composite intervals in TECHBASE. Since there is 100% overlap between the block model and the geochemical samples, a maximum of 1 data point was used to estimate each point.

In order to estimate geochemical parameters from the geochemical samples to each block in the model, data was subset by lithology (mineralized tuff or non-mineralized tuff) and variograms were created for each parameter. Strong trends were not evident in the directional variograms so models were only fit to global variograms. In addition, the variograms revealed that for most parameters, spatial trends were only evident to about 75-150 meters.

Based on the variogram models, each parameter was estimated for each block in the block model using kriging. The result is an estimate of geochemical properties for each block in the resource model.

RESULTS

The Corani waste rock exhibits highly inconsistent geochemical behaviour. As indicated above, the initial geochemical test work showed a large degree of variability in acid generating potential, composition, and leachability of contained metals. These conclusions were confirmed by the additional static testing following the initial test work. Table 1 reports the summary statistics for net neutralizing potential (NNP) and metals of concern for both the entire sample database and for each mineralization type.

Table 1 Summary statistics for the sample database for all mineralized samples and by mineralization type (362 samples).

Table 2 Summary statistics for the sample database for all non-mineralized samples (64 samples).

Group	NNP				Arsenic (ppm)				Cadmium (ppm)				Mercury (ppm)			
	Avg	SD	Min	Max	Avg	SD	Min	Max	Avg	SD	Min	Max	Avg	SD	Min	Max
Non-Min	-9	16	-93	-3	36	24	10	188	0	1	0.02	4	0.04	0.08	0.01	0.42

The table indicates that most of the mineralization types have average NNPs that exceed the generally accepted criteria for determining likely acid generating waste (an NNP less than -20). However, the range shows that some samples, even in the most likely acid generating mineralization types have NNPs in the uncertain range (NNP between -20 and 20). MnO was the only waste type to show consistent potentially acid generating behaviour based on ABA results. The whole rock analysis results also show a high degree of variability as indicated by the results presented for arsenic, mercury, and cadmium.

Based on the *Method 1* approach, the open pit will produce an estimated 129 million tonnes of PAG material. Using the *Method 2* approach, it is estimated that only 81 million tonnes of PAG material will be produced. *Method 2* also provides an estimate of contained metals for each block.

Figure 1 shows boxplots of selected metals for the sample database and for the block model using *Method 2*. The close symmetry between the boxplots from the sample database and the block model suggest that the estimation processes did not introduce significant bias.

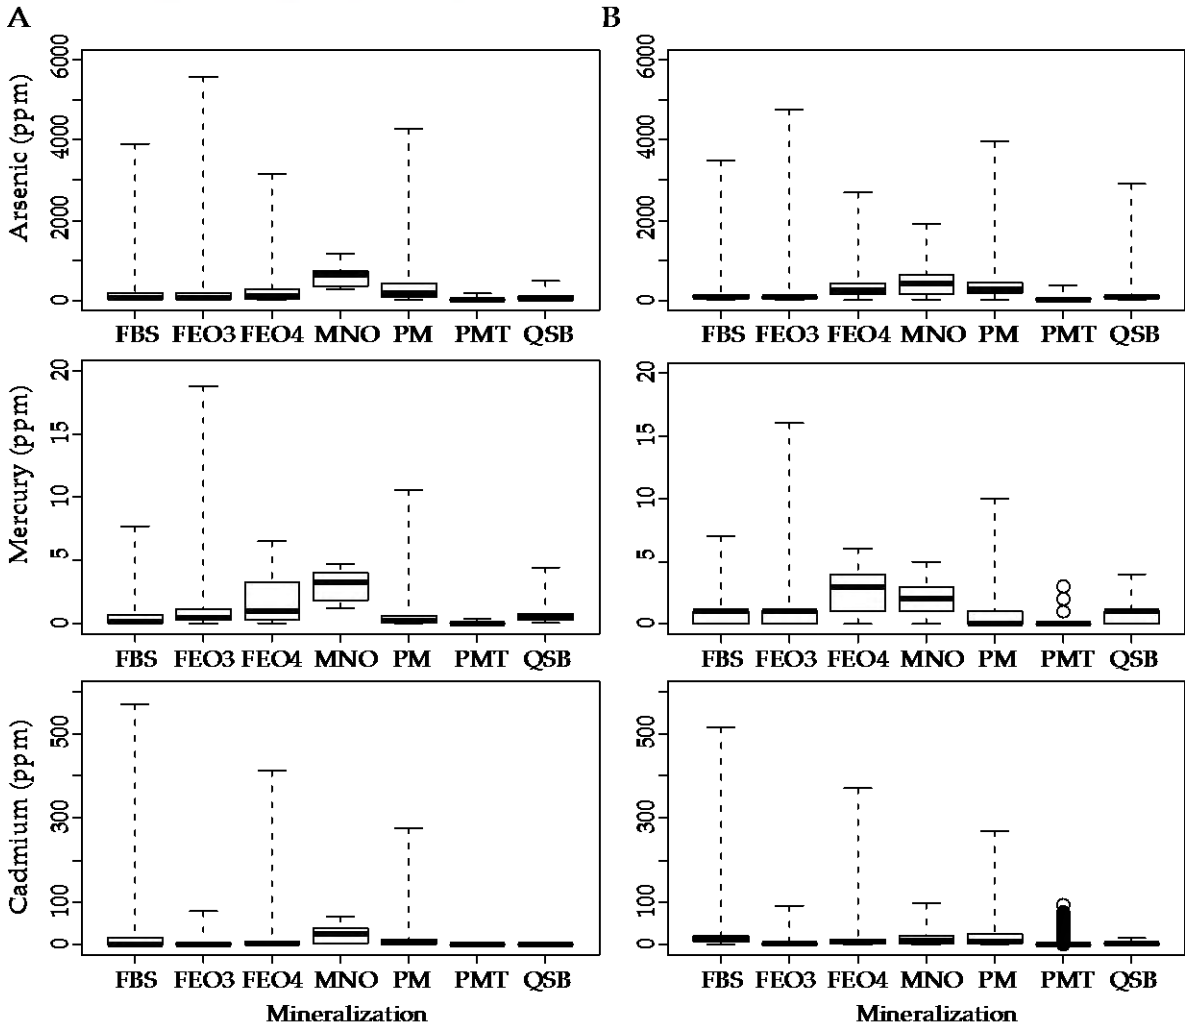

Figure 1 Box plots of selected metals by mineralization type for (A) the sample database and (B) the block model

Figure 2 is a typical cross-section through the Corani pit showing predicted net neutralizing potential using both methods. The mineralization of the section is also shown.

A significant portion of material previously classified as PAG using *Method 1* is classified as NAG using *Method 2*. In addition to an improvement in the outlook for the amount of PAG material requiring special handling, *Method 2* provides a spatially detailed description of PAG behaviour and contained metals. For instance, there are two areas in the cross-section with clearly elevated acid generating potential (centred near x=315900 and x=316800).

DISCUSSION

As the results indicate, depending on the selected method, the estimated volume and strength of PAG material can vary significantly. Each approach has a unique set of benefits and detractors

which must be considered when selecting the appropriate approach to ARD prediction. The pros and cons of each approach are outlined in Table 2.

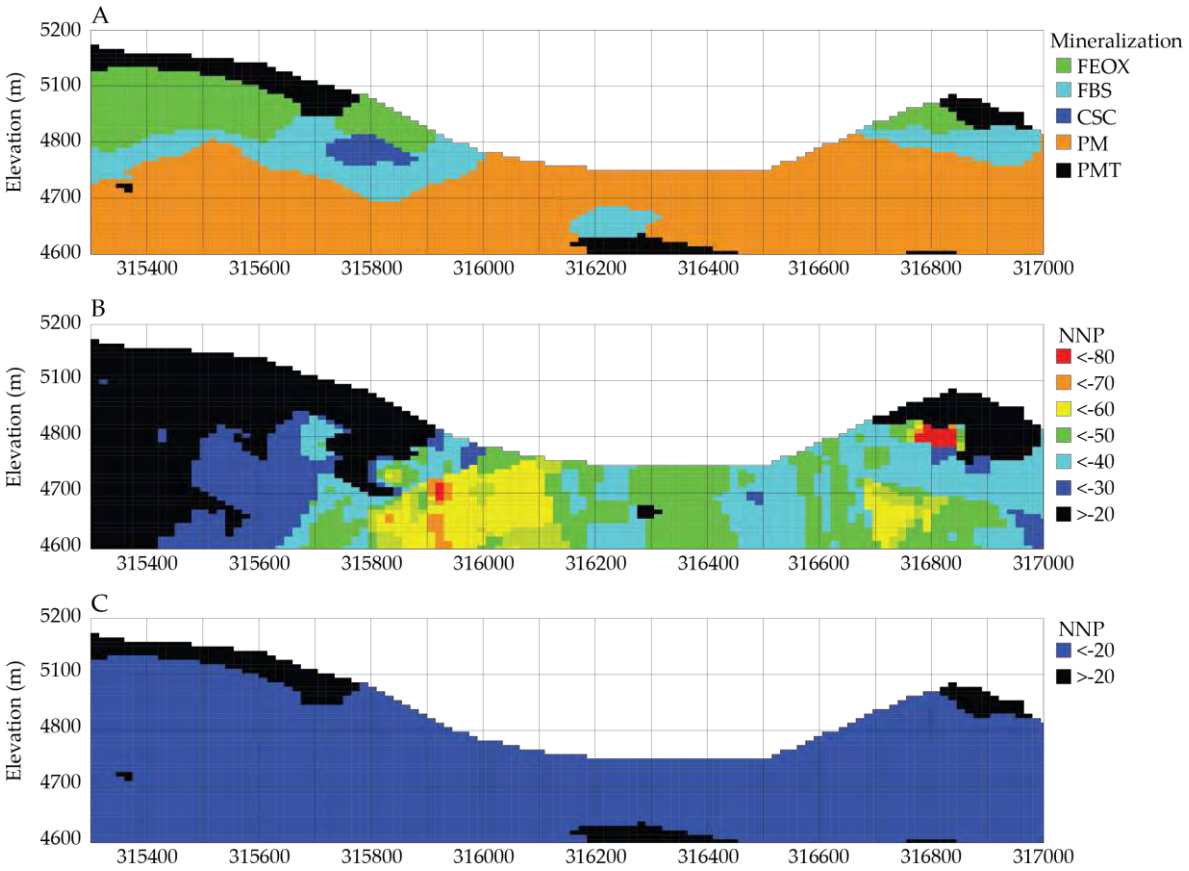

Figure 2 Typical cross-sections through the block model showing (A) mineralization (B) net neutralizing potential predicted using Method 1 and (B) net neutralizing potential predicted using Method 2. Mineralization types include iron oxide (FEOX), fine black sulfide (FBS), coarse sulfide and celadonite (CSC), pyrite marcasite (PM), and post mineral tuff (PMT-non-mineralized material).

Method 1 provides a less detailed prediction of PAG material characteristics. However, this approach relies on less data and is conservative in terms of cost and long-term treatment requirements. This method is appropriate during early stages of project development or for projects where testing of the waste rock indicates consistent acid-generating behaviour.

Method 2 introduces spatial detail to ARD prediction which can be used to refine several aspects of the mine plan. Most significantly, there are several opportunities to use this information to refine the economics of the project. Since the Corani project includes a waste encapsulation and pit backfill plan for managing PAG material, the refinement in PAG volume estimates allows for optimization in where mineralized material will be placed. For instance, if mineralized material is determined to be NAG, it may be placed in the least costly location rather than being transported to the pit or the dump where waste encapsulation is occurring. In addition, estimates of contained metals can be used to refine the estimate of smelter penalties. It appears that some mineralization types contain lower amounts of some metals than others and therefore, it would be appropriate to

assume that these may incur lower smelter penalties. *Method 2* is best applied in cases where acid generating potential is spatially variable or there is a need to refine the waste handling plan to improve project economics or to optimize waste handling procedures.

Table 2 Pros and Cons of two approaches for ARD prediction.

Method	Pro	Con
1	• Requires fewer samples • Straight-forward • Conservative	• Less detailed description of ARD hazard • May produce an overly conservative cost for treatment and processing • Cannot be used to optimize waste handling practices
2	• Includes spatial detail in ARD estimate • Can be used to optimize mine plan, processing and waste handling • Addition of detail may improve project economics	• Uncertainty is introduced from the block model • Requires more samples

The most conservative management practice for handling waste rock at a project is to classify all mineralized waste rock as potentially acid generating for purposes of basic engineering. The estimates generated using *Method 2* can then be used to refine the waste handling procedures and improve environmental conditions in detailed design and operations. Using the ARD block model, additional precautions can be taken for the waste that appears to be the most strongly acid generating. For instance, it can be placed during the dry season or more strongly encapsulated. Similarly, the same approach can be used for waste rock with large contents of arsenic or other elements of concern. This has the potential to lessen the impacts to surface water and/or reduce long-term treatment requirements.

CONCLUSIONS

Both methods considered here have strengths and weaknesses. The first method relies on a smaller sample database, is conservative, straight-forward to apply and is based on the conservative management practice of considering all mineralized material to be acid-generating. The second method requires more data but has the potential to improve project economics and optimize waste handling. The selection of the appropriate method depends on the stage of the project, the ARD risk associated with the project and the project management philosophy along with several other factors. A detailed ARD model is not only useful for environmental management, but also can be a tool in mine and process scheduling. As with all components of the mine plan, the ARD management approach should be re-evaluated and evolve along with the project. A management strategy selected during scoping is not necessarily appropriate for feasibility or final planning.

Meliadine Gold Project: Investigation of the Buffering Capacity of Waste Rock

2. *Agnico-Eagle Mines, Canada*

ABSTRACT

The Meliadine Gold project is located near Rankin Inlet in Nunavut, Canada. The Project currently comprises six deposits along a 20 km section of the Meliadine Trend. Gold occurs in low-sulfide gold-quartz veins in a prominent fault zone, hosted in an oxide iron formation and mafic volcanic flows, a Package that is similar in all deposits. Although waste rock from each deposit has low sulfur and low acid rock drainage (ARD), the acid-buffering capacity varies between deposits. Those situated west and central to the trend possess excess calcite and dolomite-ankerite buffering capacity, while deposits located to the east are slightly more silicified and possess a greater proportion of iron-bearing carbonate minerals. Various testing methods were used to define the acid-buffering capacity of waste rock from these east-side deposits, including mineralogy, static test methods, mathematical accounting methods based on mineralogy and measured carbonate content, as well as kinetic weathering test methods. Net acid generation (NAG) and kinetic test results show the presence of active and sustained buffering capacity from carbonate minerals, which corroborate the results of modified Sobek buffer capacity tests. Conversely, mineralogy and carbonate content frequently inferred the absence of buffering carbonate minerals; this could be due to the low resolution of X-Ray Diffraction (XRD), and to the possible heterogeneity of the sample which is exacerbated at trace mineral content. The compendium of results was, therefore, used to assess the ARD potential of waste rock from these deposits. Waste rock management strategies will include mixing of rock types where the proportion of uncertain or potentially acid generating (PAG) rock is small, additional tests during operation and strategic placement of potentially acid generating waste rock, and cover where the proportion is higher. These management plans are designed to overcome uncertainty on acid generation potential where it exists and avoid acidification of PAG waste rock in the long-term.

Keywords: buffering capacity, neutralization potential, mineralogy, metal carbonates.

INTRODUCTION

Agnico-Eagle Mines Ltd. (AEM) is currently studying the feasibility of constructing and operating a gold mine known as the Meliadine gold project located approximately 25 km north of Rankin Inlet in Nunavut, Canada. The Meliadine property comprises several gold deposits in a low sulfur mineralization system. Some of the lithologies from two of these deposits, Discovery and F Zone, have very low carbonate content but static and kinetic tests show sustained buffering. Multiple geochemical analyses and calculations were conducted to better define the long-term acid rock drainage (ARD) potential of these low sulfur and low carbonate rocks.

This article describes the analyses completed on waste rock from the Discovery and F Zone deposits and compares results of the different tests and concludes with recommendations for greater clarity on the determination of effective buffering capacity in low sulfur and low carbonate rocks.

GEOLOGY OF THE MELIADINE DEPOSITS

The gold deposits of the Meliadine property are hosted in volcanic flows and sediments of the Archean-age Rankin Inlet Greenstone Belt (Pincock Allan & Holt, 2008). Gold deposits occur along the east-west-trending splay off the regional Pyke Fault and on structures parallel to it. Gold is mostly present in quartz-vein stock works, laminated veins, and in weakly sulphidized iron formation, which is folded and sheared. The Meliadine ore deposits are low-sulfide, gold-quartz vein deposits as per the geo-environmental classifications provided in Plumlee et al. (1999).

The geology of each deposit is similar. Waste rock includes iron formation, which is both volcanic-hosted and sediment-hosted. It comprises greywackes, siltstones and argillites with magnetite and chert layers. Schistose and carbonate-altered mafic volcanic rocks make up most of the footwall waste rock. The hanging wall rock comprises fine-grained turbiditic meta-sediments that include greywacke, sericite-altered siltstones, graphitic argillites and gabbro dykes (AEM, 2011; AEM 2014).

PROPOSED MINE DEVELOPMENT

The six deposits to be mined includee: Wolf, Tiriganiaq, Pump, Wesmeg, F Zone and the Discovery. Waste rock from the first 4 deposits will be mixed in two large rock storage facilities. Waste rock in these mixed piles has ample excess buffer capacity; there is no concern for acidification from these stockpiles. Conversely, waste rock from F Zone and Discovery deposits will be stored in individual waste rock storage facilities adjacent to their respective open pits. Some samples of waste rock from F Zone and Discovery deposits have an uncertain acidification potential, hence the importance of defining the reactivity of the available buffering capacity of all waste rock from these deposits in order to design appropriate stockpile management plans.

ANALYTICAL METHODS

Mineralogy

Mineralogical analyses were carried out by XRD at the University of British Columbia, Earth and Ocean Sciences Department. Samples consisted of a 2 mg split of a fraction of the pulverized portion (reground to <10 μm) of the waste rock sample. The X-Ray diffractograms were analyzed using the International Centre for Diffraction Database PDF-4 using Search-Match software by Siemens (Bruker). X-Ray powder-diffraction data were refined with Rietveld program Topas 3 (Bruker AXS). This method allows evaluating quantitatively the crystalline mineral phases with a detection limit of approximately one weight percent (1 wt%). Mineral quantities represent the relative amounts of crystalline phases normalized to 100%. Non-quantitative identification to <1% was made by UBC, however, the precision of the instrument decreases substantially below one wt% (errors margins up to 100%; M. Raudsepp, 2014, pers. comm., 27 March). Concentrations less than 1% are imprecise.

Laboratory measurement of buffering capacity

The following methods of accounting for buffering capacity were completed:

1996 Modified NP Procedure (bulk NP), (MEND, 2009) – This method quantifies the total buffering capacity of a sample, including contributions from slower reacting or less reactive aluminosilicate minerals. The buffering capacity is calculated from the amount of base consumed to neutralize acid remaining from the sample acid-digested at room temperature. Bulk NP is expressed as kg $CaCO_3$/tonne.

Carbonate mineral NP (CaNP), (Price, 1997) – This method quantifies the buffering capacity from the carbonate content of a sample assuming that all the carbonate is present as calcite. CaNP is calculated from the carbonate (CO_3) content as follows: CaNP (kg $CaCO_3$/tonne) = CO_3 (wt%) *(100.09*10)/60.01. Where siderite and other divalent metal carbonates are present, the CaNP can be overestimated since these minerals release less neutralization per mole of carbonate ions than calcite or dolomite.

Mineralogical Carbonate NP (CaNP-min), (Paktunc, 1999) – This represents the buffering capacity provided by the carbonate minerals that are identified by XRD. In this study, they include calcite, ankerite and siderite. The effective carbonate NP is calculated following methods outlined in Paktunc (1999) where the amount of buffer available from each mineral is proportioned to the available carbonate ions per its idealized mineral formulae as follows: Calcite and dolomite 100%; ankerite 70%; siderite 0%. This method utilizes the weight percent (wt%) XRD results, thus it was applied only to samples subjected to mineralogical analysis. The CaNP-min value is expressed as kg $CaCO_3$/tonne.

Adjusted Carbonate Mineral NP (CaNP-adj) – This represents the NP from carbonate minerals (CaNP) based on the chemical content of inorganic carbon (TIC) rather than the weight percent of XRD carbonate minerals, but adjusts the buffering capacity according to the carbonate minerals present in the sample defined by XRD analysis. The adjustment is also based on the proportion of available carbonate ions from each mineral identified (Paktunc, 1999). Thus, if XRD identified that 50% of the carbonate minerals present in the sample were calcite and 50% siderite, CaNP-adj was

set at half of the CaNP value defined from TIC analysis. If a sample had no mineralogical data, it was assumed to have the average carbonated mineral content tabulated for the sample's lithology. The CaNP-adj value is expressed as kg $CaCO_3$/tonne.

Laboratory measurement of acid potential (AP)

There are no documented occurrences of primary sulfate minerals in the Meliadine deposit (Pincock Allan & Holt, 2008; AEM, 2011; AEM 2014). Where chemical analysis identified sulfate, it was attributed to weathering of the sample after extraction. Thus, AP was calculated from the total sulfur (S) content, based on the theory that all the sulfur in the sample occurs as available di-sulfide minerals (AP (kg $CaCO_3$/tonne) = 31.25 x S (%)). The total sulfur content of the sample was determined by LECO furnace with a S-analyzer following ASTM E 1915. A subsample was pre-treated with cold hydrochloric acid (HCl) to remove sulfate and the resulting material was analyzed for total sulfur. The difference between the two total sulfur values was assumed to be sulfate sulfur.

Evaluation of ARD potential

The determination of the ARD potential of waste rock was evaluated by acid-base accounting (ABA) using net potential ratio (NPR) of NP to AP, whereby NPR = NP/AP. The NPR was evaluated for the various forms of NP, as follows:

- NPR = bulk NP/AP
- CaNPR = CaNP/AP
- CaNPR-min = CaNP-min/AP
- CaNPR-adj = CaNP-adj/AP

Leaching test pH and sulfate content

The distilled water shake flask extraction (SFE) (ASTM D3987-06) and the paste pH (Price, 1997) were carried out on all samples. An increase in the pH of the leaching solution (initial pH was approximately 5.5) indicated the presence of readily available buffering capacity.

The single addition net acid generation (NAG) test (AMIRA, 2002) was completed on a subset of samples from each lithology. The subset of samples selected for NAG tests was different than the subset selected for mineralogical analysis.

Kinetic weathering tests were carried out following the humidity cell test (HCT) procedure (ASTM D 5744-96) on the same subset of samples subjected to mineralogical testing. Kinetic tests were run for a period of 20 to 40 weeks. Leachates were analyzed by inductively coupled plasma - mass spectrometry. These tests were used to investigate the kinetics of mineral reaction.

RESULTS AND DISCUSSION

Mineralogy

Pyrite (FeS_2) is the most common sulfide mineral found in the waste rock away from ore zones, with lesser arsenopyrite (FeAsS), trace pyrrhotite ($Fe_{1-x}S$) and rare chalcopyrite (CuFeS). F Zone and Discovery waste rock have low quantity of calcite and a greater proportion of metal-bearing

carbonate minerals such as siderite and ferroan dolomite (ankerite). The iron content of the ankerite was not defined during this study. Aluminosilicate minerals including biotite, muscovite, plagioclase feldspars and clinochlore which are documented to possess buffering capacity (Jambor et al. 2002; Jambor, Dutrizac and Raudsepp, 2007; Matson, 2009), occur in large quantities in Discovery and F Zone samples (TABLE 1).

Table 1 Minerals identified by XRD with Reitveld refinement

Mineral Group/Name	Ideal Mineral Formula	Discovery Deposit Greywacke/ Siltstone				Discovery Deposit Iron Formation			F Zone Deposit Iron Formation

Evaluation of buffering capacity

Bulk NP values are consistent, and often substantially higher than CaNP indicating that a large portion of the buffering capacity accounted for in bulk NP is from non-carbonate minerals. The reactivity of this buffering capacity cannot be verified in the long-term, thus, these measurements were not retained to assess ARD potential.

Because of the documented presence of iron carbonates the use of CaNP was not retained either. CaNP is an imprecise evaluation of buffering capacity for the Meliadine project because it negates the NP-lowering effect of metal carbonate minerals and the buffering capacity of reactive silicate minerals.

Mineralogy-based CaNP (CaNP-min) tended to be the most conservative assessment of buffering capacity. However, this method was not considered appropriate for ARD assessment because of the following factors: the uncertainty of the quantitative estimate from XRD data due to the low resolution of the instrument for trace mineral content; the evidence of available buffering capacity (from paste pH, NAG pH, and kinetic testing) in samples where little to no carbonate minerals were identified by XRD; and the substantial discrepancy between carbonate content measured by chemical analysis and weight percent carbonate content from XRD results.

Adjustment of CaNP using mineralogical data (CaNP-adj) accounts for both the trace content of carbonate defined by chemical analysis and the presence of iron carbonate minerals identified in the samples. Although this method still negates buffering capacity from aluminosilicate minerals, it is considered to be appropriately conservative for NP determination.

Supporting Information

The highly alkaline paste pH values of most samples and the neutral to alkaline SFE pH values demonstrate the presence of immediately available buffering capacity in all samples, including those where no carbonate minerals were identified by XRD. This suggests that either some effective calcite or low iron dolomite was present at concentrations that are below the XRD detection limit, and/or other effective aluminosilicate minerals are available to buffer the solution pH.

Most end-pH values of the NAG tests were also above 4.5 with little acidity released, suggesting that most samples tested (which targeted low AP and low NP samples) have enough buffering capacity to avoid ARD (except for samples 1 and 2 in TABLE 2). Corresponding mineralogical data was available for three samples of Discovery greywacke/siltstone. These show that the non-potentially acid generating (NPAG) sample (sample 3) has a low, but detectable, calcite content (0.3wt %), a low sulfur content (0.15 wt%), a bulk NPR of 2.6 and a CaNPR-adj above 1. Conversely,

samples 1 and 2 yielded acidic NAG pH values suggesting they have a potential to generate acid in the long-term. They had no detectable carbonate mineral content and lower bulk NP and CaNP-adj values than sample 3 and similar to higher sulfur contents. Samples 1 and 2 have bulk NPR values above 1 but CaNPR, CaNPR-min and CaNPR-adj values of less than 1. The relationship between CaNPR-adj, AP and mineralogy may form a trend that needs to be verified with a larger database of NAG pH values and mineralogical data.

Kinetic testing on Discovery and F Zone samples also showed active and sustained buffering capacity for the duration of testing including for samples with no XRD-detectable carbonate minerals (FIGURES 2 and 3). The very low sulfate values suggest very slow mineral reaction rates in the short to medium term. Given the dry arctic conditions at site and corresponding low leaching rate, the 40 week test duration is estimated to cover a period at site which is longer than the planned mined life (13 years).

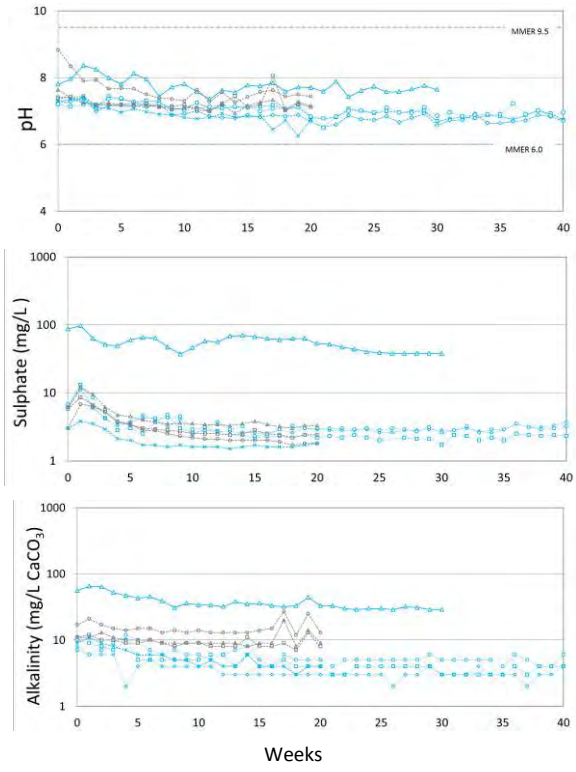

Figure 2 Kinetic test results for Discovery greywacke/siltstone samples (blue) and iron formation samples (grey)

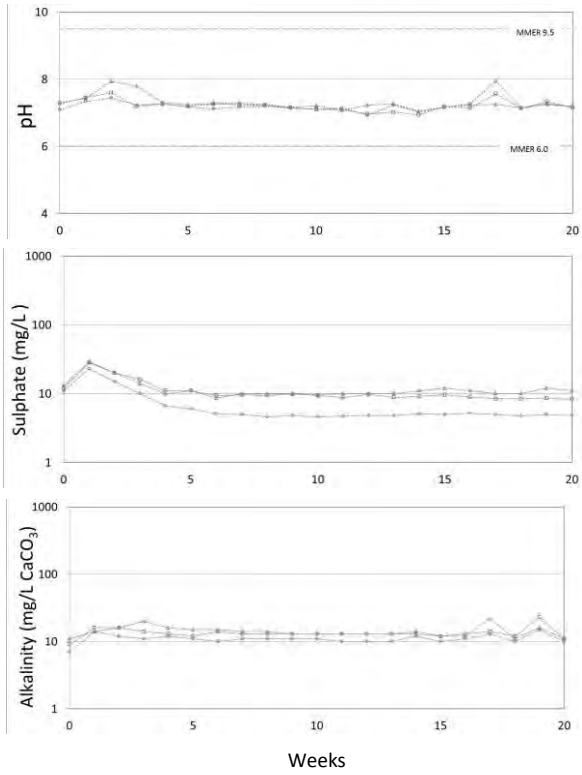

Figure 3 Kinetic test results for F Zone iron formation samples

CONCLUSION

The available neutralization capacity observed for many low carbonate samples based on paste pH, kinetic testing, NAG pH (for other samples not presented here) and carbonate content was often not reflected in XRD analysis. Similarly, the presence of sulfur identified by chemical analysis did not always correspond to identifiable sulfide mineral phases in XRD, including for samples having a total sulfur content of up to 0.55 wt%. This incongruence suggests that XRD-Rietveld does not possess a sufficiently elevated resolution to identify potentially important minerals in ARD reactions in low S, low carbonate rocks. This could be due to many factors, which include: the small subsample size subjected to XRD and the heterogeneity of the sample, the imprecision in identifying minerals that occur in trace quantities, the presence of mineral solid solutions such as the dolomite-ankerite series and that mineral phases with similar diffractogram patterns are difficult to distinguish. These factors are accentuated when the targeted element or mineral is present in trace quantities.

This imprecision decreases the relevance of relying solely on mineralogy-based evaluations of NP and NPR. Notwithstanding this, mineralogical data should be used to guide evaluations of buffer capacity, in conjuction with chemical analysis of carbonate content. Indeed, imprecise mineral identification or quantification, the presence of mineral solid-solutions (such as dolomite-ankerite) and the presence of reactive aluminosilicate minerals can lead to errors in the evaluation of the potential to generate acidic drainage.

Buffer capacity evaluation methods that are based on mineralogy require a greater mineralogical database for the project studied, and more powerful and precise mineral identification techniques such as Qemscan or Scanning Electron Microscope (SEM) with energy dispersive X-Ray (EDX) or a mineral liberation analyzer (MLA). The MLA was shown to successfully identify trace quantities of minerals down to 0.01wt% ranges (Barazzuol et al, 2012). Mineralogical analysis should be done in conjunction with chemical analyses including chemical scan, carbonate content, NAG pH with NAG solution analysis to verify that all the sulfur in the sample has been oxidized.

Results from the compendium of analytical techniques used suggest that Discovery waste rock is not likely to generate ARD in the short to medium term under the arctic (very dry and cold) site conditions. However, the development of acidic conditions in the long-term is uncertain. The uncertainty stems from the lack of precision in identifying the type and availability of buffering minerals present in trace amounts. This is also the case for F Zone iron formation rock, however this lithology constitutes a minor proportion (8%) of the total quantity of waste rock to be stored in F Zone WRST, the balance of which is NPAG and has excess carbonate-mineral buffering capacity.

Waste rock management control strategies will include mixing of rock types where the proportion of uncertain or potentially acid generating rock is small, such as in the F Zone waste rock stockpile, and for Discovery PAG rock, will include strategic placement the PAG waste rock in the stockpile and placement of a thermal cover having little to no PAG rock. These methods are planned to overcome uncertainty where it exists and avoid acidification of the Discovery and F Zone PAG waste rock in the long-term.

ABSTRACT

The effect of different geological classification systems on a ML/ARD characterization program is investigated for the KSM Au-Cu porphyry project in northwest BC, Canada. Geological models enable predictive modeling of the ML/ARD potential of material during excavation and long term storage of waste rock by allowing the representation of a large mass of material by a relatively small mass of sampled material. A robust sampling plan typically attempts to collect samples in proportion to the mass of material to be excavated. Geological models developed during advanced exploration are often used during the geochemical characterization program; however, biases towards ore at the expense of waste rock and future pit walls frequently exist. Perceived uncertainty introduced through "lumping" or "splitting" of datasets can be carried into ML/ARD prediction and water quality models and regulatory approvals. Therefore, the choice of geological model is essential as a geochemistry baseline program advances to determine quantities of potentially acid generating (PAG) and not-PAG waste rock for waste rock and water management planning and to address stakeholder and government concerns.

Three geological models of the KSM project were assessed: Lithology, Alteration, and a hybrid Mine Model. Using the proportion of samples classified as PAG in each model unit, the material to be excavated was classified as PAG or not-PAG.

These results were then compared to an ABA block based on each of the three geological models. Differences in the proportions of PAG material were identified and the underlying cause of the differences is presented.

Keywords: ML/ARD; KSM; Model

INTRODUCTION

The KSM (Kerr-Sulphurets-Mitchell) Project is located in northwestern British Columbia, Canada (Figure 1). Gold and copper mineralization is hosted in a cluster of porphyry related, deformed, and dismembered deposits. The deposits are spread over an area of roughly two by ten kilometers and contain a 2.16 billion tonne resource with an average grade of 0.55 g/t Au, 0.21 % Cu, 2.74 g/t Ag, and 44.7 ppm Mo.

Figure 1 Location of the KSM Project

The work presented here focuses on the material that will be exposed during development of the Kerr open pit. The structural dismemberment of the deposit hinders the use of a pure alteration or lithology model, therefore a hybrid model has been used during the exploration program. This hybrid model (Mine Model) uses predominantly lithological terms above the major thrust faults, where protolith is more easily recognized, and alteration below the thrust faults where pervasive alteration has obliterated primary minerals and structures.

METHODOLOGY

To characterize the acid rock drainage (ARD) potential of the KSM Project each sample was analyzed to obtain its acid generating potential (AP) and acid neutralizing potential (NP). Standard acid-base accounting (ABA) methods (Sobek et al., 1978) were used to determine the sulfide sulfur content and the Sobek neutralization potential.

The neutralization potential ratio (NPR) is the NP:AP ratio. In this paper a generic NPR value of 2.0 was used as a cut-off for the designation of potentially acid generating (PAG; NPR < 2.0) or not-PAG.

PROJECT GEOLOGY

The setting provided in this report is a summary of previously completed descriptions of the regional geology (Ditson, Wells, and Bridge 1995; Fowler and Wells 1995; Kirkham and Margolis 1995; Lechner 2008). A detailed description of the local lithologies, alteration, mineralization, and structures can be found in the 2011 Pre-Feasibility Study Update (Wardrop 2011), this information was summarized in *2012 KSM (Kerr-Sulphurets-Mitchell) Prefeasibility Study* (Tetra Tech 2012).

The Sulphurets District is located along the eastern side of the Coast Mountains, approximately 25 km east of the Coast Plutonic Complex, a north-northwesterly trending belt of Cretaceous to Early Tertiary intrusions and high grade metamorphic rocks. The area lies near the western edge of the middle Jurassic to Cretaceous age Bowser Basin within the Stikine Terrane, also known as Stikinia, which was possibly accreted to the North American continental margin in the Middle Jurassic Period. Stikinia is interpreted as Triassic and Jurassic volcanic arcs resting on Palaeozoic basement (not present at site) and overlain by Jurassic basinal sedimentary rocks.

The upper Triassic Stuhini Group has two major subdivisions. A lower, dominantly sedimentary sequence consisting of turbidites and sandstones. Overlain by an upper dominantly volcanic sequence of volcanic pillowed flows and volcaniclastic breccias.

The Lower Jurassic Hazelton Group is inferred to represent a volcano-sedimentary island arc and back arc complex. The sedimentary sequence consists of a coarse basal sedimentary sequence overlain by a lower volcanic/volcaniclastic sequence, an upper felsic volcanic-pyroclastic unit (Mount Dilworth Formation), and an uppermost marine sedimentary sequence containing subaqueous mafic volcanic flows. The upper contact of the Hazelton Group is gradational with the Bowser Lake Group.

The Hazelton sedimentary sequence is intruded by a suite of porphyritic, Early Jurassic (189 to 195 million years) rocks including alkali feldspar granite, quartz monzonite, syenite, and granodiorite collectively referred to as the Mitchell Intrusions or Texas Creek Plutonic Suite. Below the Sulphurets and Mitchell thrust faults (STF and MTF), pre- and intra-mineral intrusions have historically been exploration targets. A conceptual summary of the evolution if the Project is presented in Figure 2.

There are two main structures at the project (Figure 3) – the Mitchell Thrust Fault (MTF) and the Sulphurets Thrust Fault (STF). The STF can be identified as the primary structure at the Kerr Deposit. The footwall of each deposit is usually more altered and more sheared than the hangingwall. In most instances this alteration and shearing has obliterated primary textures making identification of the protolith difficult. Where evident the protolith is classified as either volcaniclastic or sedimentary belonging to the Stuhini Group. The host rocks have been intruded by multi-phases of the Mitchell Intrusions.

The project fits within a broad porphyry alteration model. Weak hornfelsed alteration assemblages are evidence of contact metamorphism during the emplacement of the Mitchell Intrusions. There is a broad and pervasive propylitic halo characterized by chlorite alteration with variable secondary carbonate. More proximal to the intrusions and along hydrothermal conduits phyllic (QSP; quartz-sericite-pyrite) and intermediate argillic (IARG; clay minerals) alteration dominates, generally destroys primary mineral assemblages and structures. The more intense QSP and IARG alterations are the primary targets for gold and copper exploration. Potassic alteration has been noted but is volumetrically minor in waste rock. The pyrite halo is most intense within the QSP and IARG alterations and pyrite contents can reach 20 %.

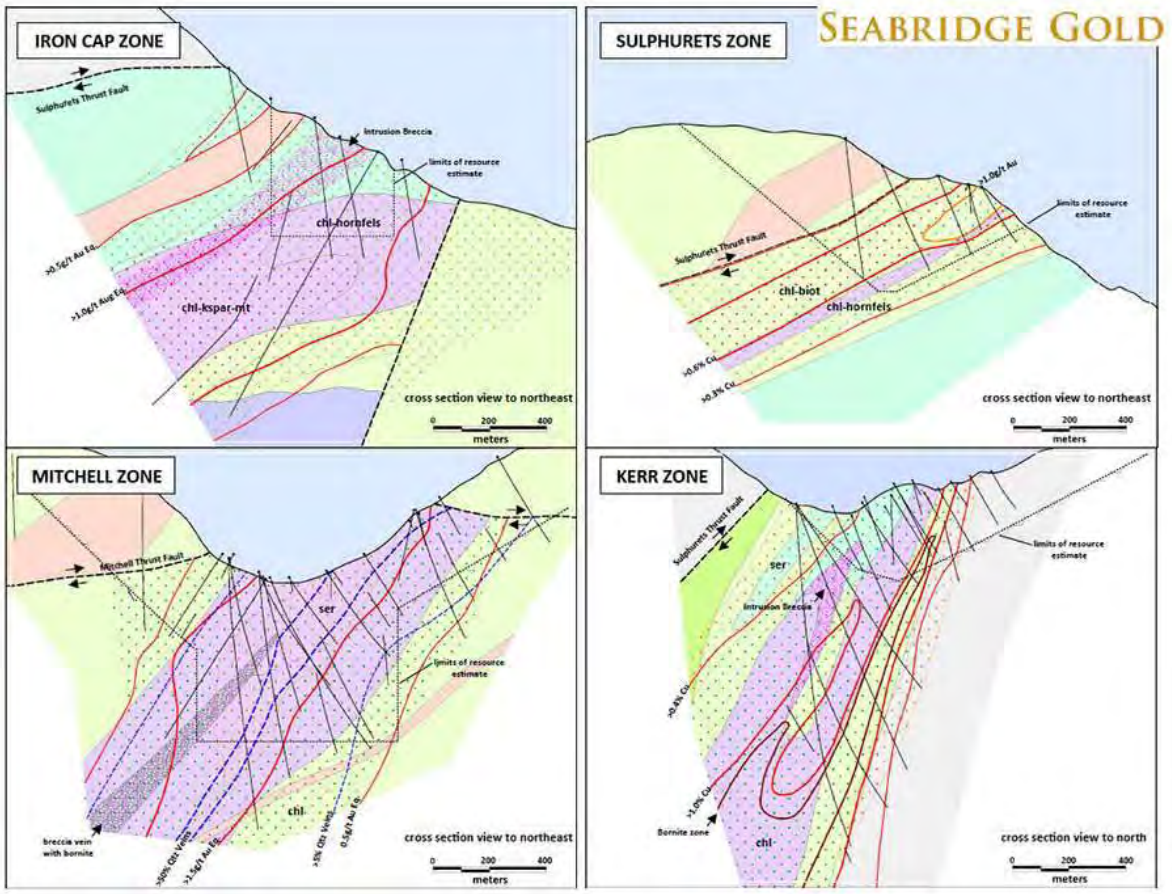

Figure 3 Schematic cross sections through KSM Project deposits

BLOCK MODEL

ABA block models were constructed for the KSM project in 2010, 2011, and 2012. Those models were updated in 2014 with additional static ABA sample data and refined geological models. The ABA block models were constructed with data collected from relatively wide-spaced drill holes from materials thought to be representative of "ore" and "waste". The resolution of individual model blocks is 25 m x 25 m x 15 m, which should allow for large excavators to segregate materials on a pit-bench scale. A general outline of the method used to generate the ABA block model is given below:

The ABA models are based on samples collected from existing drill hole assay pulps. Basic descriptive statistics were tabulated for AP and NP based on block model rock types, alteration types, degree of mineralization, and stratigraphic position relative to major thrust faults.

The models were constructed using three distinct methods outlined below and simplified in Figure 4:

- direct assignment of ABA values to blocks "pierced" by ABA samples;
- two-pass inverse distance estimation methods; and

- assignment of ABA values based on average values calculated by rock/alteration/mineralization type.

Individual model blocks pierced by an ABA sample were assigned NP and AP values from the sample and flagged as being estimated and off limits for subsequent estimation methods.

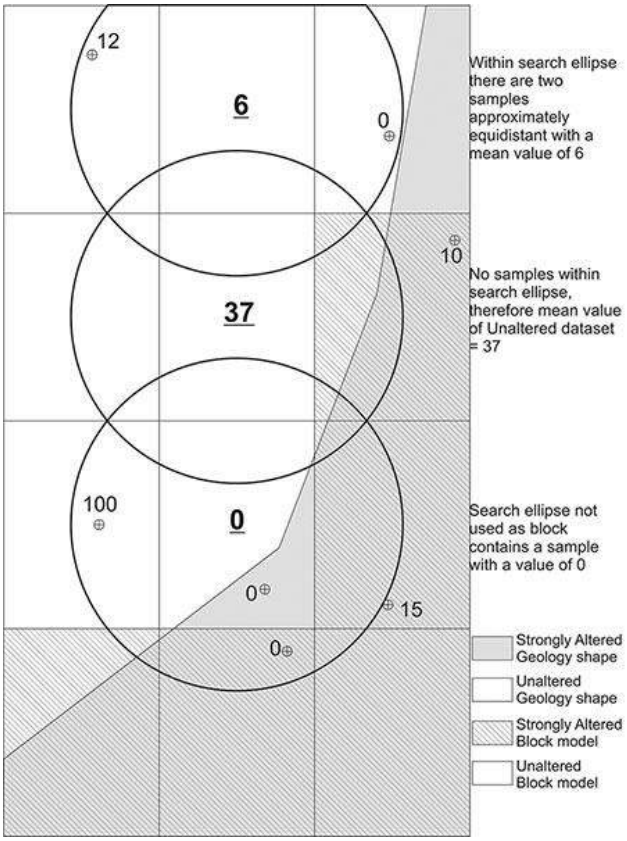

Figure 4 Conceptual diagram showing three methods for assigning a value to a block

After direct ABA assignment was completed, a two-pass inverse distance estimation method was implemented. The first pass used a 100 m x 100 m x 60 m search ellipse to locate eligible ABA samples. A minimum of one sample was required with a maximum of 8 samples used to interpolate NP and AP values. Blocks estimated by this method were flagged as being estimated and not subjected to subsequent estimates. The second estimation pass used a 200 m x 200 m x 120 m search ellipse with the same sample selection used for the first pass. Strict block/sample matching was used in both inverse distance estimation passes. This means that blocks of a certain rock type could only be estimated by samples with the same rock type. Unique search ellipse orientations were used for the Kerr, Sulphurets, and Mitchell zones. A minimum of 1 sample was required, with a maximum of 8 samples allowed with no more than 2 samples from each drill hole. An inverse distance weighting power of 2 was selected.

For blocks beyond 200 m of ABA sample data, class average values were assigned to blocks based on rock, alteration, or mineralization codes. The average values for NP and AP for these static samples are influenced by mineralization intensity. Typically, as gold and/or copper grades increase NP values decrease and AP values increase. Commingling mineralized and unmineralized

ABA samples has provided a certain degree of conservatism because most of the mineralized material will be processed and not sent to a waste rock disposal area. After the estimate and assignment of block ABA values was completed, the NPR was calculated.

RESULTS AND DISCUSSION

Lithology Model

The primary difference between the two approaches is the large difference in predicted PAG material from the heavily altered and uncategorized material below the STF (Table 1). The result is that the two approaches have an approximately 28 % difference in the total mass of predicted PAG material.

Table 1 Lithology model comparison

	From Block Model		From ABA Samples		
Lithology Model Code	PAG	not-PAG	PAG	not-PAG	Tonnage of waste (Mt)
Kerr					
Overburden	100 %	0 %	26 %	74 %	20.3

Kerr Total Mass	585.7	76.1	401.9	234.2	661.8

N.S. = no sample collected

Major units are represented by bold font

Alteration Model

The two Alteration Model approaches predict a 24 % difference in the mass of PAG material (Table 1). The two major units have much higher predicted masses of PAG material through the block model approach compared to the ABA samples.

Table 2 Alteration model comparison

Alteration Model Code	From Block Model PAG	From Block Model not-PAG	From ABA Samples PAG	From ABA Samples not-PAG	Tonnage of waste (Mt)
Kerr					
CL-PR	100 %	0 %	93 %	7 %	18.5

N.S. = no sample collected

Major units are represented by bold font

Mine Model

In the Mine Model the difference between the block model and the ABA samples can be large for major units (Table 3). Using just the ABA samples the volume of PAG material would be underestimated by approximately 129 Mt at Kerr, approximately 21 % of the mass of waste rock produced.

Table 3 Mine model comparison

Mine Model Code	From Block Model PAG	From Block Model not-PAG	From ABA Samples PAG	From ABA Samples not-PAG	Tonnage of waste (Mt)
Overburden	100 %	0 %	100 %	0 %	20.3

Kerr Total Mass	560.8	65.3	431.3	194.8	626.1

Major units are represented by bold font

DISCUSSION

The differences between the proportions calculated from the ABA samples and the proportions calculated from the Block Models are a function of block model edge effects and the influence high AP values. Blocks near the periphery of the Kerr open pit have AP and NP values assigned by either inverse distance estimation or average value of model unit. Both methods favor higher AP assignment, as both methods are influenced by the drilling and sampling focused in the mineralized and highly altered footwall. The average value assignment method is not responsible for as many assigned values as inverse distance estimation.

Figure 5 uses fictional data to illustrate the difference in calculated proportions of PAG material based on using the ratio of ABA samples (left grid) or using inverse distance estimation (right grid). In the example five samples are identified with varying NP and AP values and placed in a two dimensional grid to simulate a block model. When just the ABA sample data are used (left grid) the example predicts 60 % of the material to be not-PAG (shaded grey); based on three of five samples having a NPR more than 2.0. This result indicates that the bulk of the material in the block is not-PAG. Note that using the ratio of PAG to not-PAG samples from an ABA database does not take into account the spatial layout of samples.

Using the same example data in the same grid inverse distance estimations were used to calculate AP values for each block (Figure 5, right grid). The single high AP value in the center dominates an inverse distance estimation resulting in very few blocks being classified as not-PAG. The end result is less than 10 % not-PAG (shaded grey) by inverse distance estimation, compared with 60 % not-PAG by ABA sample. This result indicates that the bulk of the block is PAG and may require segregation or special handling.

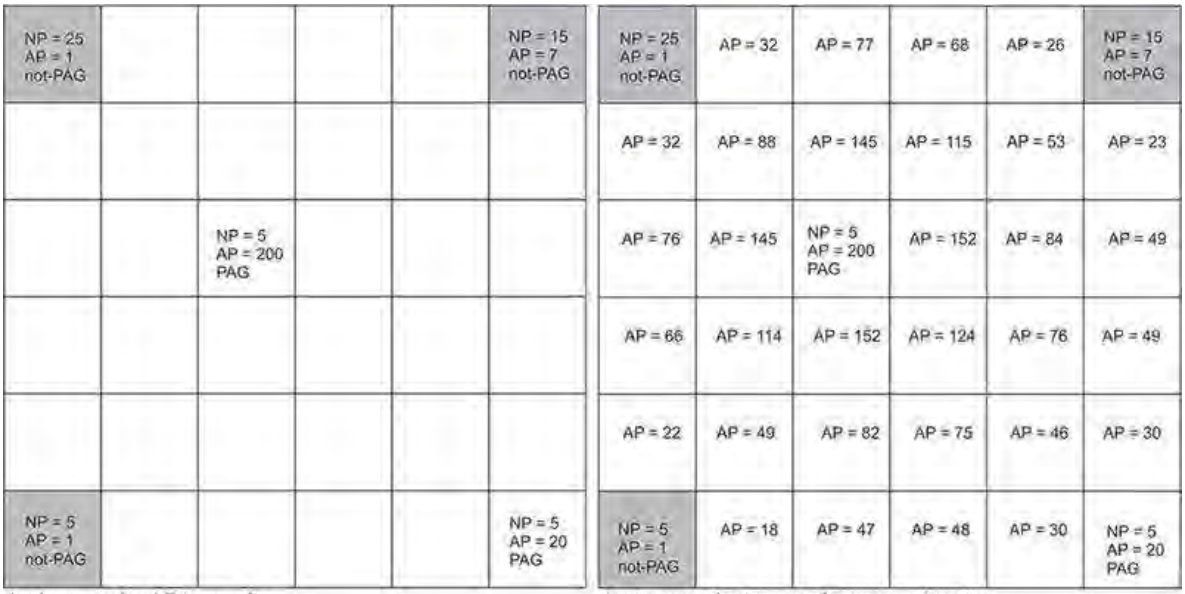

Figure 5 Conceptual diagram showing proportion of material estimated to be PAG by two differing methods

CONCLUSION

Differences were noted when comparing the proportion of PAG material predicted for the three Kerr block models to the proportions of samples classified as PAG. In the Lithology, Alteration, and Mine Models the block model predicted a higher proportion of PAG material than the ABA sample data. The primary reason for the difference is the overwhelming effect a single high AP value can have on surrounding blocks if NP and AP are usually moderate to low.

The results presented illuminate the need to consider Block Models and ABA datasets when predicting the proportions of PAG material. Additionally, the masses predicted by the deposit Block Models were quite similar irrespective of the geological model used to generate the Block Model. This result indicates that at the Kerr Deposit the Block Models are a robust and conservative approach to ARD prediction.

A Metal Attenuation Study on Waste Rock Collected from the East Dump, Antamina Mine, Peru: A Combined Mineralogical and Geochemical Approach

Laura Laurenzi, K. Ulrich Mayer and Roger Beckie

Department of Earth, Ocean and Atmospheric Sciences, University of British Columbia, Canada

ABSTRACT

In this study we evaluate the influence of secondary minerals on metal attenuation using a suite of geochemical and mineralogical tests on three samples collected from different depths in the East Dump, Antamina Mine in Peru. The bulk elemental content and mineralogy are determined using trace metal analysis by inductively coupled plasma mass spectrometry (ICP-MS) after digestion and X-Ray Diffraction (XRD), respectively. A sequential extraction procedure (SEP) is used to identify the phases associated with the metals. Optical mineralogy and scanning electron/back-scatter electron microscopy (SEM/BSE) are used to identify secondary mineral phases, elements associated with the secondary minerals and the mode of occurrence of the secondary minerals.

Precipitation of weak-acid soluble phases and sorption/co-precipitation with amorphous reducible phases are the predominant attenuation mechanisms for the metals studied (i.e., arsenic, copper, lead, molybdenum and zinc). Copper, lead, and zinc are associated with weak-acid soluble phases and reducible phases. Arsenic and molybdenum are associated with reducible phases. Iron oxides are the predominant reducible phases forming coatings around sulfides and silicate minerals, or discrete mineral grains. Metal carbonates/sulfates (with variable Cu and Zn content) and zinc silicates are the predominant weak-acid soluble phases forming coatings on calcium carbonates and silicate grains, or as discrete mineral grains. This combined mineralogical and geochemical approach elucidates the nature of secondary minerals and associated metal attenuation processes.

Keywords: Metal Attenuation, Waste rock, Geochemistry, Mineralogy

INTRODUCTION

Mine waste rock often contains sulfide minerals that oxidize when exposed to oxygen and water. Without sufficient carbonate mineral buffering capacity in the waste rock, acidic conditions can develop leading to acid rock drainage (ARD); however, if the waste rock contains sufficient carbonate minerals to buffer the acidity generated by the oxidation of sulfides, neutral conditions can persist resulting in neutral rock drainage (NRD). Dissolved metal concentrations differ in ARD and NRD because metal mobility is highly dependent on pH. In ARD, Al, Fe, Cu, Pb, Zn, Cd, Mn, Co, and Ni are generally mobile (Al et al., 2000), while in NRD metals which are either weakly hydrolyzing such as Zn, Ni or oxyanion forming such as Mo, As, Se, and Cr are generally mobile (Price, 2009). This is because in NRD, cationic trace metals can be sequestered in secondary mineral phases and sorbed onto metal (oxy)hydroxides and clay minerals (Smith, 1999; Al et al., 2000). Oxyanions are more mobile in NRD because sorption onto iron oxides increases as pH drops below neutral. Thus, secondary minerals are an important control on the quality of water emanating from waste materials (van der Sloot and van Zomeren 2012; Al et al., 2000). Understanding the mechanisms that attenuate metals from waste rock is essential for reliable predictions of water quality (Mayer et al., 2003; Al et al., 2000). The objective of this study is to identify the secondary minerals and processes that attenuate metals by examining samples collected from the full scale operating waste dump, the East Dump at the Antamina Mine, Peru. Results from this study can be compared to the results of laboratory and smaller scale tests also conducted on waste rock material from this site.

METHODOLOGY

Project Site and Sample Collection

The Antamina deposit is a copper-zinc-molybdenum skarn formed by the intrusion quartz monzonite into limestone (Lipten & Smith, 2004; Love et al., 2004; Redwood, 1999). Waste is subdivided into classes based on the criteria summarized in Table 1. The East Dump, the focus of this study, receives all classes of waste rock and is therefore geochemically heterogeneous.

Table 1 Antamina Waste Rock Classification System

Class	Description	Zn	As	Sulfide
A	(Exo,Endo)skarn, intrusive, hornfels, Marbles Limestone	>1500 ppm	>400 ppm	> 3%
B	Hornfels, marble, limestone	700-1500 ppm	N/A	<2-3%
C	Hornfels, marble, limestone	<700 ppm	<400 ppm	<2-3%

The waste rock samples used for this study were collected from two boreholes at site BH-1 drilled using a reverse circulation drill rig. At the time of drilling, the deepest material in East Dump had been in place for over ten years, while the shallowest material for more than 5 years. Composite samples of waste rock material (at 1.5 m intervals) were collected and sieved using a 2 mm (#10) mesh. Sixteen samples were initially characterized for bulk elemental content, X-ray Diffraction (XRD) and sequential extraction procedure (SEP) testing, the results of which were used to focus scanning electron/back-scatter electron microscopy (SEM/BSE) tests on three samples. The results of the geochemical and mineralogical testing on the three samples are discussed here.

Testing Framework

The bulk elemental content of the samples was determined using ICP-MS analysis after a 4-acid digestion by SGS in Vancouver, Canada. XRD was used to identify crystalline minerals. XRD data were collected using a Bruker D8 Focus Diffractometer with a scanning step of 0.029° 2θ and counting time of 100.1 s/ over a range of 3-80° 2θ. While XRD is useful for crystalline mineral phases, XRD cannot identify minerals below ~1% abundance or those that are amorphous or nano-crystalline. Accordingly, the sequential extraction procedure (SEP) proposed by Hall et al. (1996) (Table 2) was used to identify the predominant secondary phases and attenuation mechanisms for As, Cu, Mo, Pb, and Zn.

Three samples that showed elevated metal concentrations in the SEP were investigated in more detail. Thin sections of these three samples were prepared and examined using transmitted/reflected light microscopy where individual mineral grains were targeted for SEM/BSE imaging and Electron Dispersion Spectra (EDS) analysis. For the SEM/BSE analysis, the thin sections were coated with evaporated carbon and examined on a Philips XL30 SEM equipped with Bruker Quantax 200 Microanalysis system and light element XFLASH 4010 Silicon Drift detector. Semi-quantitative analysis of the EDS yielded weight percent (wt.%) of elements associated with the secondary minerals.

Table 2 Sequential extraction procedure used on samples (Hall et al., 1996)

Step	Phases	Method(1)
1	Water Soluble	50 mL deionized water shake for 1h at room temperature
2	Weakly sorbed /Exchangeable(2)	40 mL 1M $MgCl_2$ shake for 1 hour at room temperature
3	Weak-acid soluble	20 mL 1M CH_3COONa (sodium acetate) at pH 5 shake for 6h centrifuge for 10min Repeat Step
4	Amorphous reducible phases	20 mL 0.25M NH_2OH*HCl (hydroxylamine hydrochloride) in 0.25 HCl place in 60^{0}C water bath for 2h every 30min vortex contents Repeat Step but heat for only 30 min
5	Crystalline reducible phases	30 mL of 1 M NH_2OH*HCl (hydroxylamine hydrochloride) in 25% CH_3COOH (acetic acid) place in 90^{0}C water bath for 3h, vortex every 20 min Repeat Step but heat for only 1.5 hours
6	Residual Phases	4 - Acid Digest(3)

NOTES:

(1) Steps 3 – 5 are repeated using the same liquid solid ratio (LSR). Leachates are analyzed separately and the concentrations are summed.

(2) Weakly sorbed/exchangeable step taken from (Tessier et al., 1979)

(3) Residual fraction was determined by 4-acid digest at SGS, Burnaby (BC, Canada)

Results

From the lithologic logs produced at the time of drilling (not shown), samples BH-1s (1.5 – 3.0) and BH-1d (90.0 – 91.5) are composed predominantly of marble and marble diopside lithologies. Both samples contain some skarn while BH-1d (90.0 – 91.5) also contains some igneous intrusive rock. BH-1d (19.5 – 21.0) is predominantly igneous intrusive, with some marble.

The bulk elemental content of As, Cu, Mo, Pb, and Zn are presented in Table 3. Among the three samples, BH-1s (1.5 – 3.0) has the highest content of Mo and Pb and BH-1d (19.5 – 20.0) and BH-1d (90.0 – 91.5) have the higher Cu and Zn. Total arsenic is highest in BH-1d (90.0 – 91.5).

Table 3 Total metal concentrations for select elements

	Units	BH-1s (1.5 - 3.0)	BH-1d (19.5 - 21.0)	BH-1d (90.0 - 91.5)
As	ppm	104	49	118
Cu	ppm	1340	5740	5530
Mo	ppm	468	104	73.3
Pb	ppm	2080	195	593
Zn	ppm	674	4900	>10000

Generally, the primary mineralogy of the samples is consistent with the primary lithology of the samples, which includes quartz, orthoclase, albite, biotite, actinolite and calcite in all samples. Diopside, garnets, and vesuvianite were additionally found in marble diopside and skarn bearing samples, BH-1s (1.5 – 3.0) and BH-1d (90.0 – 91.5). Table 4 summarizes the sulfide and secondary mineralogy of the samples determined from XRD. The secondary minerals noted in the XRD are chlorite, gypsum, smithsonite, otavite, wulfenite, and hemimorphite. In addition there was a strong amorphous background in the diffraction patterns, indicative of amorphous minerals such as iron oxides and aluminum hydroxides. Although hemimorphite is a secondary mineral that could form in the dump due to the weathering of Zn bearing sulfides, it is also part of the supergene mineralization of the Antamina deposit (Personal communication 2013, L. Plascencia). Wulfenite found in the XRD of samples from site BH-1 (not shown here) confirms previous work using batch and field experiments that indicate that Mo precipitation is likely in the form of wulfenite (Hirsche et al. 2012; Conlan 2009).

Table 4 Mineralogy as determined by XRD

Mineral	Chemical Formula	BH-1s (1.5 - 3.0)	BH-1d (19.5 - 21.0)	BH-1d (90.0 - 91.5)
	Sulfides			
Pyrite	FeS_2	x	x	x
Molybdenite	MoS_2	x		
Chalcopyrite	$CuFeS_2$		x	x

Gypsum	$CaSO_4$	x	x	x
Smithsonite	$ZnCO_3$		x	x
Otavite	$CdCO_3$			x
Hemimorphite	$Zn_4Si_2O_7(OH)_2 \cdot H_2O$			x
Amorphous Background	n/a	x	x	x

Sequential Extraction Procedure

Figure 1 presents the SEP results for As, Cu, Mo, Pb and Zn. Only Ca and S were found in the water soluble leach step (step 1) and indicate that gypsum is the only water-soluble phase. Table 5 presents the range in concentrations extracted (in μm) for the SEP steps 2 – 5 and the % extracted for each step when compared to the total amount extracted from the SEPs. From Table 5, weak-acid soluble phases and amorphous reducible phases are considered attenuation mechanisms for Cu, Pb, and Zn and reducible phases are considered to have some attenuating control on As and Mo.

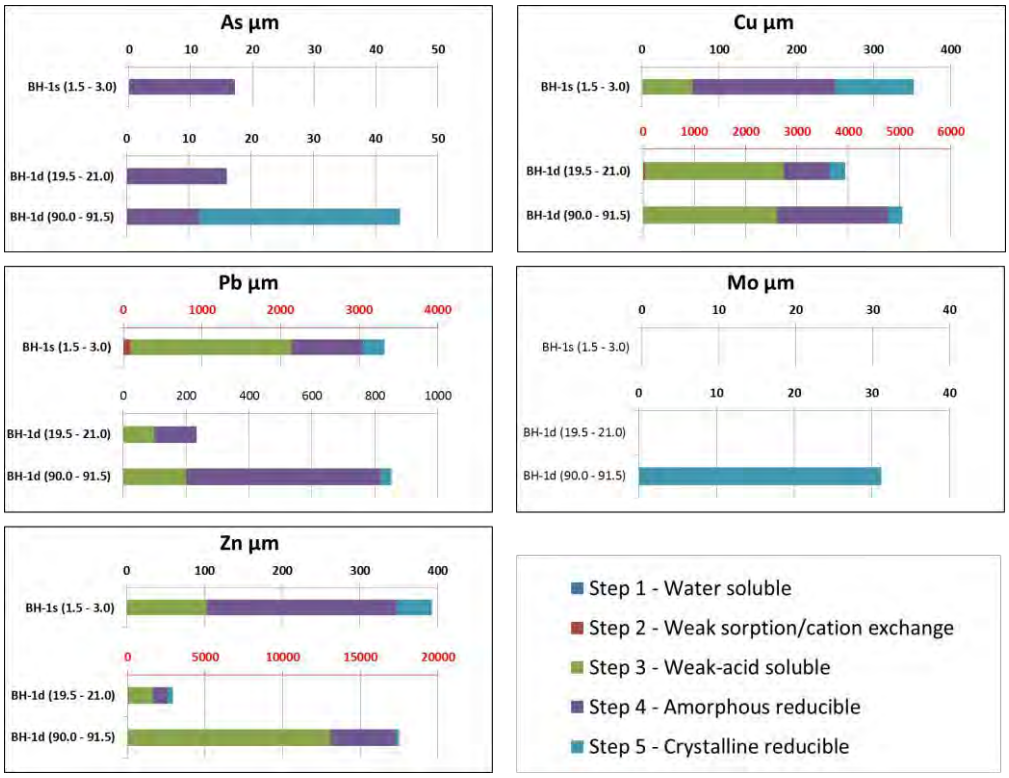

Figure 1 Sequential extraction results for select elements in µg as leached from a 1g sample. Each sub-figure has the same scale unless otherwise indicated using red text

Optical Microscopy and SEM/BSE imaging

Weak-acid Soluble Phases

Figure 2 to Figure 4 present transmitted light microscopy and SEM/BSE images for mineral grains suspected of contributing to Cu and Zn found in the weak-acid soluble leach step. Carbon is included in the semi-quantitative analyses in these figures because it is suspected that these secondary minerals are either carbonates or sulfates or some carbonate/sulfate mix and that the carbon coating used in the method preparation would not contribute significantly to the results. Figure 2 shows two distinct mineral coatings a dark black Zn/Cu carbonate, and a blue/green Cu/Zn carbonate/sulfate coating a silicate/carbonate mineral grain. Figure 3 shows a Cu/Zn carbonate mineral associated with hemimorphite. Figure 4 shows a discrete Zn/Cu carbonate mineral grain. A weak-acid soluble secondary mineral with Pb association was not found although SEP leachate results indicate that this is a potential attenuation mechanism for Pb. These results indicate that more than one Cu/Zn weak-acid soluble phase is forming. In addition, hemimorphite ($Zn_4Si_2O_7(OH)_2 \cdot H_2O$) dissolved in the weak-acid used for this step (Laurenzi, unpublished).

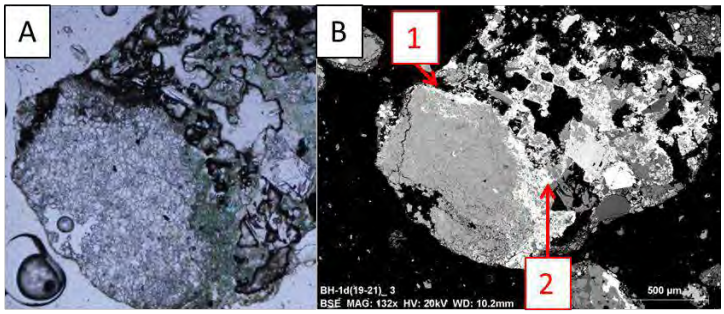

Figure 2 A) Plane-polarized transmitted light photograph of silicate/calcite mineral with black and blue/green secondary mineral coating. B) SEM/BSE image of same mineral: 1) black mineral semi-quantitative analysis; 9 wt.% Cu, 28 wt.% Zn, 22 wt.% O, 8 wt.% C, 0.2 wt.% S.; 2) blue/green mineral semi-quantitative analysis; 46 wt.% Cu, 1.5 wt.% Zn, 15 wt.% O, 5 wt.% C, 6 wt.% S

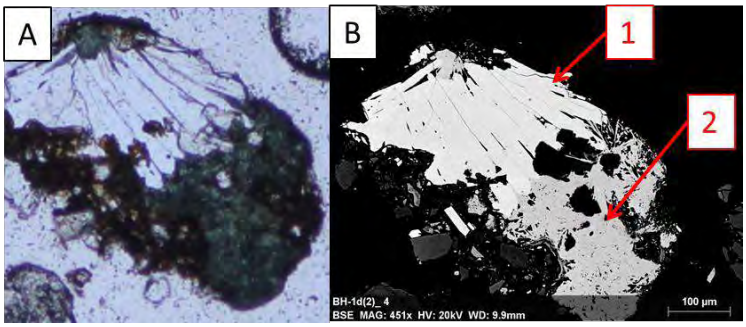

Figure 3 A) Plane-polarized transmitted light photograph of zinc silicate mineral (hemimorphite) with blue/green secondary mineral coating. B) SEM/BSE image of mineral: 1) Hemimorphite semi-quantitative analysis; 50 wt.% Zn, 16 wt.% O, 9 wt.% Si, 2 wt.% C. 2) blue/green mineral semi-quantitative analysis; 42 wt.% Cu, 13 wt.% Zn, 23 wt.% O, 9 wt.% C

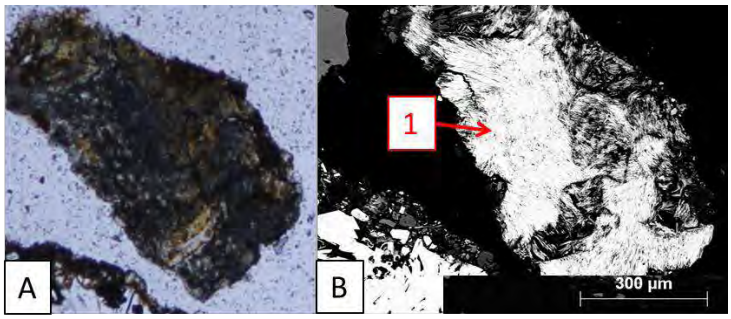

Figure 4 A) Plane-polarized transmitted light photograph of mineral. B) SEM/BSE image of same mineral: 1) mineral semi-quantitative analysis; 18 wt.% Cu, 32 wt.% Zn, 18 wt.% O, 10 wt.% C

Amorphous Reducible Phases

The predominant reducible phases are iron oxides. Figure 5 to Figure 6 present transmitted light and SEM/BSE images for iron oxides found in the samples. The iron oxides form as coatings around sulfide minerals, silicate minerals and as discrete mineral grains (not shown here). Iron oxides were found in all samples and contained variable concentrations of Cu (0.0 wt.% - 2.0 wt.%), Pb (0.0 wt.% - 4 wt.%), and (1wt.% - 7wt.%) Zn. The iron oxide in Figure 6 was determined to have 0.1 wt.% Mo.

Although As associations were not identified using SEM/BSE, the results of the SEP indicate that the As and Mo concentration may be below the detection limits of the SEM/BSE instrument. Sorption and co-precipitation onto these reducible phases is assumed to be one of the attenuation mechanisms for these metals.

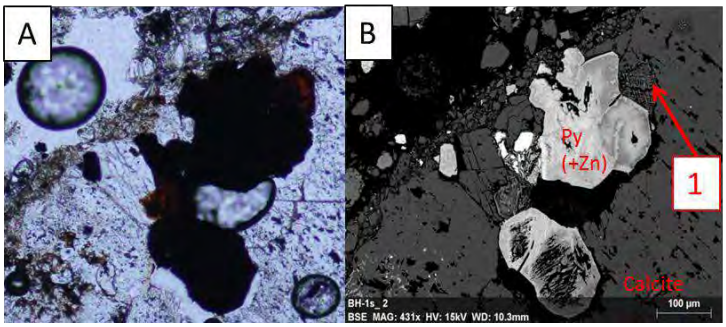

Figure 5 A) Plane-polarized transmitted light photograph of pyrite mineral with iron oxide coatings. B) SEM/BSE image of same mineral. Semi-quantitative analysis of iron oxide 1) 28 wt.% Fe, 21 wt.% O, 1 wt.% Zn, 4 wt.% Pb

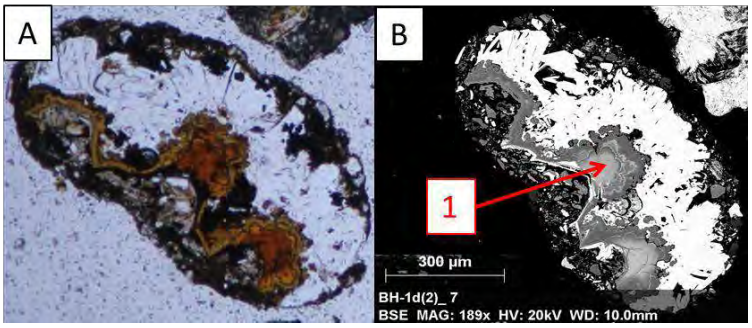

Figure 6 A) Plane-polarized transmitted light photograph of iron oxide coating hemimorphite (white mineral). B) SEM/BSE image of same mineral. Semi-quantitative analysis of iron oxide 1) 41 wt.% Fe, 26 wt.% O, 8 wt.% Zn, 2 wt. % Cu, 2 wt. % Pb, 0.01 wt. % Mo

DISCUSSION

The geochemical and mineralogical testing framework shows that weak-acid soluble and amorphous reducible phases are the predominant attenuation processes for Cu, Pb, and Zn. The main weak-acid soluble phases are copper and zinc bearing; however, their composition determined by SEM/BSE is not indicative of a single mineral phase. This supports field - experimental pile scale conclusions, that identified a blue (mostly amorphous copper sulfate) precipitate containing some malachite in a pile composed of Class A intrusive material (Peterson 2014). More work is required to determine the mineralogy of these weak-acid soluble phases. Hemimorphite, potentially a secondary mineral that formed in the East Dump, should also be considered a weak-acid soluble phase in which Zn is attenuated. The main reducible phases are iron oxides and can contain as much as 2.0 wt.% Cu, 4 wt.% Pb and 7 wt.% Zn. The variability in metals associated with the iron oxides is considered to be due to differences in the total metal content in the waste rock, flow patterns within the pile and the release rate of these metals from the waste rock. Low concentrations of As and Mo are associated with reducible phases dissolved in the SEP leachates. For As these associations were not identified in the SEM/BSE investigation possibly due to low content. While for Mo, sorption onto iron oxides, as determined from the SEP and SEM/BSE investigations, and precipitation of wulfenite, identified by XRD, are the likely attenuation processes. Based upon the results of the SEP, a lead-bearing weak-acid soluble phase was expected but was not identified in the mineralogical and SEM/BSE investigations. More work is required to identify the attenuating mechanism for lead. The metal/mineral associations seen in this study are considered to be the results of pore waters high in Zn and Cu and SO_4 and CO_3, from which Cu-Zn bearing minerals are precipitating. Due the presence of calcite in the samples the pH of the water is suspected to be near neutral, thus limiting the sorption of As and Mo.

CONCLUSION

This work focused on 3 samples collected from depth in an operational waste rock pile. This study highlights the benefit of detailed mineralogical and geochemical investigations to constrain metal attenuation phases and processes. It is important to examine samples collected from the field to support inferences made from laboratory tests.

Results from the SEP, microscopy and SEM/BSE investigations indicate that precipitation of weak-acid soluble phases and sorption onto amorphous reducible phases are the predominant attenuation mechanism for Cu, Pb and Zn. Cu and Zn are associated together with variable concentrations in weak-acid soluble phases. SEP tests show that Pb is being attenuated in a weak-acid soluble phase; however, this phase was not identified in the mineralogy or SEM/BSE work. SEP tests indicate that As is associated with reducible phases. SEP leachates and XRD tests indicate that Mo attenuation is via sorption onto iron oxides and precipitation of wulfenite, respectively.

ACKNOWLEDGEMENTS

Funding for this Project was provided in-part by Compañia Minera Antamina. Many thanks to Bevin Harrison from Antamina for her time and effort in reviewing this submission; as well as, Celedonio Aranda, Edsael Sanchez and Bartolome Vargas for excellent technical and field support at Antamina. Special thanks to my supervisors Roger Beckie and K. Ulrich Mayer and my cohorts Elliot Skierszkan, Maria Eliana Lorca Ugalde, Melanie St. Arnault, and Daniele Pedretti for their assistance in collecting samples, support and thoughtful reviews.

Management of Spontaneous Combustion for Metalliferous Mines

Matt Landers and Brent Usher
Klohn Crippen Berger, Australia

ABSTRACT

Spontaneous combustion of mine waste is usually associated with coal mines. It occurs to a lesser extent with ore deposits that contain pyrite (FeS_2) or pyrrhotite ($Fe_{1-x}S$) and carbonaceous materials. Limited research has been conducted into the prediction of spontaneous combustion and currently no single method exists for all mine sites. Prediction requires classification of the material based on geochemical properties that can be coded into a block model. The potential spontaneous combustion materials are managed accordingly to minimize atmospheric oxidation and contact with water.

Spontaneous combustion results in the production of heat (> 270 ºC near the surface and up to 1,200 ºC deep in a Waste Rock Dump; WRD), which has implications for; *inter alia*, blasting while in the pit or underground and the release of hazardous gasses such as sulfur dioxide (SO_2).

Spontaneous combustion often evolves and material can be classed according to stages of development, including: potential, current and extinct. The "potential" class includes material that has the geochemical properties that, under field conditions could lead to spontaneous combustion, but has not yet started reacting. "Current" spontaneous combustion materials have already begun to combust and therefore prevention is no longer an option; rather the material requires remediation and containment. Zones of "extinct" spontaneous combustion materials are usually associated with precipitated minerals that may contain elevated metal concentrations that need to be managed. Several metalliferous mines in Australia have issues with spontaneous combustion occurring within the pit and on WRDs. These mines have implemented a number of control techniques that can be incorporated into WRD design and mine planning to minimize the effects of spontaneous combustion and ultimately prevent it from occurring. This paper describes some of the control measures that are being implemented for one Australian metalliferous mine.

Keywords: Spontaneous Combustion, Metalliferous Mine, Pyrite oxidation

INTRODUCTION

Spontaneous combustion of mine waste is usually associated with coal mines. It occurs to a lesser extent with ore deposits that contain sufficient pyrite (FeS_2) and carbonaceous materials. Several metalliferous mines in Australia have issues with spontaneous combustion occurring within the pit and on the waste rock dump.

Limited research has been conducted into the prediction of spontaneous combustion and currently no single method exists for all mine sites. This paper outlines the factors of importance in spontaneous combustion and the onsite experience with this phenomenon at a metalliferous mine; the site is to remain anonymous and will be referred to as "Site X".

Spontaneous Combustion Process

Spontaneous combustion (also referred to in this paper as "smokers") is a phenomenon usually associated with ore deposits that contain pyrite (but may also include the sulfide minerals, *inter alia*, pyrrhotite, galena, sphalerite, arsenopyrite, chalcopyrite and molybdenite) and carbonaceous materials. The oxidation of pyrite is exothermic and can lead to a significant increase in heat.

Spontaneous combustion is usually associated with finely grained disseminated pyrite (framboidal pyrite) which is a major constituent at some metalliferous mines. The mining process contributes to exposing the pyrite and decreasing the particle size of the rock mined. This results in an increase in the surface area and reactivity of the rock. The spontaneous combustion process begins with the exposure of the material to atmospheric oxidation or contact with oxygenated water (usually rainwater).

The oxidation of pyrite and other sulfides results in a gradual increase in temperature immediately surrounding the point of oxidation. This point is insulated by surrounding rocks, preventing the release of heat, which results in further increases in temperature. Over time, the temperatures become high enough to ignite any carbon and/or organic matter that may be present, releasing gas (e.g. CO_2, SO_2, etc.) and steam. As the heat increases the rate of pyrite reaction increases. The process has been determined to be a three-stage process: stage A (ambient to 100°C), stage B (> 100°C) and stage C (> 350°C) (Rosenblum and Spira 1995; Rosenblum et al. 2001). Once the reacted material cools down, complex minerals precipitate (e.g. sulfates, halides and native sulfur); usually containing a concoction of trace elements.

Spontaneous combustion may also result from galvanic interaction. The presence of an electrolyte and two sulfides (e.g. galena and sphalerite) with different rest potential may form a galvanic cell (Kwong et al., 2003), with the sulfide with the higher rest potential forming the cathode and the lower forming the anode. Spontaneous combustion results from galvanic sulfide interaction with a rest potential difference (ΔV) greater than 0.2 V, whereas mixtures with $\Delta V < 0.1$ V do not combust (Payant et al., 2011).

Spontaneous combustion is time dependent, and early detection of the potential sources of the problem may allow for the issues to be managed appropriately, preventing the problem from developing into full – scale combustion. If combustion has already begun, management of the materials is more problematic, as excavation and movement of materials will allow further atmospheric oxidation, allowing the conditions to be optimized for sulfide oxidation, potentially increasing the rate of pyrite oxidation.

Spontaneous Combustion Prediction and Detection

Prediction of spontaneous combustion requires classification of the material based on its inherent properties. The characteristics of a material that can be used to identify the potential for material to spontaneously combust include (*inter alia*): the geochemical constituents of the materials and chemical analysis of drill core samples/waste piles (e.g. sulfur content (particularly pyrite); combustible carbon content; moisture content; environment oxygen content; oxygen avidity; presence of other volatile materials; and, temperature). Another method of prediction/ detection includes modeling the rate of heat generated versus the rate of heat dissipated (Carnes and Saghafi, 1998).

Early detection of spontaneously combustible materials allows for the associated materials to be managed appropriately, which may prevent the material from developing further into a smoker. The main detection characteristics include (*inter alia*) temperature increases, gas odor and observation of vapor/gases. Heat haze and "steam" plumes may be observed as well as efflorescence caused by the oxidation of pyrite and sublimation of sulfur. Infrared monitoring instruments or thermal probes inserted into the WRD may be used for early detection of spontaneous combustion. Spontaneous combustion has a distinctive smell; the most common and prevalent of the gases produced is SO_2, which is odorless at low concentration, however, may have a pungent rotten egg smell at high concentrations.

The intensity and the rate at which a "smoker" develops are dependent on a combination of factors; some of these factors include: composition (the presence and availability of sulfide [pyrite and other sulfides,], carbon and oxygen); friability, particle size and surface area (which can be related to mining method, such as blasting); moisture content; climatic conditions (temperature, relative humidity, barometric pressure and oxygen concentration); and, stockpile compaction, height and method of stockpiling (e.g. end – dumping versus paddock dumping).

METHODOLOGY AND SITE PROPERTIES

A spontaneous combustion management plan was developed for Site X, a metalliferous mine in Australia. The management plan was based on the factors that promote the evolution of spontaneous combustion, and has been separated into classes according to stages of development, namely: potential, current and extinct. The management options were developed based on site observations including monitoring of temperature. The Site's historical geochemical database was reviewed to develop geochemical trends; however, the outcomes from this review are not discussed in this paper. Several of the more practical methods for managing (remediating) spontaneous combustion were tested at the Site.

All of the lithological domains at Site X contain sulfide minerals (pyrite, sphalerite and galena) with some units being characterized by elevated pyrite, ranging from 10 to 27 wt %. For lithologies containing galena and sphalerite, their median abundances were low, ranging from 1 to 2 wt %. All lithologies contain carbonates (dolomite, calcite and ankerite) with dolomite being the dominant acid neutralizing mineral in all lithological units. Other non-sulfide/carbonate minerals include: quartz, mica, K-feldspar (microcline) and moderate to trace quantities of kaolinite, chlorite, montmorillonite, vermiculite, plagioclase (albite) and gypsum.

Several of the waste lithological units contained elevated sulfide concentrations with average values including: X Shale (~8.6 wt % S), Y Shale (~7.2 wt % S) and Z Shale (~5 wt % S). The sulfide is

mainly associated with framboidal pyrite (Figure 1). The overburden waste also contains significant organic carbon (> 0.5 wt %).

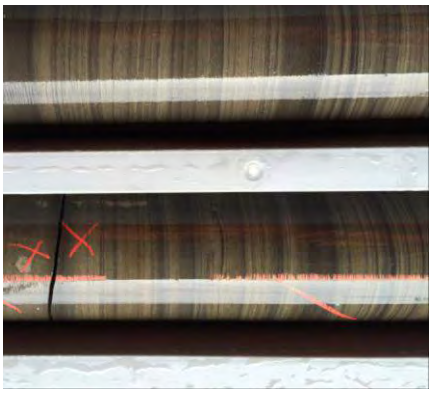

Figure 1 Interbedded framboidal pyrite and dolomite.

RESULTS AND DISCUSSION

Spontaneous Combustion Prevention, Control and Remediation

There are a number of control techniques that can be incorporated into the WRD design and mine planning to minimize the effects of spontaneous combustion and ultimately prevent it from occurring; however, there is no single control that has been proven to be completely reliable or successful. Effective control of spontaneous combustion is usually achieved by using a combination of techniques, and these techniques are dependent on individual mining situations.

Some of these controls include measures to reduce or eliminate oxygen. This may be achieved with: sealing agents; compaction of the surface material (dozing over, truck haulage routes or compaction); buffer blasting; covering the area of concern with inert material (e.g. non-acid forming [NAF] material, clay); application of a final cover layer with good water retention properties (e.g. fly ash-water slurry); and, subaqueous deposition. Control measures that have been proposed or used at several Australian sites to reduce the temperature and lower the reaction rate include: water cannons; firefighting foam; injection of water; water spraying; nitrogen injection; and, carbon dioxide injection. Other control measures to eliminate the process may include: excavation of hot or burning material; controlling the morphology of high sulfide material cells (layering etc.); the use of low-angle slopes to minimize the effects of wind (i.e. reduce "chimney effect"); the use of artificial wind barriers; submersion in water (e.g. backfill in pit and flooding); and, spreading the affected material into thin piles to allow to cool. The effectiveness of a cover is generally dependent on composition, particle size and bulk density; water content of the cover; air filled void space; heat transfer capacity; oxygen transfer; and cover thickness.

Geochemical Management: Spontaneous Combustion

The management options for spontaneous combustion can be separated according to the different stages of development of smokers, these stages include: potential smokers, current smokers and extinct smokers. The "potential smokers" class includes material that has the geochemical characteristics of a smoker, but is not currently combusting or is not currently associated with elevated temperatures (> 60 °C). Current smokers have already begun to combust and therefore prevention is no longer an option; rather the material requires remediation and containment.

Extinct smokers are materials that were active smokers but became extinct due to depletion of sulfide, oxygen or combustible carbon. These materials may result in precipitation of soluble minerals which contain trace elements that need to be managed.

Potential Smokers

Potential smokers can be detected through the block model (populated by drilling sample analysis) and/or field investigations (handheld XRF of drill mounds) prior to blasting and excavation. The most critical step in preventing spontaneous combustion from developing is to limit contact or reduce contact time with oxygen and water. Therefore, if material has the characteristics that may result in spontaneous combustion it is handled preferentially with appropriate management controls. This can prevent the material from developing spontaneous combustion and reduce the need for remediation. Potentially reactive materials are be mined shortly after blasting and managed appropriately.

Management of potential smokers - Option P1:

One of the preferred options to consider for future operations is subaqueous disposal of reactive waste. The disposal method typically involves the storage of reactive waste in a series of pits below the water table (Figure 2); the material is stored below the water table where oxygen is inhibited. The process reduces the risk of natural or manmade incidents associated with flooded impoundments or complex engineered covers. In addition to groundwater saturation, a thick (3 to 4 m) pervious cover (which may include oxygen consuming materials such as organics), is placed over the reactive waste. The reactive waste is placed such that it will remain saturated under the water table to beyond a 1 in 50-year dry condition. During the periods when the reactive waste is not saturated (for example if water tables and infiltration decrease in a prolonged drought) the system will rely on the oxygen consuming cover. Similarly, excess water from dewatering may be pumped over the reactive PAF such that the material is not exposed over dry periods. Additional benefits of this option include the reduced foot print compared to conventional disposal facilities as well as reducing volumes of encapsulation materials required elsewhere on site for waste mitigation.

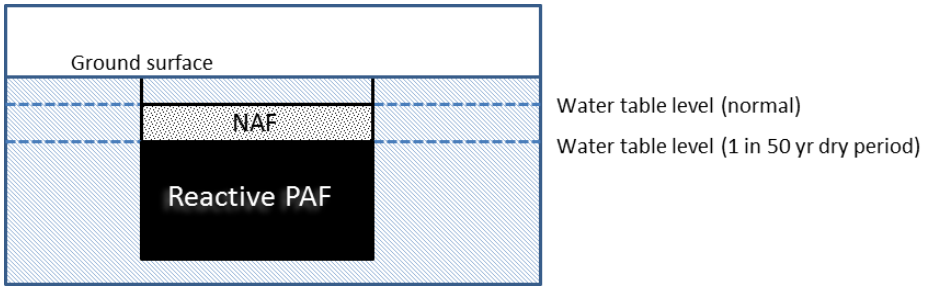

Figure 2 Subaqueous disposal of reactive PAF below groundwater level.

Management of potential smokers – Option P2:

A second option to consider for future operations is co-disposal, which involves the disposal of both tailings and waste rock simultaneously within a storage compartment (e.g. compacted clay lined dam) (e.g. Figure). The waste rock at the Site is commonly coarse, meaning there are large void spaces when placed on the WRD. The tailings waste is very fine and may be deposited within

the void spaces of the waste rock. Co-disposal also has a number of other benefits, including: provides a storage option for both waste streams (waste rock and tailings); the tailings act as a barrier to atmospheric oxidation of the PAF, therefore reduced ARD generation; low permeability of the WRD means reduced seepage; structural integrity; smaller footprint (excludes the tailings facility); and, potentially less post closure maintenance.

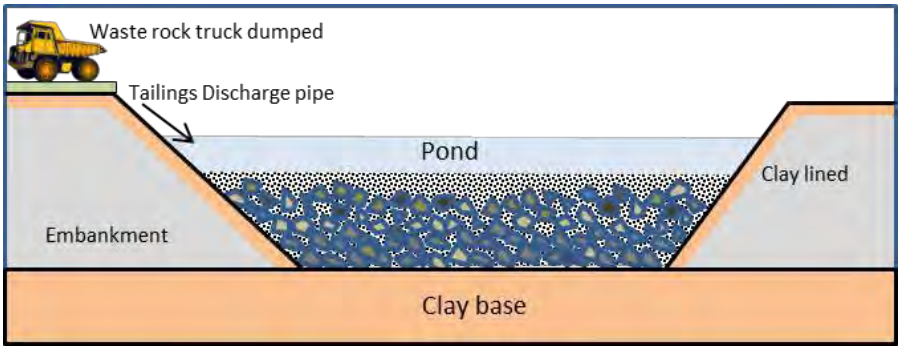

Figure 3 Co-disposal of tailings and waste rock (including reactive PAF).

Current Smokers (Remediation)

Current smokers are materials that are currently combusting (i.e. when excavated, stockpiled or during transportation; Figure 4) and are characterized as having temperature > 60 °C and/or produce gases. Remediation of current smokers also includes small quantities of material that may begin to react within the pit. There are also instances at Site X where materials used as windrows have been constructed with reactive PAF and begun to combust. These materials are all treated as current smokers.

Figure 4 Current and extinct smokers at Site X.

Remediation - Option R1

Remediation (Option R1) is only applicable for material that is combusting directly below the surface (e.g. ~ 50 cm; Figure 4). This option should not be considered for areas affected by deep "hotspots" as the material will continue to combust when encapsulated and could potentially develop into a much larger problem. Encapsulating a deep "hotspot" may cause the buildup of heat

and gases which may ultimately lead to an eruption – like event at the surface. A good understanding of the depth of the hot-spot is gathered at the monitoring stage or at least prior to any remedial work being conducted.

Generally, the smokers at Site X are associated with very steep sections of the WRD; the steeper slopes are also more difficult to compact and may be conducive to the "chimney" effect. The main step in this remediation is to reduce the WRD slopes; the chimney effect is significantly reduced and the hotspot may be less exposed to atmospheric oxidation.

If the smoking material can be spread loosely, it may be able to cool. Once cooling has occurred (this may take several weeks depending on the carbon and pyrite content of the affected area) and the slopes have been reduced, the affected area (which should show evidence of being dormant/extinct with low temperatures and no evidence of gases) is covered with NAF or clay and compacted (Figure 5). Given the intensity of the smoker and the likely minerals/metals which make up the efflorescence, a clay layer is also applied and compacted to prevent the mobilization and transportation of metals and further oxidation of any unreacted pyrite/ combustible carbon.

This management option has been tested at Site X and the observations and ongoing monitoring have indicated the materials have stopped combusting and become extinct.

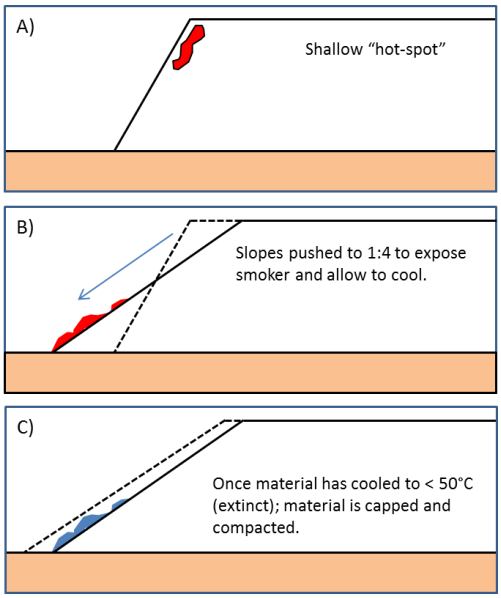

Figure 5 Spontaneous combustion remediation option 1 (R1) for shallow affected materials.

Remediation - Option R2

Remediation option R2 is used if the hot – spot proceeds deep into the WRD or for material that begins to react in the pit. Deep hotspots are usually associated with the precipitation of native sulfur, and the presence of hydrogen sulfide (H_2S) gas and cracks in the surface (presumably to release excess pressure). H_2S is generally only formed when there is not enough oxygen available for complete oxidation; often deep within a waste facility. The $H_2S_{(g)}$ is oxidized to native sulfur once exposed to atmospheric oxidation, and the presence of native sulfur often indicates that the formation of H_2S forming deep within the WRD where there is likely to be limited O_2.

The affected areas are excavated from the WRD and transported to a specially designed facility at identified and managed disposal locations. All material that is excavated and has a temperature > 60 °C is spread thinly and allowed to cool. The material is ideally truck dumped into loose ~ 2-m piles (via paddock dumping) within a specially designed facility (e.g. compacted clay layer) (Figure A). Previous investigations have shown that 2-m piles are below the critical mass for spontaneous combustion to occur (Waters and O'Kane, 2003); this assumption will also be investigated for materials at Site X. The 2-m piles are be monitored until the material is below 60°C and become extinct. This monitoring includes daily observations and the inclusion of several temperature probes in the piles to assess whether there are any temperature spikes. Once the material is shown to be extinct (i.e. monitoring indicates there are no temperature rises and there is no visible smoke), it can be spread evenly as a 2-m lift and then covered with inert material and compacted (Figure B). The excavation of the affected material causes rapid combustion once disturbed (i.e. the rate of pyrite oxidation is enhanced due to the availability of oxygen) producing excessive gas and vapor.

The spontaneous combustion storage facility should not be located in a place that receives runoff from other facilities, or above or adjacent to major streams. Similarly, the site should not be located near clean material (NAF and clay) stockpiles. The number of spontaneous combustion management sites is minimized, including the size of the footprint.

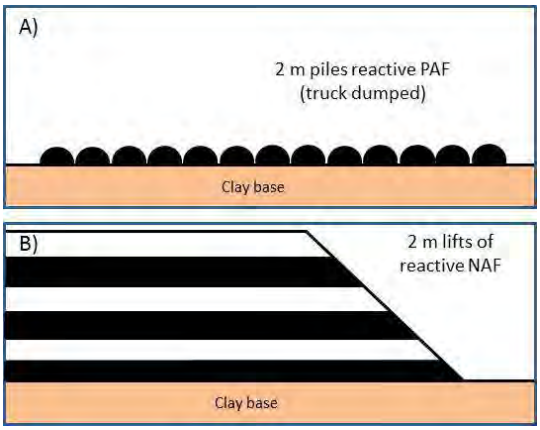

Figure 6 Spontaneous combustion Emplacement Facility.

Remediation - Option R3

Remediation option R3 is based on management and remediation strategies undertaken by another mine with similar geology, waste material and climate, which has also had issues with spontaneous combustion from reactive shale. A number of options were tested at this analogue site, with the most successful being the addition of a mixture of quicklime (CaO) and water to the affected area; this is now part of routine operations. The addition of the mixed quicklime/water slurry were able to achieve a reduction in temperature from 300 to 60 °C within 30 minutes of application for a 20-m cut/0.5-m lift.

Although the application of the quicklime/water mixture is proving to eliminate the issue, it is an expensive solution. The cost of quicklime delivered to site is ~A$600 ton (> A$2,000 for a single mixture).

Remediation - Option R4

The location of some smokers is such that this material is difficult or impossible to excavate and remove in a safe manner (e.g. smokers on the pit walls). There are limited remediation methods to deal with the issue in these cases. There are a few gel sealants which can be sprayed onto the affected area, although these are effective, they can generally be expensive. Miron (1995) and Chakravorty and Kolada (1988) investigated a number of gel sealants for the mitigation of spontaneous combustion for coal mines. These may be effective but were not considered applicable due to cost or scale at this Site.

Extinct Smokers

Extinct smokers should be closely monitored to make sure they are actually extinct. Residual heat (> 60 °C) is indicative that the material may still be combusting under the surface. The dormant/extinct smokers are associated with mineral precipitates (ash/efflorescence; Figure 4) which are likely to carry a large quantity of soluble solids and metal loads. The metals that are present as readily soluble salts are susceptible to leaching particularly after the first rains which may dissolve and transport these materials to sensitive receptors. For this reason the ash/efflorescence is excavated and encapsulated.

CONCLUSIONS

The management options for spontaneous combustion were separated according to the stages of development of spontaneous combustion (potential smokers; current smokers; and, extinct smokers). As spontaneous combustion develops from a potential smoker to a current smoker, the management options must change from prevention and confinement to remediation and confinement, respectively. The various options are summarized in Table for each stage of spontaneous combustion development. Some of the management options have tested this for current spontaneous combustion. The outcomes of these trials are summarized in Table 2.

Table 2 Remediation, management and monitoring options summary.

Developmen t Stafe	Management/ Remediation Option	Description	Trial Outcome
Potential Spontaneous combustion	P1 – Subaqueous Disposal	Disposal of reactive PAF material (and other reactive material) below groundwater table.	Not tested to date
	P2 – Co-disposal	Co-disposal of reactive PAF material with tailings within a facility.	Not tested to date
Current Spontaneous combustion	R1 – Decline slopes	Reduce the spontaneous combustion affected WRD slopes to 1:4, allow affected material to cool and then encapsulate. Closely monitor.	The trial was successful at eliminating spontaneous combustion with temperatures reduced to < 60 °C and reduction of gas emissions.

	R2 – Layer – cake	Material > 60°C is be spread thinly as a < 2 m^3 pile and allowed to cool. Once cooled the material is spread as a 2 m lift and covered with NAF. Closely monitor.	The trial was successful at eliminating spontaneous combustion with temperatures reduced to < 60 °C and reduction of gas emissions.
	R3 – Quicklime/ water	Application of quicklime/water mixture to spontaneous combustion affected areas.	The trial was not successful and enhanced pyrite oxidation resulting in the production of gases.
	R4 – Gel application	Application of gel to spontaneous combustion affected areas.	Not tested to date
Extinct Spontaneous combustion	Extinct material	Close monitoring.	
	Extinct Ash (soluble minerals)	Ash is excavated and encapsulated within a PAF cell.	

All of the management and remediation options need to be monitored closely to assure spontaneous combustion is not developing and contaminants are not being released to the environment. Monitoring may include: Oxygen levels; temperature; gas (O_2, SO_2 and H_2S associated with spontaneous combustion); surface water, seepage water and groundwater qualities and volumes; and, physical stability.

Evolution of a Waste Rock Dump Management Plan for a Metalliferous Mine

Matt Landers and Brent Usher
Klohn Crippen Berger, Australia

ABSTRACT

As part of sound mine waste management, a thorough understanding of the geochemical properties of waste materials is needed. Waste rock is a significant factor to consider in the environmental management of metalliferous mines and a detailed waste rock dump (WRD) management plan is required. These plans may evolve over the life of a metalliferous mine as new data and a better understanding of the geochemical nature of waste rock types become available. A case study in Australia is discussed where the plan had to undergo significant modifications as a result of a geochemical characterisation program that yielded a much improved understanding of key waste types and material volumes. Inaccurate geochemical classification of waste rock resulted in significant variance between the estimated volumes of non-acid forming (NAF) and potentially acid forming (PAF) materials quantified by the site's 'block model', and the true volumes disposed on the WRD or determined by pit technicians. The initial classification of PAF and NAF was quite broad and did consider different types of material which could lead to salinity, neutral mine drainage (NMD; metalliferous NAF) or which could identify acid consuming (AC) material. As a result, initial WRD design was geared to effectively mitigate sulphide oxidation and subsequent generation of acidity, metals and salinity. These discrepancies had large implications for mine planning and led to the adoption of new strategies and a revised WRD design to minimise the impacts of acid and neutral mine drainage (AMD and NMD). This case study discusses the evolution of the WRD design as the geochemical understanding has improved and measures that have been implemented by the mine to minimise reactivity and water quality impacts.

Deportment of Sulfide and Neutralization Potential by Particle Size Distribution in Limited Buffering Mine Wastes

David Tait[1], Andrew Barnes[1], Claudio Andrade[2], Matt Dey[1], Rob Bowell[1] and Carl Williams[1]

1. *SRK Consulting, United Kingdom*
2. *Barrick Gold, Canada*

The evaluation of Acid Potential (AP) and Neutralization Potential (NP) through industry standard static testing methods is a first step in mine waste characterisation programs and the assessment of Acid Rock Drainage (ARD). The common Acid Base Accounting (ABA) classifications often report results as 'uncertain' or 'low AP' for low sulfide-low carbonate materials.

Bulk sample analyses have limitations in applications to overall large field scale waste rock dumps. Reaction rates are dependent on grain-size and surface area, among other factors, with the potential for segregation of sulfide or carbonate minerals to the different size fractions to alter the effective ARD potential relative to the bulk measurements.

This study evaluated the deportment of sulfide sulfur, carbonate NP and bulk NP by grain-size in low NP waste rock samples. The aim was to evaluate potential bias introduced by the standard bulk analysis procedures, particularly due to the pulverisation of the bulk samples.

Samples were sieved to three size fractions: sub 1 mm, 1-5 mm and 5-12 mm. The sieved fractions were split into two portions: the first portion was analysed by the Modified Sobek procedure on the 'as sieved' material without grinding/grain-size reduction to provide a measure of the 'available NP' for each fraction (i.e., the quantity of NP available under field conditions). The second portion was subject to grinding and subsequent analysis by the conventional Modified Sobek method as well as sulfur and carbon content by LECO analysis.

Evaluation of the NP results showed that 'available NP' of the sieved non-pulverised materials was approximately an order of magnitude lower than bulk NP values, and agree with other similar studies conducted by the authors. Overall, the tests indicate that bulk NP data for low carbonate materials could present a considerable over-estimation of NP, and should be applied with care to ARD studies.

CHAPTER 3

PREDICTION OF DRAINAGE FLOW

The Calculation of Actual Evaporation from an Unsaturated Soil Surface

Murray Fredlund[1], Dat Tran[2] and Delwyn Fredlund[3]

3. Golder Associates, Canada

ABSTRACT

The calculation of Actual Evaporation, AE, is required when calculating the net moisture flux across the ground surface. The Wilson-Penman (1990) equation appears to provide reasonable estimations of actual evaporation, AE, from saturated clayey soils but tend to over-estimate actual evaporation from coarse-grained soils. Two distinct approaches have emerged in recent years for the calculation of actual evaporation from unsaturated coarse-grained surfaces. Both approaches are based on the concept that evaporation tends to "shut-off" as the natural water content approaches residual water content conditions. The first approach to calculating AE from unsaturated soils has involved the adjustment of calculated total suction at the soil surface. The second approach determines an "evaporation-rate reduction point" from the drying soil-water characteristic curve and then calculates a vapor pressure reduction factor when calculating AE. Both approaches constitute an attempt to take "surface resistance" to evaporation into consideration. The paper compares the theoretical context for both approaches (i.e., total suction adjustment and vapor pressure adjustment), for the calculation of actual evaporation.

Keywords: Actual evaporation, potential evaporation, total suction, surface resistance, vapor pressure.

INTRODUCTION

The primary components associated with the determination of water balance (or net infiltration, *I*) at ground surface are shown in Eq. [1].

Infiltration (*I*) = Precipitation (*P*) – Actual Evaporation (*AE*) – Transpiration (*T*) – Runoff (*R*) [1]

Evaporation models can first be classified on the basis of whether Potential Evaporation, *PE*, or Actual Evaporation, *AE*, is calculated (See Figure 1). Most methods used in geotechnical engineering practice are based on energy balance and aerodynamic considerations. It has become apparent that "surface resistance" plays an important role in the computation of actual evaporation, *AE*. Several evaporation models that have been used in geotechnical engineering practice until the late 1990s did not take the "surface resistance" of the soil into consideration. Examples of these models are shown in Figure 2.

The calculation of actual evaporation has proven to be one of the most complex analyses associated with unsaturated soil mechanics. Models that have been proposed and used in geotechnical engineering for calculation of evaporative flux can be divided into two broad categories; namely, those that take "surface resistance" into consideration and those that "do not take surface resistance" into consideration (See Figure 3). "Surface resistance" has proven to be a significant factor in calculating "actual evaporation".

Figure 3 shows that the Wilson (1990) and Wilson et al., (1997) models for actual evaporation have been incorporated into numerical modeling codes in two different ways; namely, where consideration is given to "surface resistance" (e.g., SVFlux 2009), and where consideration has not been given to "surface resistance" (e.g., SoilCover, 1994 and Vadose/W, 2008). The word "*modified*" has been added to the description identifiers for each method where "surface resistance" has been taken into consideration.

The effect of "surface resistance" turns out to be of particular significant when considering evaporation from dry, coarse soils in arid regions. Wilson (1990) noted that the Wilson-Penman (1990) method would over-predict actual evaporation from soil surfaces in dry regions. It now appears that the primary reason for the over-prediction of actual evaporation was the omission of the "surface resistance" term. Wilson (1990) also pointed out that osmotic suction effects were not taken into consideration in the Wilson-Penman method. This paper does not address the issues related to osmotic suction but focuses on clarifying the formulations that attempt to address "surface resistance".

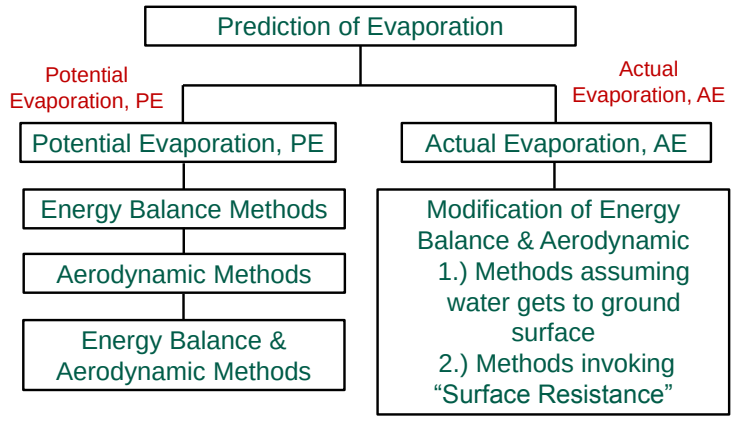

Figure 1 Evaporation models classified in terms of whether potential evaporation, PE, or actual evaporation, AE, is being calculated.

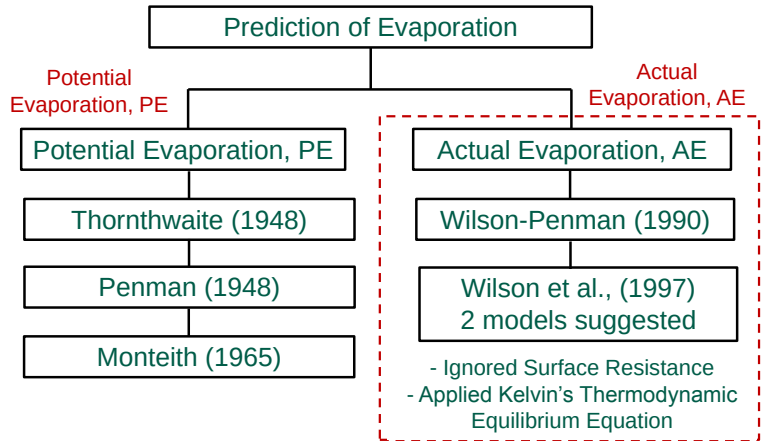

Figure 2 Evaporation models that did not take "surface resistance" of the soil into consideration.

Fredlund et al., (2012) suggested that an adjustment should be made to the total suction calculated at the soil surface to account for non-equilibrium conditions. The adjusted total suction was incorporated into the computer code of SVFlux (2009). The proposed procedure was verified using datasets found in the research literature. Actual evaporation models were solved using both "coupled" and "uncoupled" methodologies. The revised procedures to calculate actual evaporation were referred to as: i.) the *modified* Wilson-Penman (1990) method, ii.) the *modified* "Limiting Function" method (Wilson et al., 1997), and iii.) the *modified* "Experimental Function" method (Wilson et al., 1997).

Tran (2013) re-visited the Penman-Monteith (1965) formulation that incorporated the concept of a "canopy cover" (i.e., a type of "surface resistance") from vegetated surfaces and found that the formulation could also be applied to evaporation from unsaturated soil surfaces. In this case an empirical methodology was used to adjust the calculated vapor pressure at the soil surface. The calculated actual evaporations from the revised Penman-Monteith methodology were compared to measurements of evaporation made on several sand column tests. Consequently, there were now two methodologies available for the calculation of "actual evaporation" from unsaturated soil surfaces.

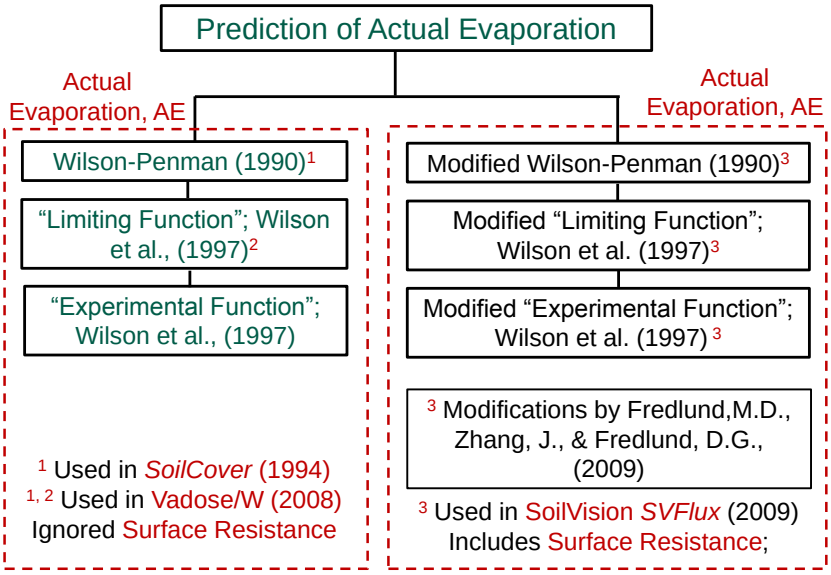

Figure 3 Broad classification of models based on modifications of the original Penman (1948) equation

The objective of this paper is to provide a summary (and clarification) of the various methods that have been proposed within geotechnical engineering for the calculation of actual evaporation, *AE*. The scope of this paper is limited to a presentation of the theories involved and reference is made to the datasets from laboratory column test measurements that have been used to verify the theoretical formulations.

Evaporation Models Based on Thermodynamic Equilibrium at the Evaporating Surface

Figure 4 identifies some of the variations of the Penman (1948) method that have been proposed for the calculation of actual evaporation. These models did not initially take "surface resistance" into consideration but were later *modified* by Fredlund et al., (2012) to account for "surface resistance".

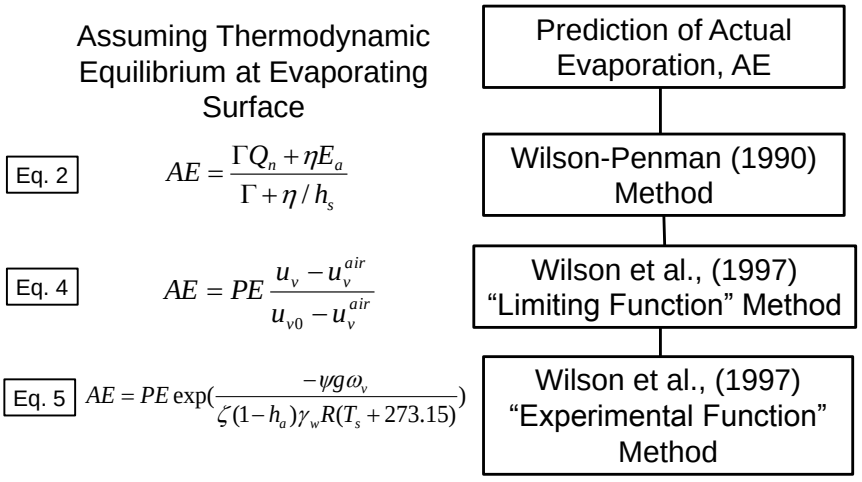

Figure 4. Actual evaporation equations based on thermodynamic equilibrium at the soil surface.

The Wilson (1990) and the Wilson et al., (1997) methods for calculating actual evaporation are assumed to be driven by a vapor pressure gradient that satisfy thermal equilibrium at the ground surface. The water in the soil at ground surface can be negative (i.e., corresponding to an equivalent

total suction). Soil suction (i.e., total suction) at ground surface was assumed to reduce the vapor pressure and thereby reduce evaporation from ground surface. The Wilson (1990) and the Wilson et al., (1997) equations appears to provide reasonable calculations of actual evaporation when the clay soils at ground surface remain near saturation but appear to over-estimate actual evaporation from unsaturated, coarse-grained soils.

The 1948 Penman equation was based on the vapor pressure gradient between the water surface and the overlying air as the primary driving mechanisms that influenced the vapor pressure gradient; namely, net radiation and wind speed (i.e., mixing of air) at the ground surface. The properties of the soil did not come into the analysis and it was assumed that water was available for evaporation at ground surface.

Wilson-Penman (1990) Model

Wilson (1990) made one modification to the Penman (1948) equation which then became known as the Wilson-Penman (1990) equation as shown in Figure 4:

$$AE = \frac{\Gamma Q_n + \eta E_a}{\Gamma + \eta / h_s} \qquad [2]$$

where: AE = actual evaporation rate from a soil surface in mm/day; Γ = slope of saturation vapor pressure versus temperature curve, $kPa/^oC$, Q_n = net radiation at the water (or saturated ground) surface, mm/day, η = psychrometric constant, $kPa/^oC$, $E_a = 2.625(1 + 0.146W_w)(u_{vo}^{air} - u_v^{air})$, mm/day, W_w = wind speed at 2 m, km/hr, h_s = relative humidity at the soil surface (i.e., $h_s = u_v^{soil}/u_{vo}^{soil}$, where u_{vo}^{soil} = saturated vapor pressure in the soil at ground surface, kPa). The inclusion of the relative humidity term in the denominator took into consideration the affinity (or holding power) of the soil for water at ground surface. While net radiation (and wind) attempted to remove water vapor away from the soil surface, the soil attempted to retain water. The Wilson-Penman (1990) model appeared to provide reasonable results in situations where the soil at ground surface remained essentially saturated and the permeability of the near ground surface soil was such that water could be transmitted to the soil surface.

Actual evaporation was calculated in an uncoupled manner when using the Wilson-Penman (1990) method. The assumption was made that the ground surface thermal flux was zero. The soil surface temperature was computed using the following empirical relationship.

$$T_{soil} = T_a + \frac{1000\left(R_n - R_g\right) - L_v AE}{C_f \eta f\left(u\right) L_v} \qquad [3]$$

where: T_{soil} = soil temperature at soil surface, ^oC, T_a = air temperature, ^oC, C_f = conversion factor, (i.e., 1 kPa = 0.00750 mHg), η = psychrometric constant, 0.06733 $kPa/^oC$, $f(u)$ = function depending speed, $f(u)$ = 0.35 (1.0 + 0.146 W_w), W_w = wind speed, km/hr, R_n = net radiation, $J/m^2/day$, R_g = ground surface thermal flux, $J/m^2/day$, and L_v = volumetric latent heat of vaporization, J/m^3.

Wilson-Fredlund-Barbour (1997) "Limiting Function" Model

Wilson et al., (1997) suggested that actual evaporation could be written as a "Limiting Function" between actual evaporation and potential evaporation (See Figure 4). This model assumed that the temperature at the soil surface was the same as the air temperature. Therefore, the vapor pressure (and relative humidity) at the ground surface was the same as the relative humidity in the air above the ground surface.

$$AE = PE\,\frac{u_v - u_v^{air}}{u_{v0} - u_v^{air}} \qquad [4]$$

where: u_v = actual vapour pressure at the soil surface, kPa; u_{v0} = saturated vapour pressure at the soil surface temperature, kPa; u_v^{air} = vapour pressure in the air above the soil surface, kPa. Calculations using the Wilson-Fredlund-Barbour (1997) "Limiting Function" model were essentially the same as those from the Wilson-Penman (1990) model. Once again, the model over-predicted actual evaporation for dry, coarse-grained soils in arid regions.

Wilson-Fredlund-Barbour-Penman (1997) "Experimental Function" Model

A series of drying tests were undertaken in the laboratory on thin layers of sand, silt and clay soils (i.e., about 1 mm thick). It was observed that all three soils with different grain sizes gave similar ratios between actual and potential evaporation as shown in Figure 5.

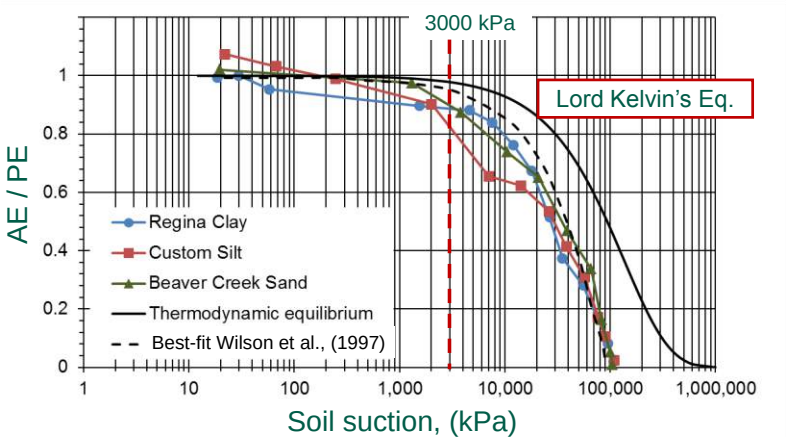

Figure 5 Ratio of actual evaporation to potential evaporation for thin soil layers (Wilson, 1990).

Also shown on Figure 5 is Lord Kelvin's equation. The laboratory data has a similar shape to the Lord Kelvin equation; however, it is translated to the left by approximately 70% of a log cycle. The dashed line in Figure 5 is the result of incorporating an empirical factor of 0.7 into Lord Kelvin's equation.

$$AE / PE = \exp\left(\frac{-\psi g \omega_v}{\zeta(1-h_a)\gamma_w R(T_s + 273.15)}\right) \qquad [5]$$

where: ζ = a dimensional empirical parameter with a suggested value of 0.7; h_a = relative humidity of overlying air; ψ = total suction (i.e., matric suction plus osmotic suction), kPa; ω_v = molecular

weight of water, 0.018 kg/mol; γ_w = unit weight of water, 9.807 kN/m^3; g = gravity acceleration, m/s^2; R = universal gas constant, 8.314 J/(mol.K); and T_s = soil surface temperature, ^{o}C. Equation [5] was based on, and is applicable for evaporation from thin soil layers. The air and soil temperatures were assumed to be the same.

Limitations of Evaporation Models Based on Thermodynamic Equilibrium at the Evaporating Surface

Numerous attempts have been made to apply Lord Kelvin thermodynamic equilibrium equation at the ground surface (McCumber and Pielke, 1981; Camillo et al., 1983; Wilson, 1990). However, attempts to apply thermodynamic equilibrium at ground surface failed to take into consideration the resistance to water movement at the soil-atmosphere interface. Researchers began to realize that Lord Kelvin equation was invalid close to the soil surface (Wetzel and Chang, 1987 Kondo et al., 1990 and Lee and Pielke, 1992).

Figure 6 compares relative evaporation, RE, and relative humidity to soil suction for a sand column test performed by Wilson (1990). The results show that RE dropped to approximately 40% at a suction of 20 kPa while the relative humidity began to reduce at soil suctions in excess of 3000 kPa. The results suggest that another physical mechanism is involved in evaporation near-ground-surface for drying of sand.

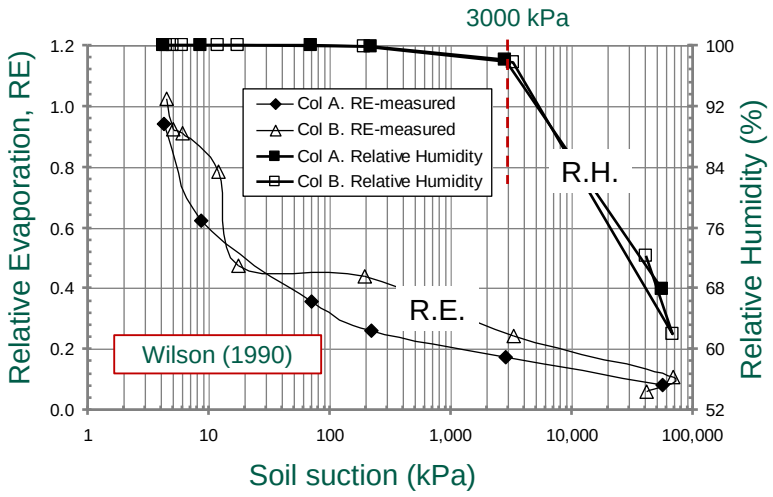

Figure 6 Measured relative evaporation, RE, and relative humidity, RH, from a sand column tested by Wilson (1990).

Similar results from a column evaporation test on sand have been presented by Bruch (1993) and Yanful and Choo (1997). The observed deficiencies in applying the thermodynamic equilibrium equation have led to the development of two types of models that attempt to take "surface resistance" into consideration.

Actual Evaporation Models that take Surface Resistance into Consideration

There are two main classes of models that provide a more reliable calculation of the relative humidity (or vapor pressure) at the soil surface. Both classes of models have been proposed to more accurately calculate actual evaporation from unsaturated and dry soil surfaces. For the first class of models, the relative humidity at ground surface is calculated through use of a modified thermodynamic relationship as suggested by numerous researchers (Alvenas and Jansson, 1997;

Bittelli et al., 2008; Fredlund et al., 2011; and recently Dunmola, 2012). A complete model has been formulated by Fredlund et al., (2012) and is referred to as the "total suction adjustment" approach. The corresponding model has been implemented in SVFux (2009) software from *SoilVision Systems.* The total suction at the soil surface depends on residual suction conditions defined by the drying soil-water characteristic curve, SWCC. The model is referred to as the Fredlund-Zhang-Fredlund method. Details of the method have been published in the SVFlux (2009) User's Manual and by Fredlund et al., (2012).

The second class of models utilizes an empirical method of modifying the relative humidity at the soil surface humidity based on the findings of several researchers (Kondo et al., 1990; Lee and Pielke, 1992; Tran, 2013). The formulation of the model is based on the original Penman-Monteith (1965) equation that incorporates the "canopy concept" associated with evaporation from vegetated surfaces. Tran (2013) formulated a model utilizing the concept of "surface resistance". The model is based on evaporation-rate reduction observed when drying soils near residual water content conditions. The procedure is referred to as the "vapor pressure adjustment" procedures.

The relationship between the "total suction adjustment" procedure and the "vapor pressure adjustment" procedure is illustrated in Figure 7. The evaporation of moisture near ground surface has been shown to be quite complex. As a result it is not possible to simply apply the thermodynamic equilibrium equation at the soil surface without applying an adjustment to either total suction or relative humidity.

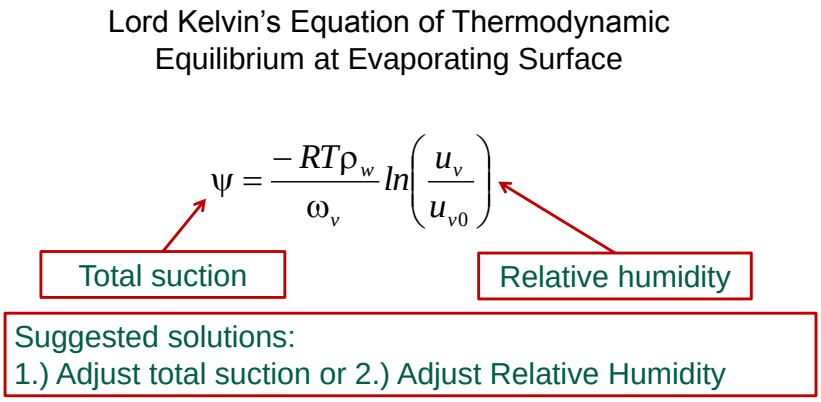

Figure 7 Relationship between adjustments applied to either total suction or relative humidity to accommodate "surface resistance".

There are two distinctly different classes of actual evaporation models that take the concept of "surface resistance" into consideration (See Figure 8). While the formulation of the two models is different, both models appear to capture the importance of significantly reduced evaporation rates from dry, coarse-grained soils. Column evaporation datasets have been used to show that both models provide reasonable predictions of actual evaporation under dry conditions (Fredlund et al, 2012; Tran, 2013).

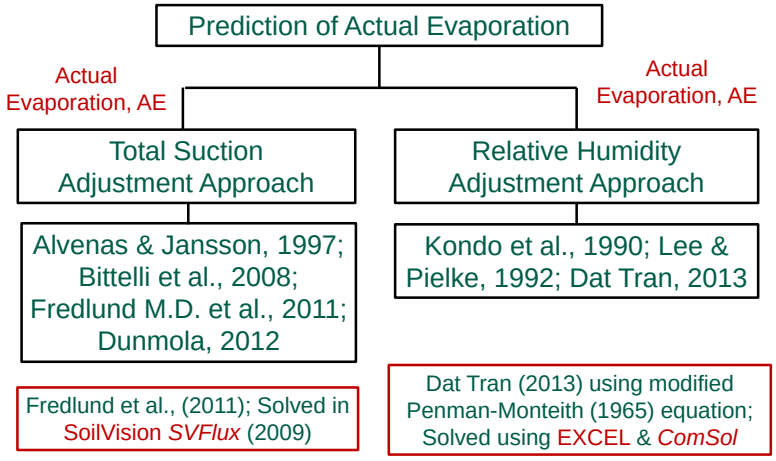

Figure 8 Classification of models taking the concept of "surface resistance" into consideration.

Definition of "Surface Resistance"

"Surface resistance" can be defined as the resistance to water vapor diffusion from near the soil surface (Aluwihare and Watanabe, 2003). The original usage of the term was in connection with evaporation from leaves and vegetated ground surfaces (i.e., the canopy effect) (Monteith, 1965). "Surface resistance" was illustrated by Aluwihare and Watanabe, (2003) and is reproduced in Figure 9.

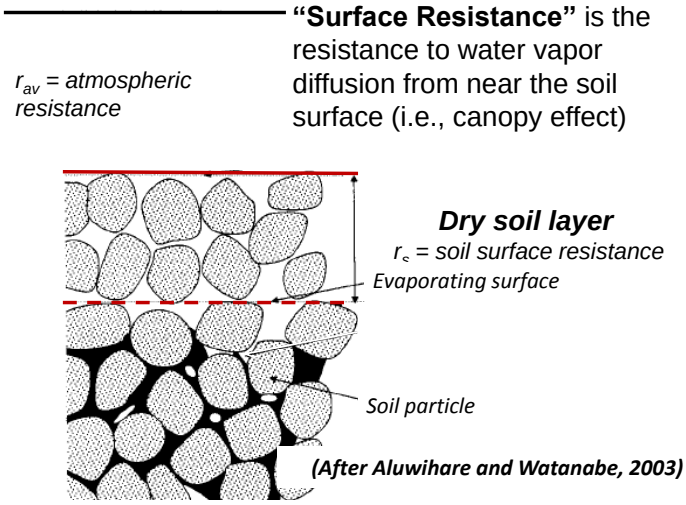

Figure 9 Illustration of "surface resistance" components (after Aluwihare and Watanabe, 2003).

Several researchers have attempted to quantify "surface resistance" and have written its magnitude in terms of the inverse of hydraulic conductivity (Fen Shu, 1982; Carmillo & Gurney, 1986; and van de Griend & Owe, 1994). Evaporation from a soil surface is based on molecular diffusion through a thin layer at the soil surface and turbulent diffusion in the air.

Fredlund-Zhang-Fredlund (2009) Formulation Using the "Total Suction Adjustment" Approach

Several researchers have attempted to adjust the total suction at the surface of a drying soil in order to more accurately simulate actual evaporation (Alvenas & Jansson, 1997; Bittelli et al., 2008; Fredlund, M.D. et al., 2011; Dunmola, 2012). The formulations take the form of a further modification to the Penman (1948) equation and makes use of an adjustment to total suction. The

formulation is called the "total suction adjustment" approach. Details of this approach were proposed by Fredlund, M.D. et al., (2011) and were also implemented into the SVFlux (2009) computer model (Fredlund et al., 2012). The equation for relative humidity can be used to describe the ratio between *AE*/*PE*; however, it is necessary to apply an adjustment factor, δ, to the total suction values as shown in equation [6]:

$$h_s = \exp\left(\frac{10^{\delta}\psi g \omega_v}{\gamma_w R(273.15+T_{soil})}\right) \quad [6]$$

where: δ = a dimensionless total suction adjustment factor generally varied from 0 to 3.

The Total Suction Adjustment Factor

The empirical total suction adjustment factor, (written in terms of negative pore-water pressures, u_{wa}), is shown in equation [7].

$$u_{wa} = u_{wo}10^{\delta} \quad [7]$$

where: u_{wa} = adjusted negative pore-water pressure, u_{wo} = original pore-water pressure from water phase partial differential equation, and δ = empirical adjustment factor. The adjustment of the negative pore-water pressure must be made when using the Wilson (1990) and Wilson et al., (1997) formulations for actual evaporation. An adjustment factor of 1.8 closely simulated the evaporation rate from columns of sand tested by Wilson (1990). The adjustment factor varies for different soils with the largest values being applicable for coarse-grained soils. The adjustment of the total suction applies for coupled and uncoupled solutions. The adjustment factor should remain equal to zero when evaporation is being computed from a saturated clay soil. The adjustment in the total suction attempts to simulate "surface resistance" near ground surface.

Figure 10 illustrate the rationale behind the calculation for the δ adjustment factor. The residual suction from the drying SWCC, is used as the reference point for calculating the δ adjustment factor. The empirical adjustment factor, in essence, translates the SWCC over to the 3000 kPa point on Lord Kelvin's curve. Typical values of the δ adjustment factor for various residual suction values are illustrated in Figure 11. The maximum δ adjustment factor for coarse sand soils is 3.48 while no adjustment is required for clayey soils with a high air-entry value.

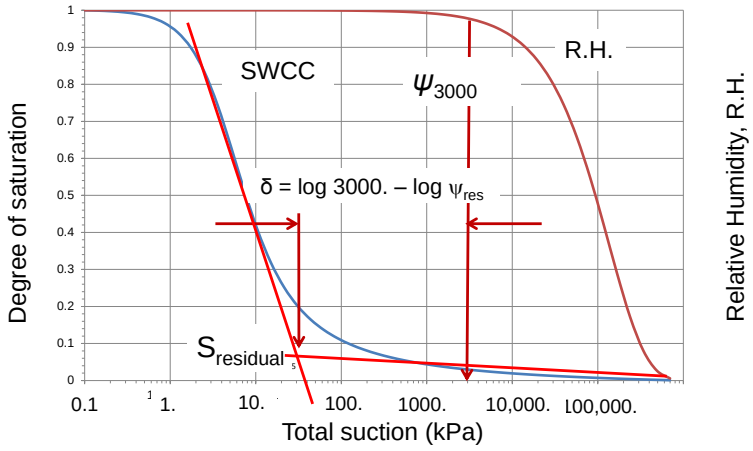

Figure 10 Illustration of the construction procedure to obtain the δ adjustment factor.

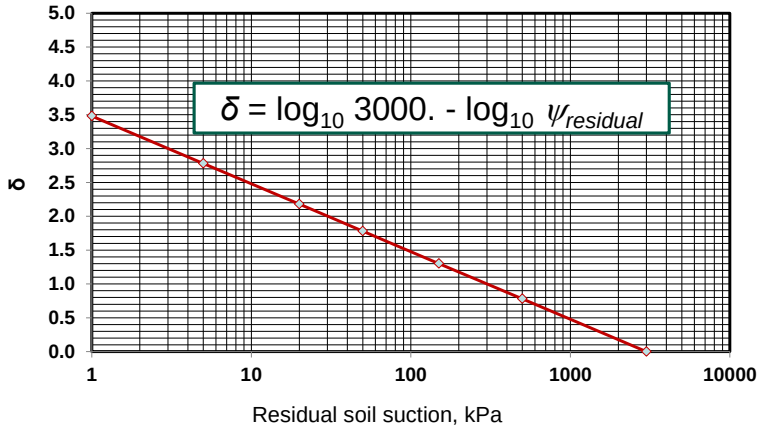

Figure 11 The δ adjustment factors for various residual suction values.

Fredlund-Zhang-Fredlund (2009) Model Calculations of Actual Evaporation from Sand Columns

Measurements by Wilson (1990) of evaporation from a sand soil column can be compared with numerical model calculations using the Fredlund-Zhang-Fredlund (2009) model in the SVFlux and SVHeat software (*SoilVision,* 2009). Both "coupled" and "uncoupled" solutions provided a reasonable simulation of actual evaporation from a sand soil. The numerical simulation results used a δ value of 1.8 and were published in Fredlund et al., (2011) and Tran et al., (2014). Space does not permit repeating the results of the simulation in this paper.

Tran (2013) Evaporation-Rate Reduction Model utilizing the Penman-Monteith (1965) equation

Several researchers have suggested the use of an empirical and indirect parameterization of the surface humidity (Kondo et al., 1990; Lee and Pielke, 1992; Tran, 2013). The complete formulation of the model is based on the Penman-Monteith (1965) model with "surface resistance".

Evaporation-Rate Reduction Point

A reduction in actual evaporation rate has been observed from the data collected on a series of soil columns tests in the research literature. The evaporation-rate starts to reduce from potential evaporation-rate when the suction is somewhere between the air-entry value and residual suction.

$$\psi_R = \begin{cases} \psi_{aev} & if \;\; a=0 \\ \psi_{res} & if \;\; a=1 \\ \psi_{res}^{a} \times \psi_{aev}^{1-a} & if \;\; 0<a<1 \end{cases} \quad \textbf{[8]}$$

where: ψ_R = suction at evaporation-rate reduction point, kPa; ψ_{aev} = air-entry value based on the SWCC, kPa; ψ_{res} = residual suction from the SWCC, kPa; a = an empirical factor which varies between 0 and 1. Published results show that the best-fit value of "a" for sand and silt are 0.60 and 0.75, respectively.

Proposed Methods for Predicting Relative Humidity

Predicting the relative humidity at the soil surface is required in the evaporation model. Lee and Pielke (1992) used the soil moisture availability term, β, to designate the evaporation-rate reduction point, θ_R.

$$\beta = \begin{cases} \frac{1}{4}\left[1-\cos\left(\frac{\theta}{\theta_R}\pi\right)\right]^2 & \theta < \theta_R \\ 1 & \theta \geq \theta_R \end{cases} \quad [9]$$

where: β = coefficient representing the surface moisture availability; θ_R = volumetric water content at evaporation-rate reduction point; θ = soil volumetric water content of the top soil layer.

The actual water vapour pressure can be computed from the soil moisture availability factor.

$$u_v = \beta \times u_v^{sat} + (1-\beta) \times u_v^{air} \quad [10]$$

where: u_v = actual vapor pressure at the soil surface, kPa; u_v^{sat} = saturated vapor pressure at the soil surface, kPa; u_v^{air} = actual air pressure immediately above the soil surface, kPa.

Calculation of Soil Surface Resistance

Several researchers introduced equations to estimate "surface resistance" including Fen Shu (1982), Camillo and Gurney (1986) and van de Griend and Owe (1994). Soil surface resistance varies from zero at the wet soil surface to several thousand at the dry soil surface. The van de Griend and Owe's (1994) equation for soil surface resistance is shown and is written as follows:

$$r_s = 10 \times e^{0.3563(\theta_{\min} - \theta_{top})} \quad [11]$$

where: r_s = soil surface resistance at top 0 – 1 cm, s/m; q_{top} = volumetric water content of the top 1 cm layer, (%); q_{min} = an empirical minimum above which the soil is able to deliver vapor at a potential rate, (%). The original model sets q_{min} = 15% as a fixed value for all soils.

Tran's (2013) Modified Penman-Monteith (1965) Equation

The Penman-Monteith's equation, (i.e., combination of energy balance and mass balance) was used to derive a soil-atmospheric equation that considers the effect of "surface resistance" on actual evaporation.

$$AE = \frac{\Gamma Q + \eta \dfrac{f'(u)}{f(u)} E_a}{\Gamma + \eta A \dfrac{f'(u)}{f(u)}} \qquad [12]$$

where: AE = transpiration rate from a soil, mm/day; E'_a = aerodynamic evaporative term, $E'_a = f(u)(u_{ao} - u_a)$, mm/day/Pa; Q_n = heat budget, mm/day; u_{ao} = saturation vapor pressure of the mean air temperature, kPa; u_a = vapor pressure of the air above the surface, kPa; $f(u)$ and $f'(u)$= the transmission functions for mass and heat, respectively. Further details related to the transmission functions, $f(u)$ and $f'(u)$, can be found in Tran (2013).

Ability of the Tran (2013) Model to Simulate Actual Evaporation from Sand Soils

Soil column drying tests for the Beaver Creek sand (Wilson, 1990) and Processed Silt (Bruch, 1993), were re-analyzed using the Tran (2013) model. The actual evaporation rate obtained using the numerical model (i.e., using ComSol Metaphysics software and Excel); along with measured water contents and temperatures at the soil surface showed close agreement was observed between all the laboratory results and the computed results. Comparisons between the numerical model results and laboratory test results can be found in Tran (2013) and Tran et al., (2014).

The proposed soil-atmosphere flux equation describing evaporation from a soil surface takes into consideration net radiation, wind speed, relative humidity of the air and soil surface, and "soil surface resistance". The evaporation rate is shown to decrease during the drying process mainly as a result of an increase in soil surface resistance.

Concluding Remarks on Modeling Actual Evaporation

Two approaches were examined that attempted to incorporate "surface resistance" into the formulation of the models. One approach was referred to as the "total suction adjustment" approach and the other was referred to as the "relative humidity adjustment" approach. The application of the modified actual evaporation models have been compared to measured evaporation rates from several sand column tests. The comparative simulations showed that both the total suction adjustment approach and the relative humidity adjustment approach produced greatly improve the simulation of actual evaporation.

ABSTRACT

The near-surface water balance of mine impacted landscapes is a key control on re-vegetation performance, and on the hydrologic and water quality impact at the watershed scale. As part of Teck Resources Limited's applied research and development program focused on managing water quality in mine-affected watersheds, 12 sites in western Canada (southeastern British Columbia and western Alberta) representing a range of waste rock dump reclamation surface management options (i.e. soil cover, surficial mounding) were instrumented in 2012 to measure meteorological and soil water response and to quantify the near-surface water balances with a focal objective to improve estimates of ranges of net percolation into waste rock dumps under a range of scenarios.

Subsurface water and meteorological conditions varied substantially, as expected for the range of elevation, slope aspects, vegetation, soil covers, geographic location and surface preparation of the selected sites. Patterns in water balance trends emerged in the first year of analysis with net percolation (NP) into underlying waste rock typically decreasing for increased vegetation and soil cover, as well as for decreases in rainfall or snowmelt. Increased vegetation cover resulted in a greater volume of water removed from near-surface through evapotranspiration. The lowest NP (as % of water input) was estimated for a mature, reclaimed conifer forest site and a dense agronomic grass/alfalfa covered site. Net percolation estimated for a soil covered waste rock slope was approximately 15% (of water inputs) less than an adjacent bare waste rock slope. Decreased NP was partly attributed to greater water storage in the finer-textured soil cover. Net percolation through the soil cover is expected to further decrease with time as vegetation establishes relative to the bare waste rock slope. Net percolation for a mounded, bare waste rock slope was less than estimated for an adjacent smooth slope. Net percolation below a trough was similar to the smooth slope, but decreased at the crest and mounded mid-slope positions due to thinner snowpack (less snowmelt) from wind scouring. Additional monitoring and analysis of site-specific water balances will help define the shift in the relative proportions of water entering the deposits as vegetation matures.

INTRODUCTION

Mining activities undertaken by Teck Resources Limited (Teck) to access the metallurgical coal resource in the Elk Valley of southeastern British Columbia and in northwestern Alberta result in waste rock dumps with material susceptible to long term weathering and erosion processes. The waste rock is known to increase concentrations of some constituents of interest (CIs) in downstream surface water and groundwater systems. Post-depositional weathering of the waste rock is accelerated by oxygen ingress and weathering products can be transported with infiltrating water. These two processes are both controlled by the degree of saturation of the unsaturated waste rock.

The amount of water that infiltrates into waste rock landforms is a function of the near-surface water balance. This surface water balance is a key control on vegetation establishment and its long term performance and will affect the hydrology, hydrogeology and geochemistry of affected watersheds. For example, selenium (Se) concentrations in mine-affected rivers are reported to have increased over the last three decades (Lussier, Veiga & Baldwin, 2003; Chapman, Berdusco & Jones, 2007) and the understanding of Se release and transport from waste rock dumps is still developing. Research has indicated that Se is more readily transported in the soluble form of selenate suggesting a strong link to water movement (Chapman, Berdusco & Jones, 2007).

Controls on the movement of water through and out of waste rock dumps include the volume, rate, and flow path of net percolation (NP) waters. The term 'net percolation' is defined as water that migrates into and downward in the material profile to depths not influenced by atmospheric processes (i.e. evapotranspiration). This water may eventually be released from waste rock to adjacent groundwater or surface water. Important aspects of NP include:

- Volume: NP volumes are a primary control on water volumes reporting as basal and toe seepage from waste rock dumps and have important implications for mine-affected watershed water balances and water management strategies. NP volumes may be an important control on solute loadings in basal and toe seepage;
- Rate: The flow velocity of NP through mine wastes, as well as the height of the waste deposit, will control the residence time of pore-water in the waste rock profile. Residence time may be an important consideration on the dissolution of CIs; and
- Flow Path: Water may move via preferential pathways (i.e. macro-pore flow) or via matrix flow, which is more distributed. Preferential flow through waste rock will decrease the surface area contacted by NP and residence time of NP in waste rock dumps, which are opposite to the trends for matrix dominated flow. Preferential flow paths will increase the time required to flush CIs from a waste rock dump compared to matrix dominated flow as NP following preferential flow paths bypasses and does not flush oxidation products from all of the waste rock.

As part of Teck's applied research and development program focused on managing water quality in mine-affected watersheds, 12 sites representing different waste rock dump reclamation surface management options were instrumented in 2012 to measure meteorological and soil water dynamics. Data from these sites was used to quantify the near-surface water balances with a focal objective to improve estimates of ranges of NP into waste rock dumps for a variety of conditions.

METHODOLOGY

The study sites are located at four coal mining operations in the Elk Valley, BC and one in northwestern Alberta: Line Creek (LC); Greenhills (GH); Elkview (EV); Fording River (FR); and Cardinal River (CR; Figure 1). The climate at all of the study sites is humid continental. Climate normals data (1981-2010, Environment Canada, Sparwood station at 1140 m asl) indicate the Elk Valley mines are located in a region with mean annual precipitation of 613 mm (411 mm as rainfall, 202 mm as snow). Mean annual precipitation from climate normals data (1981 – 2010, Environment Canada, Jasper East Gate at 1003 m asl) for the Cardinal River area is 599 mm (448 as rainfall, 151 mm as snow). The study sites monitoring instruments were commissioned in the summer and fall of 2012 and have been collecting data since. This paper reports on data for each site over one hydrologic year starting October 1st, 2012 through September 30th, 2013. A large rainfall event in the Elk Valley from June 18th – 21st, 2013 largely influenced the amount of precipitation observed in the first year of monitoring as this event resulted in 81% more rain in June than the monthly climate normal for that month.

General Site Descriptions

The study sites were chosen to investigate the effect of elevation, surface soil placement, re-vegetation types, site orientation (slope/aspect) and microtopography on the near-surface water balance (Table 1). The study site locations include two instrumented sites at Greenhills Operation North Thompson mine area that are part of a paired cover trial with a uniform sloped soil cover (GH_NTC) and bare waste rock (GH_NTW) slope. A soil cover was also placed on the Turn Creek dump (FR_TCR) at Fording River Operation. Three sites (LC_BHE, LC_RHE and LC_RME) were installed on benched plateaus of the West Line Creek dump at the Line Creek Operation at different elevations and with varying degrees of vegetation cover. A reclaimed mature forest site (FR_CSP) at the Fording River Operation provided an optimal scenario to understand the effect of mature tree re-vegetation on near-surface water retention and net percolation. Data collected on a south-facing, vegetated slope of the Bodie Dump (EV_BRD) at the Elkview Operation allow quantification of the effect of a thick grass-legume vegetation cover and slope aspect. Similarly, instruments installed at the Cardinal River Operation north-facing (CR_B5D) and south-facing (CR_B4D) slopes were used to observe differences due to aspect and soil placement. The sloped surface in the Greenhills Rosebowl mine area (GH_RMS) and Cardinal River Cheviot area (CR_CMS) have been prepared using a mounding technique creating crests, mid-slopes and troughs, which help evaluate the effect of mounding on re-vegetation success and overall NP rates.

Performance Monitoring Instrumentation

All sites were instrumented with both soil profile monitoring (suction, temperature and water content) and meteorological stations with the exception of CR_B4D, which was installed with only a net radiation sensor. Components of a soil monitoring station included one primary *in situ* water content monitoring station consisting of eight thermal conductivity (pore-water suction) and eight time-domain reflectometry (TDR, water content) sensors, and four secondary *in situ* water content monitoring stations, each consisting of four TDR sensors. Meteorological stations measured rainfall (CS700 Tipping Bucket Rain Gauge), air temperature and relative humidity (HC2-S3 Probe), wind speed/direction (R.M. Young Model 05103AP-10 Wind Monitor), net radiation (Net Radiation Kipp & Zonen model NR-LITE2 Net Radiometer), and snow depth (Sonic Ranger 50A). Eddy covariance stations were installed at LC_RHE, LC_BHE, FR_CSP, and GH_NTW, and included a gas analyzer

(either LICOR Li-7200 closed-path for forest and grasses, or a Li-7700 open-path CO_2/H_2O analyzers for bare waste rock), an ultrasonic anemometer (Windmaster, Gill Instruments), an air temperature and relative humidity sensor (HMP45 sensor, Vaisala), and a net radiometer (CNR4, Kipp & Zonen). Nine Gee lysimeters were installed under the trough, crest, and slope areas of the GH_RMS study to directly measure net percolation rates. Lastly, 24 sap flow sensors were installed in 12 trees at FR_CSP to measure sap flow velocity and estimate water uptake rates by each tree.

*Substrate for all sites was waste rock.

Water Balance Analysis

Water balances were developed for each site over one hydrologic year starting October 1st, 2012 through September 30th, 2013. For these snow-dominated sites, water input was defined as the sum of rainfall minus rainfall interception, plus snowmelt (hereafter referred to as effective precipitation, P_{eff}). The following components of the water balance were measured or estimated to calculate daily changes in storage (ΔS) in the top ~1 m of material at the primary station profiles:

$$\Delta S = R + M - AE(T) - RO - NP \quad (1)$$

where: R is rainfall, M is snowmelt, $AE(T)$ is actual evaporation or evapotranspiration where appropriate, RO is surface runoff, and NP is net percolation (all units are mm d^{-1}). Runoff at all sites was assumed to be zero as a result of the high hydraulic conductivity of the waste rock and cover soils.

Precipitation

Rainfall (volume and intensity) was measured with a tipping bucket rain gauge (TBRG, Campbell Scientific 700). Precipitation was verified by comparing multiple TBRG records at sites with similar elevation, the precipitation record from the Sparwood, BC climate station (1140 masl, Environment Canada) and other total precipitation gauges operated by McMaster University and Teck. Precipitation was assumed to be rain if the mean daily air temperature was greater than 2°C.

Daily average snow depth was measured continuously using an automated Sonic Ranger 50A (SR50) sensor. Snow surveys completed at the end of March 2013 provided snow depth and density data to calculate a transect-average snow-water equivalent (SWE) across each site. A continuous record of snowpack SWE was estimated with snow density equations (Bartlett, MacKay & Verseghy, 2006).

Melt

Point-based daily snow ablation amounts for each site were estimated using the energy balance equation and daily averages of meteorological data using the approach reported by Dingman (2002) and Burles & Boon (2011). The energy fluxes from ground heat flux and rain were assumed to be zero. Sensible heat was calculated as a function of measured wind speed and air temperature. Sublimation and evaporation were accounted for by the latent heat term which was a function of the vapour pressure gradient between the air and snow surface. The melt period was initialized with peak SWE and run to complete snowpack removal. The SR50 snow depth record in combination with field observations (including time-lapse photos) were used to determine the timing of snowpack disappearance.

Evapotranspiration

Potential evaporation was estimated using the Penman (1948) or Penman-Monteith combination method (Monteith, 1965) for sites with well-established vegetation. Canopy conductance (C_{can}) was estimated using leaf area index data collected in 2013 (Integral Ecology, 2013). A relationship

between evapotranspiration (E(T)) and soil water deficits was used to relate potential evapotranspiration (PE(T)) to actual E(T) via the following equations:

$$AE(T) = PE(T) \cdot Available\ Water\ Ratio \quad (2a)$$

$$Available\ Water\ Ratio = (VWC - WP)/(FC - WP) \quad (2b)$$

where: VWC is the volumetric water content of the surficial soil profile (average of top 15 to 30 cm depending on vegetation and expected depth range accessible to evapotranspiration), WP is the wilting point and FC is the field capacity. WP and FC are defined as the volumetric water contents at 1500 and 10 kPa of suction, respectively. The available water ratio approached 1 at FC and declined as the availability of water decreased to the WP for plants (available water ratio = 0). Eddy covariance estimates of AE(T) were found to positively correlate with measured leaf area index (LAI) (Integral Ecology, 2013); therefore, AE(T) estimates calculated using Eq. 3a and 3b were constrained using the developed LAI-AE(T) relationship for conditions ranging from bare to vegetated ground.

Interception

Rainfall intercepted was assumed to be evaporated daily and estimated using a modified version of the forest rainfall interception model in Rutter and Morton (1977). Daily maximum rainfall interception was set equal to the canopy storage capacity for conifers (1 mm; Schmidt & Gluns, 1991). Intercepted snowfall in the trees at Fording River C-spoil was not considered during the first year of analysis due to the complexity in quantifying this process and scope of the study.

Storage

Changes in water storage (ΔS) through the soil profile were calculated using the volumetric water content (CS616 Time Domain Reflectometry Sensors) measured at the primary monitoring station. The volume of water was weighted for sensor depth and summed over the entire profile.

Net Percolation

It was assumed that NP occurred when there was a downward vertical hydraulic gradient as calculated from the soil suction values between 75 and 100 cm depth and if there was a net loss in storage within the bottom half of the instrumented profile. For this case, NP was assumed to be equal to the net loss in storage from the bottom half of the profile, as it was assumed AE(T) fluxes would not affect water storage at that depth. This assumption was supported by matric suction depth profiles (not presented) which exhibited the greatest changes with time and occurrence of upward gradients in the upper 50 cm.

If the water storage capacity of the bottom soil profile exceeded the field capacity (FC; 10 kPa of suction) during snowmelt infiltration or rainfall events, then NP was estimated via the water balance in Eq. 1. This NP estimation method was used during snowmelt infiltration and rainfall events as there was often a surplus of water during melt and rainfall events if the gradient / storage method for calculating NP described above was used. It was assumed that seepage rates could be near steady-state during melt and rainfall events and that NP could be occurring even if there was not a measured decrease in storage.

Analytical Model Calibration

Water retention curves (WRC) were developed using the water content and suction monitoring data. These were then used to estimate values of FC and WP. Water retention curves, however, are difficult to develop for heterogeneous, coarse-textured materials. Estimates of AE(T) were most sensitive to FC and WP parameters; therefore, sensitivity of water balance estimates were assessed by varying the FC and WP values ± 2 to 10%. Measured water content and the match of measured and calculated water storage was used to inform FC and WP estimates and constrain AE(T) values. Assuming no runoff, water input that was not removed by AE(T) was then assumed to eventually report to NP.

RESULTS AND DISCUSSION

The soil water contents and meteorological conditions were variable, which was expected given the range of elevation, slope aspects, vegetation, soil covers, geographic location and surface preparation of the selected sites. Meteorological conditions at the various sites were similar but with key differences that can be attributed to elevation, geographic location, and slope aspect. Precipitation increased with increasing elevation. LC_BHE, the highest elevation site (2,150 m asl) had the greatest measured total annual precipitation (1,210 mm). For sites in the 1,500 to 1,800 m asl elevation range, total annual precipitation ranged from approximately 800 to 950 mm. Sites located at the Cardinal River Operation were greatly influenced by the dry, warm winds blowing down the eastern slopes of the Rocky mountains. Data records indicate snowpack disappearance occurred earlier on the south-facing CR_B4D slope compared to north-facing B5D likely due to higher solar energy input received on the south-facing slope. Earlier snowmelt and snowpack disappearance was also observed on other south-facing slopes including EV_BRD and CR_CMS.

Patterns in water balance trends emerged in the first year of analysis with NP into underlying waste rock typically decreasing for increased vegetation and soil cover, as well as for decreases in rainfall or snowmelt. The highest NP occurred at LC_BHE due to greater P_{eff}, low AE(T), and less water holding capacity in the coarse waste rock compared to other monitored sites (Table 2). Increased vegetation cover resulted in a greater volume of water removed from the near-surface through AE(T), that would have otherwise resulted in NP. For example, the lowest NP (as % P_{eff}) calculated was for the mature, reclaimed conifer forest site (FR_CSP) and the dense agronomic grass/alfalfa covered site (EV_BRD). Lower NP at EV_BRD compared to FR_CSP was attributed to a higher water holding capacity in the material underlying the thick grass cover combined with lower P_{eff} on a south-facing slope. As the individual site cover systems evolve, vegetation communities mature, and water balance trends become more apparent the mechanisms having the largest impact on controlling net percolation through waste rock dumps and achieving re-vegetation objectives can be identified, quantified and evaluated as potential watershed management tools.

Net percolation estimated for a soil covered, waste rock slope (GH_NTC) was approximately 15% (of P_{eff}) less than an adjacent bare waste rock slope (GH_NTW). Research has shown that cover systems have the potential to limit infiltrating water (i.e. NP) through a waste rock dump (MEND, 2012). Water storage in the shallow subsurface was greater in the finer-texture soil cover at GH_NTC compared to GH_NTW (Figure 2). NP through the soil cover is expected to further decrease in future years as vegetation establishes, thus more available soil water will be removed through AE(T) (Integral Ecology, 2012).

The water balances for the covered sites at FR_TCR and GH_NTC, and the mature forest site at FR_CSP, were analyzed over a shorter period than other sites as data was not available until later in the fall. NP estimates (as a % of P_{eff}) are likely slightly over-estimated for these sites as heavy rainfall in early October prior to the first day of the water balance estimations were not included in the P_{eff} values but may have been contributing to NP during the analysis period.

The weighted net percolation for a mounded, bare waste rock slope (GH_RMS), considering the overall effect of troughs and crests, was lower than that calculated for an adjacent smooth slope (GH_NTW) (Table 2). Net percolation estimates at the GH_RMS were corroborated by direct measurement of NP by lysimeters. Net percolation in a trough at GH_RMS was similar to the smooth slope at GH_NTW, but decreased at the crest and mounded mid-slope positions due to thinner snowpack (less snowmelt) from wind redistribution. Increased water availability in the troughs, as well as wind and sun shading, are expected to increase vegetation productivity over time in the troughs relative to the crests which will increase AE(T) and further decrease NP at GH_RMS.

CONCLUSION

Patterns in near-surface water balances have begun to emerge in the first year of monitoring of a range of waste rock dump reclamation surface management options. Net percolation as estimated from data collected from field moisture and climate instruments decreased with increasing vegetation cover and the addition of a surficial soil cover. Overall NP at a mounded waste rock site was estimated to be less than for an adjacent smooth waste rock slope. The effect of mounding on NP should be considered on a site-specific basis, however, as differences in precipitation, depth of troughs, slope aspect and prevailing wind direction will influence the results.

Table 2 Cumulative annual water balance fluxes for all 12 study sites. All fluxes are presented in millimeters. Net percolation values are presented as a percentage of effective water inputs (rainfall plus snowmelt).

Water Balance Modeling of Preferential Flow in Waste Rock Materials

2. *Barrick Gold Corporation, USA*

ABSTRACT

For waste rock with a high percentage of gravel particles the spatial distribution of the gravel particles can create macropores and discontinuity in the pore-size distribution. Consequently, many studies have shown that preferential flow may dominate unsaturated flow conditions in waste rock in some cases and that two or more functions may be needed to describe the unsaturated flow in waste rock materials. Most unsaturated flow models use the Richards' equation to predict unsaturated flow behavior in soil matrix, and cannot simulate preferential flow through macropores. Alternatively, MACRO 5.1, a dual-permeability model, uses a kinematic wave equation to describe water flow in macropores, while the Richards' equation is used for water flow in micropores (soil matrix).

In order to simulate the potential for preferential flow, MACRO 5.1 was used to predict unsaturated flow behavior in a planned waste rock facility at a proposed mine in northwestern Pakistan. The site is extremely dry with a ratio of annual potential evaporation (3900 mm) to precipitation (32 mm) of 120. For this kind of climate region, if a model only involves matrix flow mechanism and neglects preferential flow, it would project unrealistic no deep percolation. The influence of waste rock dump geometry (area and thickness) on predicted percolation volumes exiting the base of the dump were also evaluated to predict wetting front arrival times and percolation rates.

The modeling results demonstrate that the large evaporative demand results in minimal deep percolation and a long delay from the time of waste rock dump placement to the beginning of outflow from the dump. For the higher dump, outflow from the dump is predicted to begin 204 years after dump placement and reach a maximum outflow rate 612 years after placement. Outflow from the lower dump is predicted to begin 82 years after dump placement and attain its maximum outflow rate 490 years after placement.

Keywords: Unsaturated flow, waste rock, macropore, dual-permeability model, kinematic wave equation

INTRODUCTION

For waste rock with a high percentage of gravel particles the spatial distribution of the gravel particles can create macropores and discontinuity in the pore-size distribution (Milczarek et al., 2006; Al-Yahyai et al., 2006; Poulsen, 2002). Therefore, the moisture retention characteristic relationship between water content and soil water pressure potential and relationship between unsaturated hydraulic conductivity and water content (K(θ)) or soil water potential (K(ψ)) may require two or more functions to describe the unsaturated hydraulic properties for the entire pore-size distribution.

Most unsaturated flow models use the Richards' equation to predict unsaturated flow behavior, such as HYDRUS (Simunek et al., 1998), UNSAT-H (Fayer, 2000), SWIM (Verburg et al., 1996), and VADOSE/W (GEO-SLOPE International Limited, 2002). However, for gravelly materials the existence of macropores can lead to macropore flow (preferential flow), which cannot be simulated by the Richards' equation. For arid climates that experience periodic high intensity precipitation events, neglecting preferential flow may result in large under predictions of deep percolation. For porous media containing macropores, Larsbo et al. (2005) proposed a dual-permeability model (MACRO 5.1), where a kinematic wave equation (Germann, 1985) is employed to describe the water flow in macro-pores, while the Richards' equation is used for the water flow in micropores (soil matrix).

In order to account for macropore flow in a proposed waste rock facility in arid northwestern Pakistan, the one-dimensional dual-permeability model MACRO 5.1 was used to predict unsaturated flow behavior in the unvegetated waste material. The simulations predicted wetting front arrival and deep percolation rates under conditions which account for evaporation and surface run-off. The influence of waste rock dump geometry (area and thickness) on predicted percolation volumes exiting the base of the dump were evaluated using the MACRO 5.1 model predicted wetting front arrival times and percolation rates.

METHODOLOGY

Model

MACRO 5.1 is a dual-permeability model, separating the total porosity into two separate flow components, micropores and macropores. Each flow domain is characterized by a degree of saturation, conductivity, and water flow rate. The two domain model describing water flow requires modifications to the traditional van Genuchten (1980) moisture retention curve (MRC) function. The modified van Genuchten MRC function of the soil matrix (micropores) is described by (Larsbo et al., 2005):

$$S = \frac{\theta_{mi} - \theta_r}{\theta_s^* - \theta_r} = (1 + |\alpha_{vg}\psi|^{n_{vg}})^{-m_{vg}} \qquad (1)$$

where S is the effective soil water saturation. This equation assumes a fictitious saturated water content (θ_s*), which is defined in place of the saturated water content (θ_s), where $\theta_s^* \leq \theta_s$. θ_{mi} is the micropore water content and the remaining parameters are the same as that in the standard van

Genuchten equation; θ_r is the residual water content and α_{vg}, n_{vg}, and m_{vg} are fitting parameters related to pore-size distribution of the material (where m_{vg} is set equal to 1 - 1/n_{vg}).

The modified van Genuchten-Mualem equation utilized in MACRO 5.1 is in the form (Larsbo et al., 2005):

$$K_{mi} = K_b \left(\frac{S}{S_{(\theta b)}}\right)^l \left\{ \frac{1-(1-S^{1/m_{vg}})^{m_{vg}}}{1-(1-S_{(\theta_b)}{}^{1/m_{vg}})^{m_{vg}}} \right\}^2, \ \theta \le \theta_b \qquad (2)$$

where K_{mi} is the unsaturated hydraulic conductivity in the soil matrix, l is the tortuosity factor (assumed to be equal to 0.5 (Mualem, 1976)), $S_{(\theta b)}$ is the effective water saturation at the break point between macro- and microporosity (θ_b), and K_b is the hydraulic conductivity at θ_b (K_b = saturated hydraulic conductivity for soil matrix). The other parameters are the same as in equation 1.

Larsbo et al. (2005) define the hydraulic conductivity function for the macropores (K_{ma}) as a simple power law of the macropore degree of saturation (S_{ma}):

$$K_{ma} = K_{s(ma)} S_{ma}{}^{n^*} = (K_s - K_b) S_{ma}{}^{n^*}, \ \theta > \theta_b \qquad (3)$$

where $K_{s(ma)}$ is the saturated hydraulic conductivity of the macropores, n^* is a "kinematic" exponent reflecting macropore size distribution and tortuosity, and K_s is the total saturated hydraulic conductivity.

Model Domain

The total depth of the domain was 8 m, conservatively below the "zero flux plane", which is an imaginary plane above which water can move upward due to evaporation but below which water moves downward only. Node spacing near the surface was made smaller (e.g. 0.3 cm) to facilitate an accurate solution under conditions of large and rapid changes of soil water pressure potential in response to evaporation and precipitation. Node spacing at other depths were set to be progressively larger (e.g. 0.4 to 4 cm) to reduce model run time.

Hydraulic Properties

Average waste rock material hydraulic parameters were developed from a database of waste rock material saturated hydraulic conductivity and moisture retention data compiled by GeoSystems Analysis, Inc (GSA). The materials were chosen to represent coarse, high permeability material in order to provide a conservative estimate of percolation. Geometric mean K_s and van Genuchten (1980) hydraulic properties used for the simulation are provided in Table 1.

The soil water pressure potential at which macropores and the soil matrix partition (ψ_b) varies in the literature. Schaap (2005) suggested $0 > \psi_b \ge -4$ cm, while Jarvis (2007) reported the range $-6 \ge \psi_b \ge -10$ cm based on his literature review. At matric potentials above the partition point (less negative), K(θ) can increase by up to several orders of magnitude (e.g., Poulsen et al., 2002). To error on the side of greater macropore flow, a conservative ψ_b of -10 cm was assigned.

The hydraulic parameters needed to describe micro- and macropore flows as defined in equations 1 through 3 are presented in Table 1. K_b (soil matrix saturated hydraulic conductivity) applied in equation 2 and the kinematic exponent (n*) listed in equation 3 were established from previous work in which equations 1 through 3 were fit to moisture retention and unsaturated hydraulic

conductivity measurements made on two waste rock samples (Keller et al., 2009). Based on the similarity of the fine earth fraction (<4.75 mm) for the Keller et al. (2009) sample and the database samples, K_b was assigned as the estimated unsaturated hydraulic conductivity of the Keller et al. (2009) sample at -10 cm (1.06×10^{-4} cm/sec) and n* was set equal to 2.4, the average of the Keller et al. (2009) measured values of 2.0 and 2.8. The modified van Genuchten soil water retention function and hydraulic conductivity function used in the simulations are presented on Figure 1.

Table 1 Waste rock material van Genuchten parameters

K_s (cm/sec)	α (cm^{-1})	n (-)	θ_r (cm^3/cm^3)	θ_s (cm^3/cm^3)	Ψ_b (-cm)	θ_b (cm^3/cm^3)	K_b (cm/sec)	n* (-)
4.50×10^{-2}	0.131	1.911	0.048	0.315	10	0.215	1.06×10^{-4}	2.4

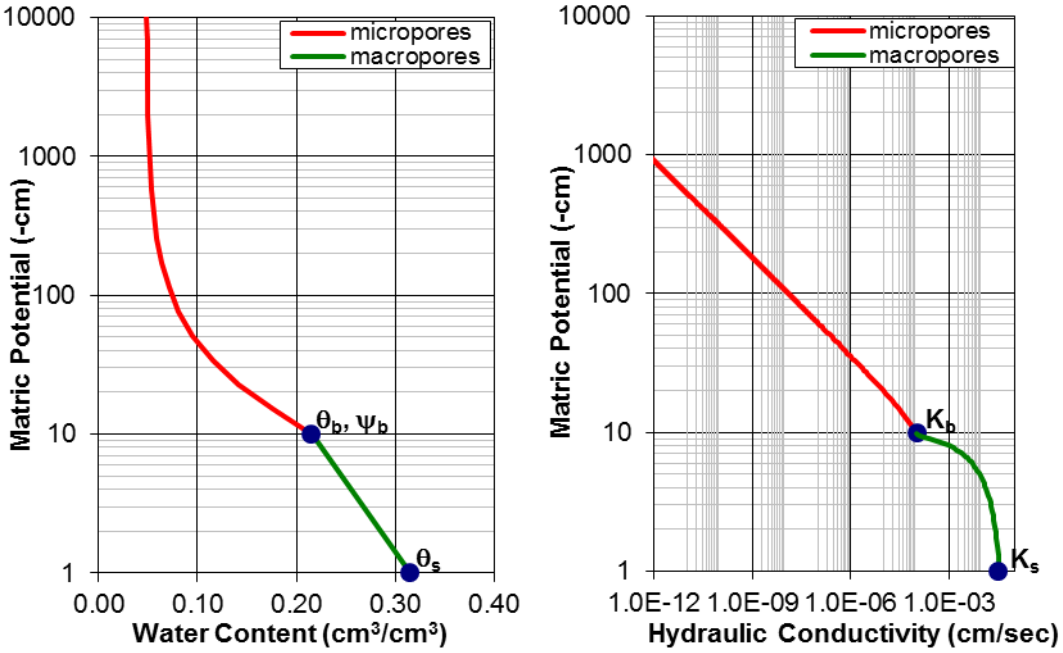

Figure 1 van Genuchten soil water retention function (left) and hydraulic conductivity function (right)

Climate Data

Synthetic daily 100-year precipitation data for the project site developed from historical climate records was used as the precipitation data input for the simulation. For the synthetic 100-year dataset, the maximum daily rainfall was 72 mm and the maximum annual rainfall was 192 mm. Hourly rainfall data was generated from daily rainfall data by assigning rainfall durations from one to twenty-four hours for each day and dividing the daily rainfall amount by the assigned rainfall duration. Rainfall durations were assigned using a random generator with the assumption of an even distribution of rainfall durations. Hourly rainfall intensities ranged from a high of 15 mm to less than 1 mm, with the majority of hourly rainfall intensities being less than 1 mm. This range of rainfall intensities is similar to measured rainfall intensities, which ranged from 29.3 mm/hr to 0.9

mm/hr for rainfall durations of 1 to 24 hours and reoccurrence intervals of 5 to 1000 years. The calculated hourly rainfall for each day was applied beginning at the first hour of the day and applied at each subsequent hour until the daily rainfall amount was satisfied.

Average daily temperature (maximum and minimum) and potential evapotranspiration (PET) required as model input were derived from a 3.25 year temperature and PET data record collected at the project site weather station. The applied sinusoidal annual temperature and PET relationships are shown on Figure 2.

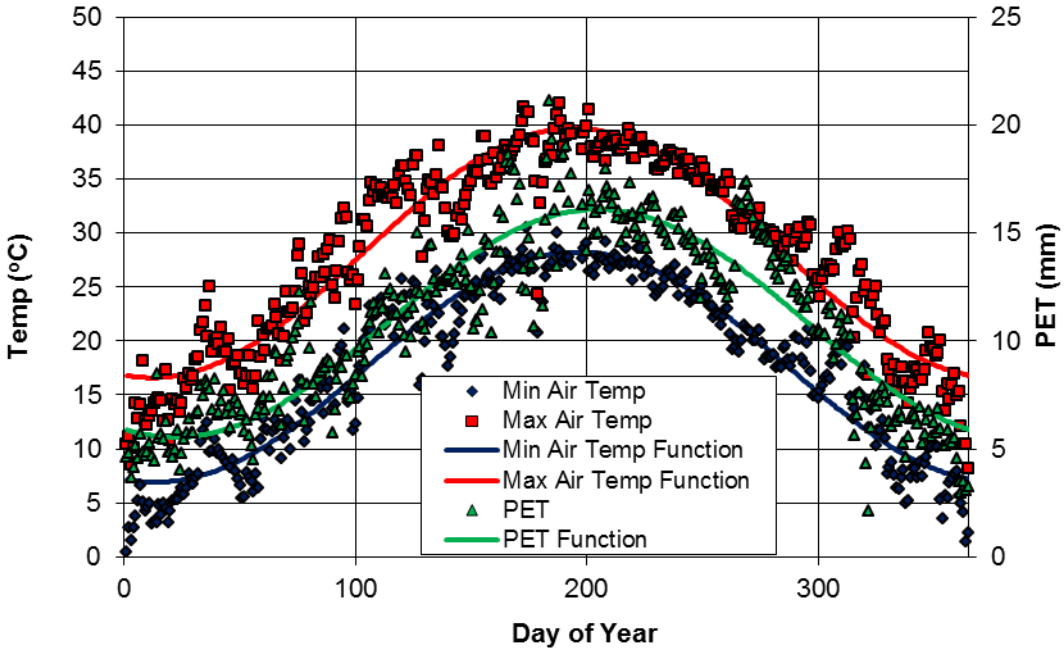

Figure 2 Measured average minimum and maximum air temperature and PET and sinusoidal functions applied in the model

Runoff Estimate

MACRO 5.1 does not model runoff but instead assumes all precipitation either evaporates or infiltrates into the soil micro- and macropores. Not considering runoff could potentially lead to a significant over prediction of deep percolation. As an alternative, the SCS runoff curve number method (USDA, 1986) was used to estimate runoff. The SCS runoff curve number method provides an estimate of runoff depth (*RO*) using the empirical relationship:

$$RO = \frac{(P - 0.2S)^2}{P + 0.8S} \qquad (5)$$

where *P* is rainfall and *S* is equal to 1000/*CN* – 10. *CN* is the curve number whose major factors are hydrologic soil group, cover type, and surface treatment. *CN* values obtained from USDA (1986) for newly graded, nonvegetated areas ranged from 77 for soils with high infiltration rates (hydrologic soil group A) to 91 for soils with low infiltration rates (hydrological soil group C). A CN value of 77 was assigned considering that the waste rock material will be relatively coarse. Estimated daily runoff was subtracted from the precipitation for that day and this modified precipitation amount (or net precipitation) was used as the daily precipitation input for the model.

Boundary and Initial Conditions

The upper boundary was set to allow evaporation while receiving hourly precipitation input. The lower boundary was set to allow free drainage (unit gradient flow). Given the arid conditions at the project site, it was assumed that the waste rock will be laid down at a very dry moisture content equivalent to a pressure head of -40,000 cm (approximating the permanent wilting point for desert plants), which is equivalent to a water content of 0.049 cm^3/cm^3. This initial water content was uniformly applied over the model domain.

Waste Rock Dump Geometry and Estimated Waste Rock Dump Outflow

The design of both dumps consists of three lifts. In order to estimate infiltration into, and outflow from the entire waste rock dump, each dump was mimicked by three columns. Each column represented the cumulative height (L) of the dump bench and the surface area (A) of the bench, as depicted on Figure 3. Column (i.e. bench) height and surface area and total dump waste rock volume are provided in Table 2. The column representation of the waste rock piles was relatively accurate, though slightly overestimated the design volume by 4 to 5 percent.

Table 2 Column (bench) height, surface area, and total dump waste rock volume

Dump	Column	Height (m)	Area (m^2)	Waste Rock Volume (m^3)
	1	60	2,085,224	
Higher	2	120	1,833,968	2,609,465,039
	3	180	12,579,308	
	1	24	1,075,843	
Lower	2	84	1,048,152	390,921,729
	3	144	1,924,005	

The model predicted average deep percolation rate and average water content increase at 8 m below ground surface (bgs) was then used to calculate the cumulative percolation volumes that exit the bottom of the dump. The percolation volume (Q) exiting the dump as a function of time was calculated and summed using:

$$Q(t) = \sum_{i=1}^{n+1} Q_i(t) = \sum_{i=1}^{n+1} \cdot q_i(t) \cdot A_i \qquad (6)$$

where t is time, q is the model predicted deep percolation rate at the bottom of column i, and A is the area of the dump with a thickness equal to column i.

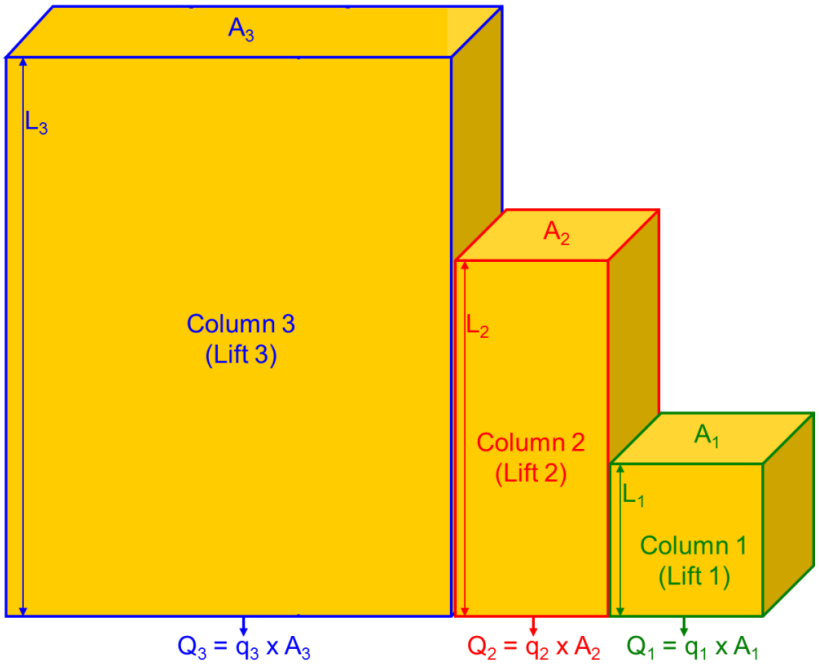

Figure 3 Hypothetical dump geometry consisting of three column heights

RESULTS AND DISCUSSION

Simulation of Waste Rock 100-Year Water Balance

The 100-year model predicted deep percolation, defined as the predicted percolation at 8 m bgs, and water content at 8 m bgs are presented on Figure 4. The simulated water balance is presented in Table 3. The large evaporative demand of the arid climate results in evaporation of the majority of precipitation (70%). Twenty percent of precipitation is predicted to become deep percolation with the remaining 10% of precipitation mass going to runoff or storage.

Arrival of the leading edge of the wetting front at 8 m bgs occurs at approximately 20 years as depicted by a sharp increase in water content (Figure 4). There is an approximate 4 year lag time before first arrival of the wetting front and the beginning of deep percolation, during which time the water content increases until reaching the water holding capacity of the waste rock material. After deep percolation begins, moisture content and percolation rate display moderate perturbations in response to arrival of water pulses stemming from larger precipitation years. From the onset of deep percolation to simulation year 100 the average deep percolation rate is 8.5 mm/yr (2.7×10^{-8} cm/s). The average water content during this same time period is 0.078 cm^3/cm^3, representing a 0.029 cm^3/cm^3 increase from initial water content conditions.

Table 3 Model predicted 100-year water mass balance at 8 m bgs

Total Precip (mm)	Total Runoff		Storage		Total Evaporation		Total Percolation	
	mm	% Precip	mm	% Precip	mm	% Precip	mm	% Precip

Predicted Long-Term Outflow Volumes for the Waste Rock Dumps

Long-term percolation volumes from the base of the higher dump and lower dump waste rock columns were estimated from the model predicted average deep percolation and associated change in water content at 8 m bgs. Using a 60 m waste rock column as an example, to increase the waste rock water content by 0.029 cm^3/cm^3, such that deep percolation can occur, is equivalent to adding 1.74 m of water to the 60 m column. Based on an estimated average deep percolation rate of 8.5 mm/yr, the addition of 1.74 m of deep percolation would take 204 years, at the end of which the average percolation rate at 60 m bgs will be 8.5 mm/yr. This calculation was performed for each column and cumulative dump outflow calculated using the profile surface area and Equation 6. Like the model simulations, the calculation of long-term dump outflow assumes one-dimensional flow under homogeneous material conditions. The calculation also assumes that the 100-year synthetic climate record used in the simulation continues for subsequent centuries.

Figure 5 presents estimated cumulative dump outflow over a 750 year period, and dump outflow rates for the higher dump and lower dump. For the higher dump, outflow from the lowest 60 m lift at the average percolation rate is predicted to begin 204 years after placement of waste rock with outflow from the 120 m column 408 years after dump placement. Maximum drainage from the higher dump is predicted to begin 612 years after placement of the waste rock, at which time the dump outflow attains a predicted flow rate of 4.5 l/sec (71 gal/min). Outflow from the lower dump is predicted to begin 82 years after placement of waste rock from the lowest lift with a doubling of flow 286 years after dump placement in response to deep percolation from second lift. Maximum drainage from the lower dump is predicted to occur 490 years after dump placement, with the outflow rate reaching 1.1 l/sec (17 gal/min).

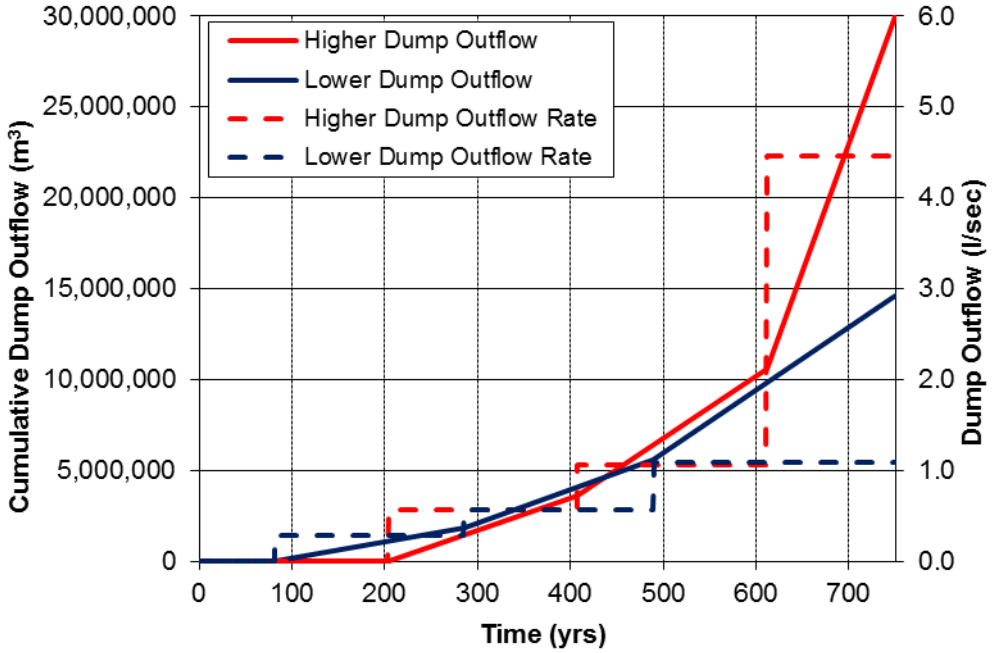

Figure 5 Predicted cumulative outflow and outflow rate.

CONCLUSION

The modeling results demonstrate that the large evaporative demand results in minimal deep percolation and a long delay from the time of waste rock dump placement to the beginning of outflow from the dump. An increase in water content from initial conditions (0.049 cm^3/cm^3) to 0.078 cm^3/cm^3 is predicted to occur before dump outflow begins. For the higher dump, outflow from the dump is predicted to begin 204 years after dump placement and reach a maximum outflow rate of 4.5 l/sec (71 gal/min) 612 years after placement. Outflow from the lower dump is predicted to begin 82 years after dump placement and attain its maximum outflow rate of 1.1 l/sec (17 gal/min) 490 years after placement.

The dump outflow predictions are conservative due to the hydraulic property assignment assuming homogeneous coarse, high permeability material. Finer grained waste rock material will reduce deep percolation due to greater moisture retention and evaporation and also increase total moisture retention. Furthermore, textural contrasts within waste rock can dominate flow processes by promoting lateral spreading, thereby increasing the time for deep percolation to occur at depth.

Other factors contributing to the predictions being conservative are:

- The analysis assigned a conservative value for the soil water pressure potential at which macropores and the soil matrix partition, resulting in greater macropore flow and less evaporation.
- Airflow within waste rock dumps can act to redistribute water and increase evaporative losses which would also decrease deep percolation.

Prediction of Seepage from a Platinum-Group Metals Tailings Storage Facility

Koovila Naicker and Keretia Lupankwa
Golder Associates, South Africa

ABSTRACT

The Platreef mineralized belt is located in the Northern Limb of the Bushveld Igneous Complex (BIC) in South Africa's Limpopo Province and hosts the highest concentration of Platinum Group Elements (PGE) and gold in Africa. The BIC comprises of the mafic-ultramafic Rustenburg Layered Suite (RLS) that is separable into five distinct compartments one of which is the Northern or Potgietersrus limb (length of 110km and a width of 15 km). The Critical Zone of the RLS is dominated by pyroxenite, anorthosite, norite and olivine- rich rocks and is characterized by regular layering of chromite and PGE-mineralization. The Platreef is correlated to the Upper Critical Zone with chromitites and PGE rich zones being direct correlates of the Upper Group 2 and Merensky Reefs. Sulphide minerals: Pyrrhotite [Fe_7S_8], pentlandite [$(Ni,Fe)_9S_8$], chalcopyrite [$CuFeS_2$], millerite [NiS], troilite [FeS], pyrite [FeS_2] and cubanite [$CuFe_2S_3$] occur in the BIC.

Geochemical characterisation conducted on the Upper Critical Zone lithologies involved static and kinetic testwork (by use of humidity cells) for ore, wall rock, waste rock and tailings material. The geochemical characterisation data was use to assess groundwater impacts from the proposed Tailings Storage Facility (TSF) from the Project.

Selected ore, hanging wall and footwall units or 28% of samples representing the underground mine unit classified as likely (sulphide sulphur >0.3% and Net Potential Ratio <1) acid generation potential. The Platreef Rougher tailings material was found to be non-acid generating due to low sulphide-sulphur content (0.015%). Humidity cell tests (HCT) results indicated low metal loading rates for tailings and rock samples after two weeks. Seepage mass load ranges were modeled as a function of tailings material properties, Goldsim water balance and HCT results and used as source-term input in the solute-transport model to assess impacts to the groundwater regime.

Keywords: Bushveld Igneous Complex, platinum tailings, humidity cell, source-term; groundwater

INTRODUCTION

A geochemistry prefeasibility study was conducted to assess the risk of Acid Rock Drainage (ARD) and Metal Leaching (ML) associated with a PGE project, as part of the Environmental and Social Impact Assessment. The proposed Tailings Storage Facility (TSF) presents unique specific water quality risks during operational and post closure phases of the TSF, partly associated with the ARD/ML potential of the tailings material. The geochemistry study aimed to quantify these risks based on the Goldsim TSF water balance, static and kinetic (humidity cell test - HCT) results from laboratory generated tailings material. The source-term developed for the proposed TSF was used as inputs in the Feflow solute transport model.

BACKGROUND

The Project includes a recently discovered underground deposit of thick PGE-nickel-copper-gold mineralization, in the Northern Limb of the Bushveld Igneous Complex (BIC). The PGE deposit will be extracted using conventional underground mining methods over a period of 30 years. Tailings material and residue (from the water treatment plant) will be produced at a rate of 3.81 million (dry) tpa.

Geology

Archaean rocks belonging to the western end of the Pietersburg Greenstone Belt and associated granitoid gneisses constitute the oldest rocks (3.6 -2.5 Ga) in the area surrounding the Project and include:

- Goudplaats- Hout River Gneiss Suite: banded migmatitic gneiss with leucocratic to dark-grey granites and pegmatites;
- Turfloop Granite: Fine to medium grained, grey and pink granodioritic /monzogranitic;
- Lunsklip Granite: Medium to coarse grained or porphyritic pink to grey syenogranite; and
- Uitloop Granite: Medium grained to porphyritic reddish alkali granite.

The Transvaal sequence overlies the Archaean basement greenstones and granitoids to the east. The BIC intrudes the Transvaal Supergroup and is the world's largest mafic layered intrusion (Cawthorn and Boerst , 2006). The BIC is subdivided into three suites namely, the mafic-ultramafic Rustenburg Layered Suite (RLS), the Lebowa Granite Suite and the Rashoop Granophyre Suite (Figure 1). According to (Cawthorn and Boerst, 2006), the RLS typically consists of the following zones from bottom to top:

- The Marginal Zone: Comprised of generally finer grained rocks and contains abundant xenoliths of country rocks. The main rock type is norite. This unit is not always present.
- Lower Zone: Dominated by pyroxenite and harzburgite. Completely absent in some areas.
- Critical Zone: Dominated by pyroxenite, anorthosite, norite and olivine- rich rocks. It is characterized by regular rhythmic layering of cumulus chromite and PGE mineralization.
- Main Zone: Consists of norite and gabbronorite, minor mottled anorthosite and pyroxenite.

- Upper Zone: consists of magnetite gabbronorite, olivine-magnetite gabbronorite and olivine-apatite diorite. It is characterized by vanadium mineralization.

The RLS is separable into five distinct compartments known as the Western Limb, the far- Western Limb, the Eastern Limb, the Northern or Potgietersrus limb and the Southern Limb. The northern limb is a slightly sinous, north-west striking sequence of igneous rocks (dip 40º to 45º W) with a length of 110km and a width of 15 km (Kinnard, 2004).

The RLS hosts major deposits of PGEs, chromite ($FeCr_2O_4$), vanadium (V) and nickel (Ni), with minor copper (Cu), gold (Au) and silver (Ag) mineralization. The PGEs (mainly platinum [Pt] and palladium [Pd]) are hosted in three major mineralized horizons, namely: Upper Group 2 (UG2) chromitite and Merensky reef in the Critical Zone of the western and eastern limbs; and the Platreef of the northern limb (Cawthorn and Boerst 1999).

Six separate mineralized zones occur throughout the Upper Critical Zone of the Project. Cyclic units T1M and T2 are the best developed and show good continuity. The other mineralized zones contain erratic mineralization and disrupted continuity. Much thicker than the normal Merensky Reef, the Turfspruit T1M and T2 ore zones are much less affected by contamination from sedimentary xenoliths than most of the other units in the footwall. The Pseudo and UG2 Reefs found stratigraphically below the TCU usually are less continuous, being disrupted by sedimentary xenoliths and associated contamination/alteration. Sulphide minerals that occur in the BIC include, Pyrrhotite [Fe_7S_8], pentlandite [$(Ni,Fe)_9S_8$], chalcopyrite [$CuFeS_2$], millerite [NiS], troilite [FeS], pyrite [FeS_2] and cubanite [$CuFe_2S_3$] Schouwstra and Kinloch, 2000.

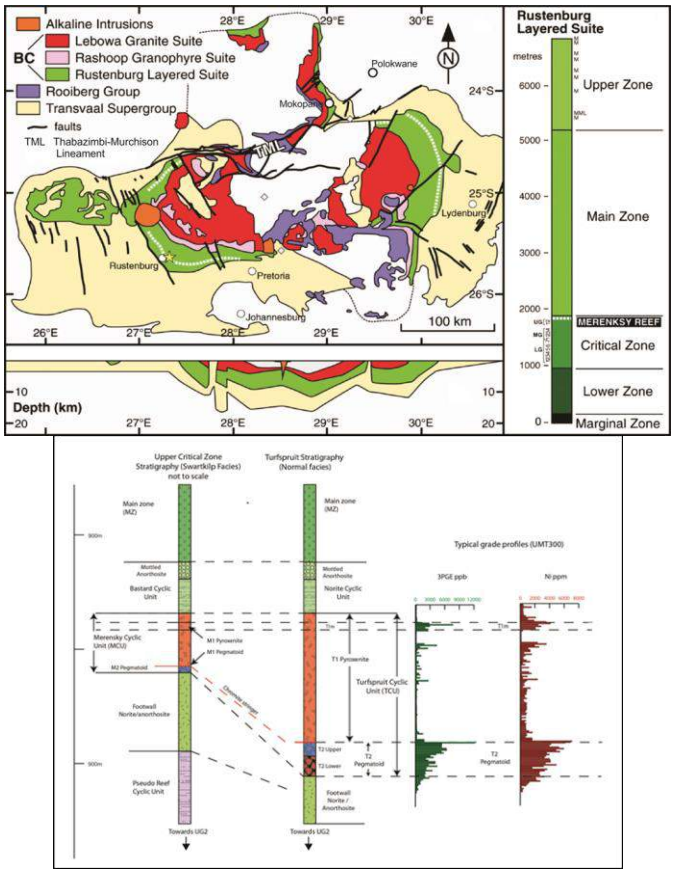

Figure 1 a) Simplified geological map of the BIC showing RLS b) Revised stratigraphy for the Project area

The stratigraphic sequence in the Project area have been revised following a recent discovery of a cyclic magmatic (Figure 1b) sequence consists of apparently uncontaminated pyroxenite, harzburgite, and dunite in the upper part of the Platreef (Grobler et al., 2012). This sequence has been termed Turfspruit Cyclic Unit (TCU) and correlated to the Upper Critical Zone of the Western and Eastern Limbs. Mineralization in the TCU shows generally good continuity and is confined to pegmatoidal orthopyroxenite and harzburgite.

In the project area, sulphides occur typically as disseminated grains, varying in size from a 5 μm to 2 cm blebs. The blebs occur mainly in serpentinized peridotite and calc-silicate rocks. The base metal sulphides also occur in places as intergrowth with secondary silicates (alteration assemblages dominated by talc, tremolite and serpentine) and in secondary hydrothermal veins traversing primary or secondary silicates.

Climate

The project area is situated in the Central Bushveld bioregion in the South Africa, with an altitude of approximately 1100 m above mean sea level. The project area lies within a water scarce region. The available information indicates only 10.5 years of combined rainfall data from weather stations in the area. The area falls in a summer rainfall climate region with the peak rainfall period from November to February when the area receives ~70% of the annual average rainfall (Figure 1). The annual minimum and maximum temperatures are 13.0 ^{0}C and 26.3 ^{0}C (average temperature is 19.7 ^{0}C). The area falls in evaporation zone 1C (Midgely et al, 1990). The mean annual S-pan evaporation is 1 700 - 2 000 mm/a.

Water Balance

A water balance model for the proposed TSF was constructed in Goldsim on a daily time step. Gauge number 0633881 (MAP=572 mm) was used. Runoff factors were informed by average runoff for the quaternary catchment (Middleton et al., 2009). Design criteria for the TSF, used in the water balance modeling are summarized in Table 1. The simulated water balance results are provided in Figure 3 and that water balance is a deficit water balance.

Table 1 Design criteria for proposed TSF

Parameter	Design Specifications
Total storage capacity	135 000 000 tonnes (over 36.5 years)
Deposition rate	3 800 000 dry tonnes/annum
Footprint area	250 ha (Basin area 203 hectare)
Slurry density	50% solids by mass
Tailings SG	3.13
Deposition method	Spigot
Decant method	Barge

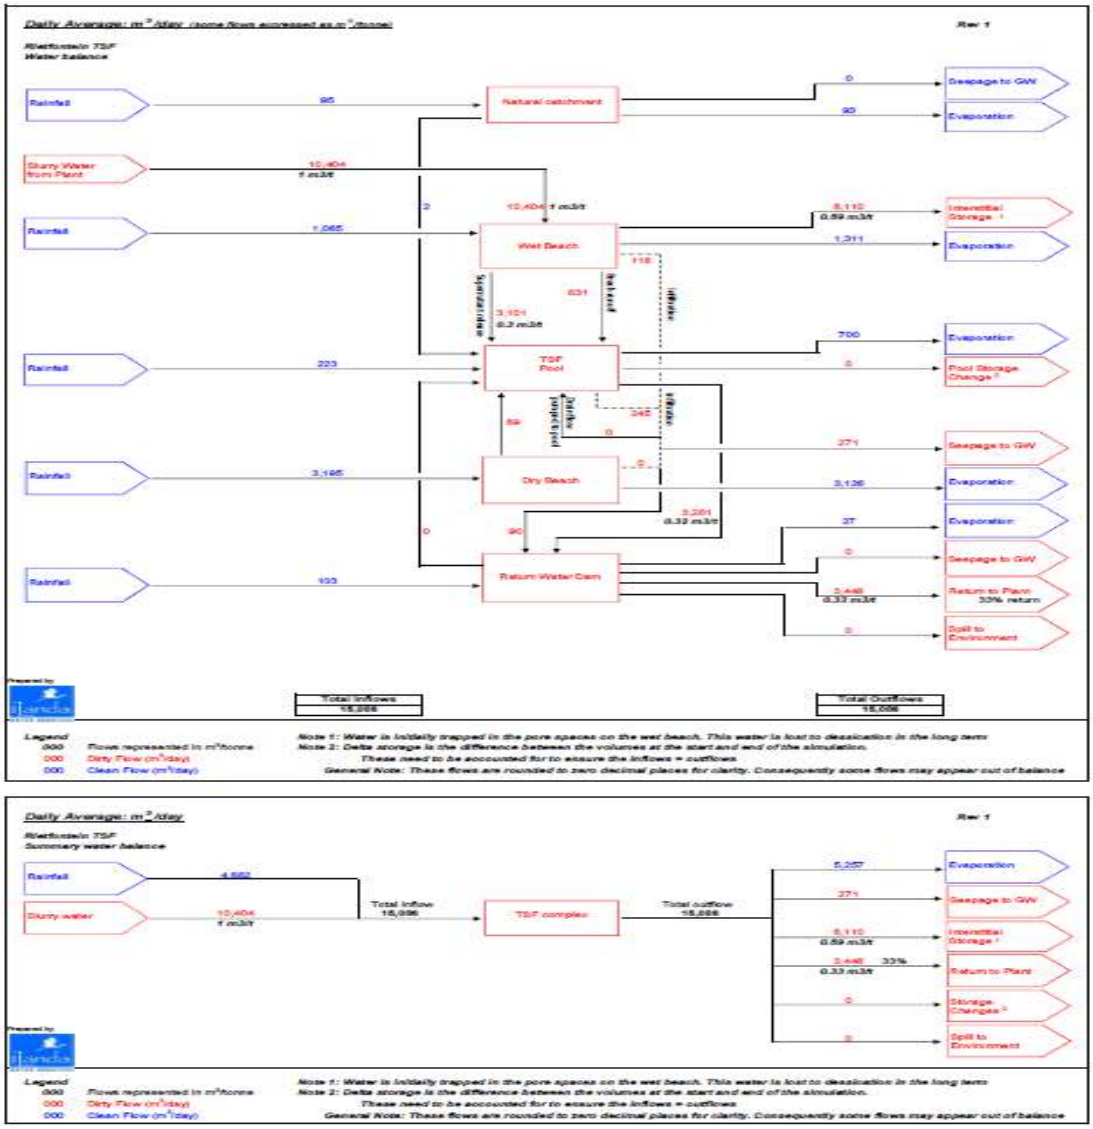

Figure 3 TSF water balance diagram

TAILINGS MATERIAL CHARACTERISATION

Rougher tailings material was received from a scoping study batch test done on a composite sample representing the current LOM blend: 15%T1; 42.5%T2U and 42.5%T2L. The Rougher tailings sample comprised 90-95% of the final tailings material. Metallurgical lock cycle test results for the final tailings indicated; particle size distribution of 80% passing 75µm and total S (0.25%), Cu (0.06%) and Ni (0.14%) concentration. The assay results for the Rougher tailings (open circuit) sample decreased by half for S, Cu and Ni. The assumption that the Rougher tailings sample tested is representative of the final tailings that will be produced is unknown and represented a limitation of the geochemical prefeasibility assessment.

Static Results

Acid base Accounting

Acid Base Accounting (ABA) results for the Rougher tailings sample is provided in Table 2. The circum-neutral paste pH (6.8) indicates the short-term pH of pore fluid in the sample and correlates with the low sulphide-sulphur (0.015%) concentration recorded.

Table 2 ABA results for Rougher Tailings

Parameter	Unit	Value
Paste pH	-	6.8
Total C	%C	0.16
Total S	%S	0.10
Sulphide-S	%S	0.015
Sulphate-S	%S	0.020
Neutralization Potential (NP)	kg $CaCO_3$eqv/t kg	5.99
Sulphide Acid Potential (SAP)	kg $CaCO_3$eqv/t kg	1.56
Sulphide Neutralizing Potential Ratio (SNPR)	ratio	3.84

X-Ray diffraction

Table 3 summarizes the mineralogical composition of the Rougher tailings. Silicate minerals dominate the tailings mineralogy and is consistent with the Platreef geology which is mainly mafic-ultramafic rocks, consisting of > 90% mafic minerals (enstatite, diopside, augite, actinolite, lizardite, biotite, chlorite) and anorthosite, which is felsic. Pyrite and/or pyrrhotite were not detected due to the limit of detection (<0.5%)

Table 3 Mineralogical composition (wt%) results of Rougher tailings material

Weathering Rate[1]	Mineral Name	Formula	Rougher Tailings (%)
Fast Weathering	Biotite	$KMg_{2.5}Fe^{2+}_{0.5}AlSi_3O_{10}(OH)_{1.75}F_{0.25}$	12
	Chlorite	(Mg,Fe2+)5Al(Si3Al)O10(OH)8	6.7
	Diopside	$CaMgSi_2O_6$	6.2
Intermediate Weathering	Enstatite	$Mg_2Si_2O_6$	45
	Actinolite	Ca2(Mg,Fe2+)5(Si8O22)(OH)2	5.3
Slow weathering	Lizardite	$Mg_3(Si_2O_5)(OH)_4$	3.6
	Talc	$H_2Mg_3(SiO_3)_4$	13
	Plagioclase	Na,Ca)(Si,Al)$_4O_8$	7.8
Resistant	Quartz	SiO_2	0.93

Whole rock analysis

The extent of element enrichment in Rougher tailings was assessed with the aid of the geochemical abundance index (GAI), which compares the measured concentration of a particular element with the estimated median crustal abundance (INAP, 2010). Elements with a GAI value ≥ 3 (12 to 24 times the median crustal abundance) included Cr, Pt, Mo and Te and are of potential contaminants of concern (PCOC) in the tailings material.

Supernatant Analysis

The supernatant (process) water of the Rougher Tailings sample was separated from the tailings solid for analysis. The supernatant was found to have alkaline pH (8.52) and TDS of 202 mg/l. Chemical constituents contributing to the dissolved salt load included Cl, Alkalinity, NO_3, SO_4, Ca, Mg, Na, K and Si. Trace metals that are likely PCOC are B, Ba and Mo (concentrations > 0.1 mg/l). The dissolved Mo concentration (0.25 mg/l) observed for the tailings supernatant was in the same order as the distilled water leach (0.13 mg/l) and acid leach Mo (0.66 mg/l) concentration.

Kinetic Results by humidity cell method

The ASTM D 5744-96 method (Standard test method for accelerated weathering of solid material using a modified humidity cell) covers the procedure that accelerates the natural weathering rate of geologic materials. For the initial (week 0) flush 750 ml of distilled water was used according to MEND (2009) HCT method. The HCT (week 0) TDS was recorded as 423 mg/l (Figure 4a) and decreases in first two weeks due to the flushing of historically oxidized ARD and weathering products. Loading rates of major and trace metals followed the same trend and thereafter varied slightly with small changes in pH, due to solubility changes. An increase in the week 12 Ni loading (Figure 4b) can be expected as Ni is released as pentlandite is oxidized/weathered.

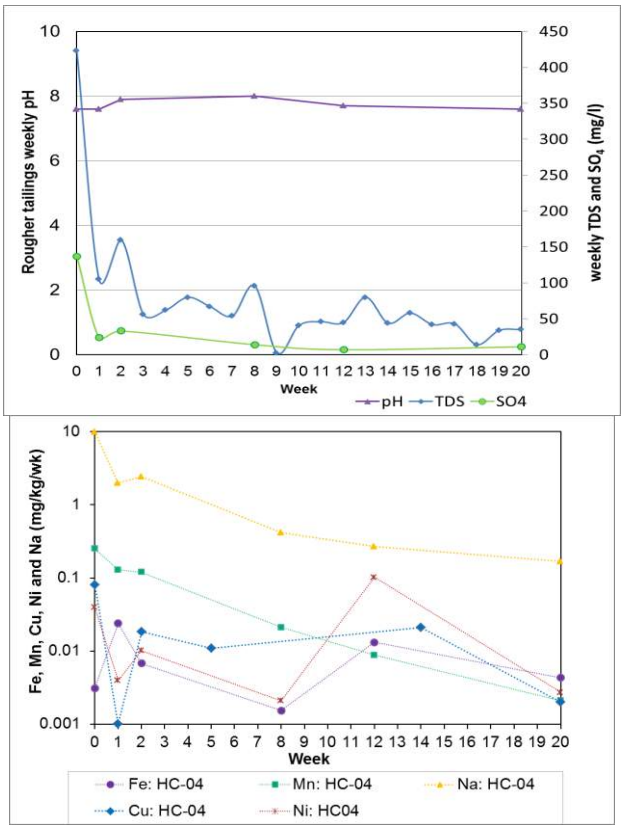

Figure 4 Rougher tailings HCT results: a) Variation of pH, TDS and SO_4 b) Weekly loadings Fe, Mn, Cu, Ni and Na

TSF SOURCE-TERM DEVELOPMENT

The TSF source-term model consisted of two key components: a flow module and a geochemical module supported by the TSF water balance and humidity cell results.

Flow Module

The water balance simulations of the average seepage to ground water (271 m^3/day, Figure 3) provided guidance on the average vertical seepage emanating from the base of the proposed TSF. Staged development curves (tonnes/area)) for the proposed TSF was sourced from the TSF capacity design analysis. The pool and wet beach seepage volumes (low, likely and high case) were modeled dynamically; using the surface area at the time of calculation.

The modeled seepage volume from the TSF base and entering groundwater is provided in Figure 5a-b. The predicted seepage volumes under post-closure are significantly lower than during operational phase. Seepage from the TSF at post-closure is driven by rainfall infiltration (unsaturated flow processes) and evaporation. The following assumptions were made for the flow module:

- Dry conditions are expected for the dry beach and TSF wall resulting in runoff (only and no seepage flow contribution from these areas. The assumption is based on the water balance model that assumed that no deposition occurs on the dry beach;
- The saturated conditions at the pool section are associated with the permanent head of water at the pool and moist conditions associated with the wet beach. In practice, the wet beach moves as the deposition location changes resulting in higher infiltration losses and a gradual increase in return water followed by a sudden reduction;
- The pool (and wet beach) area varies from 2-5% (average case 2.4%) of the total area, after evaporation effects. Seepage from pool and wet beach was calculated by applying the Darcian equation with K= $1e^{-7}$ m/s (based on laboratory measurements on final tailings – fine fraction);
- The calibrated groundwater flow model provided the average recharge of 1% or $1.24e^{-05}$ m/d based on average low aquifer transmissivities ~$1.0x10^{-3}$ m^2/d in the Turfloop Granite underlying the TSF site The contact zone between diabase dykes and the host Turfloop Granite rocks at the TSF site, are clayey and non-water bearing thus assumed not to be a conduit;
- It is assumed that approximately 95% of the vertical seepage is captured by the under drainage seepage collection system. and downstream cut--off drains.; and
- The recedence of the phreatic surface was assumed to be 10 years. For closure to post-closure phases, infiltration rates of 0.5-1.5% MAP (without cover) were assumed for the dry TSF.

Geochemical Module

Kinetic testing (HCT method) is not a direct indication of on-site drainage chemistry but simulates accelerated metal-mine waste material weathering rates. The difference between actual field conditions and HCT can differ by at least an order of magnitude. Liquid to solid ratios were used for field scaling evaporation in the project area is high.

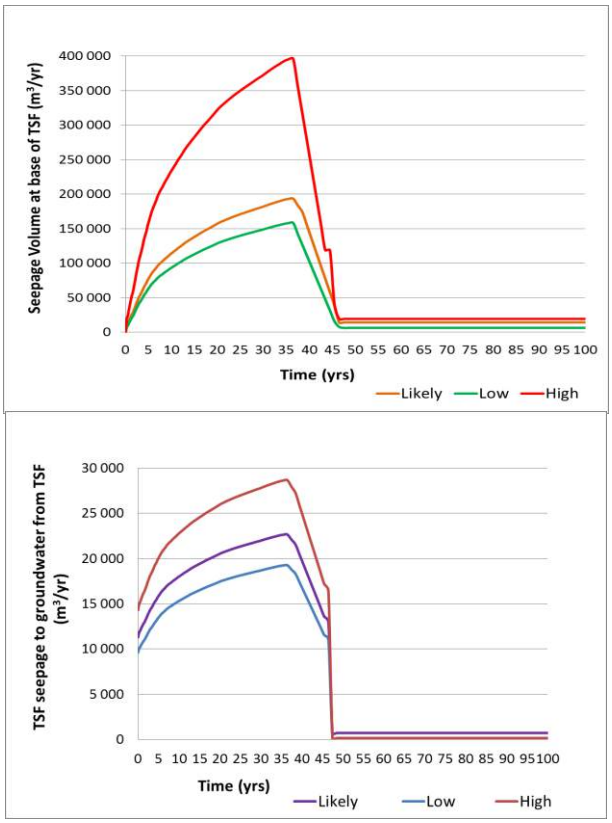

Figure 5 Modeled seepage flow volumes a) from the base of proposed TSF b) entering groundwater

Equilibrium-speciation modeling assessed mineral solubility controls on the weekly HCT seepage under oxidizing conditions (pe 2-5) and gas equilibration). Ferrihydrite - $Fe(OH)_3$ and Gibbsite - $Al(OH)_3$) were found to control dissolved Fe and Al concentrations in the seepage. The following assumptions were made for the geochemical model and source-term development:

- Operational input seepage qualities were assumed to remain constant over time i.e. the measured supernatant TDS of 202 mg/l was used without considering evaporation and recirculation effects;
- Post-closure field capacity of 15-22% (average 20%) was assumed for scaling HCT data. The HCT utilized 500 ml deionized rinse water weekly (except week 0) for 1000 g Rougher tailings sample (1:2 liquid: solid ratio). Based in assumed field capacity the average weekly TDS concentration (77 mg/l, Figure 4a) was scaled up by factor 2.3, 2.5 and 3.3 for the low, likely and high case seepage TDS concentration;
- Salt depletion rate (~7%) was estimated from the week 0 (high case) TDS and 77 mg/l; and
- The TSF seepage quality interaction with the underlying weathered zone does not change the seepage quality that is reporting to the groundwater.

Seepage concentration and TSF source-term mass loading ranges to ground water is shown in Figure 6a-b. The sharp increase in the modeled post-closure high case TDS concentration (256 mg/l)

is based on the 15% m/m moisture content; and to a lesser extent from ARD products generated from trace sulphide minerals (0.015%) as phreatic surface recedes and the TSF dries out.

CONCLUSION

A source-term has been developed for platinum TSF by integrating; PFS engineering design, Goldsim model simulation results, and geochemical characterisation results. The source-term TDS concentration time series was input into the solute transport groundwater model to quantify impacts. Several assumptions were made during the geochemical assessment and source-term development; including limited representativeness of the final tailings, and need to be addressed in the feasibility assessment.

Resistivity Tomography with Hydraulic and Geotechnical Data to Conceptualize Weathered Hydrogeology

Paul Hubbard and Anthony Rex
SRK Consulting, United Kingdom

ABSTRACT

In low permeability metamorphic rock increased fracturing associated with weathering and fault zones can exert a significant control on shallow groundwater flow and solute transport. Formulating a detailed understanding of these structural and lithological controls is therefore critical for the development of a hydrogeological conceptual model for the weathered zone. Electrical resistivity tomography (ERT) is a shallow geophysical technique that can significantly aid fracture zone characterization; however the data needs to be integrated with other site investigation data for detailed interpretation.

In this study a hydrogeological conceptual model for seepage from a tailings facility in West Africa was developed through the integration of ERT with geotechnical and hydrogeological test data. This paper presents the results of geophysical, geological and hydrogeological investigation and interpretation to create a hydrogeological conceptual model for fracture flow in the shallow weathered zone. Fracture logging and vertical hydraulic data were found to be essential for fully interpreting the ERT data and the depth of the relatively permeable weathered zone. The depth of the fractured weathered zone at the site was found to be highly variable, which was considered to be a result of the anisotropy of the host rock. This variability in the depth of the weathered zone, combined with a complex fault zone geometry, led to a conceptual model with shallow 'weathered channels' and zones of fracturing influencing groundwater flow and solute transport.

In an area of sparse drill data the development of such a refined hydrogeological conceptual model would have not have been possible without the ERT interpretation. Thus, the ERT technique proved to be an effective method to characterise shallow weathered hydrogeology, but only when integrated with relevant geotechnical and hydrogeological field data. The benefits of this analysis have continued through to the follow-on saturated zone solute transport modelling and helped to inform the groundwater monitoring plan.

Keywords: hydrogeological conceptual model, resistivity tomography

INTRODUCTION

A combined hydrogeological, geophysical and geotechnical investigation was undertaken as part of an assessment of seepage impacts from a tailings facility. The main objectives of the project were to develop a groundwater model for predicting the potential for solute transport and to inform on-going monitoring and mitigation measures. To achieve these aims a hydrogeological conceptual model was needed that characterized the potential increase in flow in the shallow fractured zone, which was initially presumed to be located between 30m to 80m depth. This paper focuses on how Electrical Resistivity Tomography (ERT) combined with geotechnical and hydrogeological test data were used to characterise the depth and flow within the weathered zone as well as indicating potential flow boundaries from sub-vertical fault structures, thus improving our understanding of shallow groundwater flow at this site.

Hydraulic measurements in shallow, weathered horizons in metamorphic basement terrain can often provide highly variable results. Often this variability can be due simply to weathering profile heterogeneity or the presence of previously unidentified fault features. Improved conceptualisation of the weathered fractured zone can aid weathered layer definition and the general understanding of shallow flow at a site, which in turn informs hydraulic test interpretation, numerical model design etc.

The use of ERT as a rapid, cost effective tool in weathered hydrogeology is well documented (Krishnamurthy, Chandra, & Kumar, 2008; Singal, 2010; Elster, Holman, Parker, & Rudge, 2014). ERT sections can allow for a more detailed understanding of subsurface variations. However, the changes observed in the resistance can be the result of a number of factors such as lithology, structure or fluids, as well as interference effects, hence the sections must be interpreted with relevant ground data.

This paper describes how geotechnical logging of weathering, fractures and lithology, supported by hydraulic test data, can be used with ERT data to interpret the weathering profile. ERT sections were used to interpolate the base of the fractured weathered zone and the occurrence of faults. This data was used to significantly improve the hydrogeological conceptual model at a mine site scale.

BACKGROUND

The site

The site is situated in Saharan Africa in Archean rocks of the West African Craton basement. The regional geology comprises volcanic and volcanosedimentary rocks metamorphosed to greenschist to lower amphibolite facies. In the study area the main lithologies are steeply eastward dipping meta-basalts to the east and meta-volcanosedimentary/volcaniclastic sandstones and grits to the west. The lithological units strike north to south, with a similar north to south orientated, steeply east dipping foliation.

The dominant structural trend is also north to south in accordance with the main shear zone to the west, which hosts the mineralisation. Splay faults are typically observed near lithological contacts and later stage east to west orientated faults off-set lithological units. The area is cross cut by thin, north northeast to south southwest and west to east trending non-foliated mafic dikes.

The topography is peneplainal; very flat with the exception of the tailings facility. The area is void of surface water, with rare sharp torrential rainfall events leading to overland flow along dry river beds (Wadis) and localised flooding due to the clays in the upper soil.

The hydraulic gradient across the site is generally quite flat and only increases noticeably near the open pits. Seepage from the base of the tailings facility at the site has led to a slight rise in groundwater levels in the vicinity of the facility.

Packer tests had previously been conducted around the pit area as part of an earlier feasibility study. A low hydraulic conductivity was reported for the fresh basement of $1x10^{-9}$m/s to $1x10^{-11}$m/s. The hydraulic conductivity range for the shallow rocks was much more variable with values between $1x10^{-5}$m/s to $1x10^{-10}$m/s given for packer tests shallower than 80m depth. Based on the packer data no consistent depth range was apparent for the fractured weathered layer.

Groundwater in the area is generally very saline, with fresher water limited to the shallow alluvium found beneath the courses of larger wadi features at distance from the site. The tailings seepage water is also very saline and has no appreciable difference in salinity to the local groundwater (both have a total dissolved solid content in the range of approximately ~30g/l to 60g/l).

The weathered hard rock aquifer model

The typical model for hard rock weathered aquifers in crystalline systems has been described in various studies as a composite layered groundwater system, with layer permeability largely driven by the weathered condition of the rock (Wyns, Baltassat, & Lachassange, 2004; Lachassagne, 2008; Dewandel, 2006). Subvertical tectonic zones or brittle cooling zones from dikes can then create localised deeper zones of increased permeability within the fissured and basement layers. The principle layers of the composite weathered aquifer are described as:

Saprolite: a high porosity, low permeability, clay rich, oxidised layer often up to tens of metres in thickness, which can act as a major storage reservoir for the aquifer. The saprolite can be divided into two sub-units comprising an upper regolith and a lower more structured 'laminated layer'. If fractures are well preserved the base of the laminated layer may also exhibit increased tranmissivity (Dewandel, 2006);

Fissured layer: a layer of increased, open, sub-horizontal joints formed through weathering and decompression resulting in zones of high transmissivity. Typically, denser jointing is present in the upper part of the fissured (fractured) layer with a frequency of joints decreasing downwards as the layer transitions into fresh basement. In isotropic rocks such as granites, joints tend form parallel to topographic surface, whereas in highly foliated metamorphic rocks, such as the project site, joints will also develop along foliation planes;

Fresh basement: characterized by a low number of open fractures with negligible permeability except in tectonic or dike zones, and low storage.

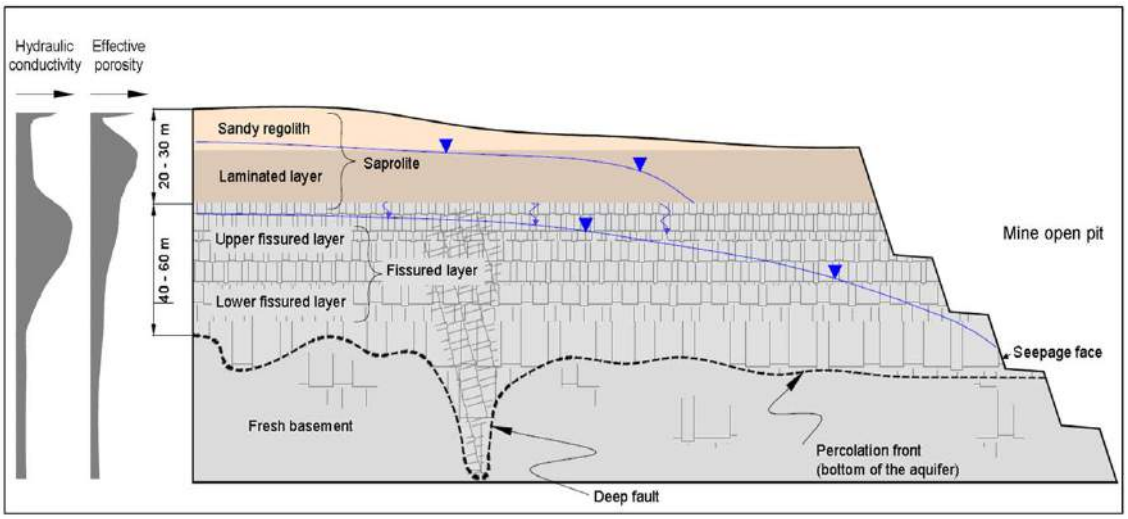

Figure 1 Idealised conceptual model of single phase weathered profile layers cross cut with a vertical fault zone, with dewatering under active mining conditions. Based on work by Wyns, Baltassat, & Lachassange, 2004; Dewandel, 2006; Elster, Holman, Parker, & Rudge, 2014 and SRK

The conceptual model for a weathered crystalline system for a single phase of weathering, with dewatering occurring through mining is shown in Figure 1. A multi-phase weathering model is described by Dewandel (2006) as leading to more variability in the weathered base and a reduced fractured layer thickness. Whilst this weathered hard rock model was generated based on crystalline/granite research, and has since been applied in weathered metamorphic systems e.g. (Courtois, Lachassagne, Wyns, & Blanchin, 2010), it is clear that foliation in metamorphic rocks may lead to more inclined joints.

FIELD METHODS

The hydrogeological characterisation of the study site was developed from existing data derived from nearby open pit studies, such as drill logs, packer test results, and water level measurements combined with additional field methods undertaken for this study. These included diamond core and down-the-hole hammer (DTHH) drilling with geotechnical and lithological logs; ERT geophysics; and airlift, rising head and constant rate pumping tests.

The main methods applied in this paper are discussed below:

Electrical resistivity tomography (ERT)

The electrical response of the earth is essentially influenced by porosity, saturation, fluid type, clay content and metal (sulfide) content. Therefore ERT (or electrical imaging) methods can be effective for weathering depth surveys as they can give a strong response to the high porosity and clay content in the saprolite. Additionally, in the case of the project site, the salinity of groundwater would be expected reduce the resistivity further in highly saturated zones.

ERT measurements are taken along an array of electrodes with the active electrode spacing increasing on each traverse to gain a greater penetration depth. ERT was selected for this investigation due to the need for additional, cost effective ground data, its ability to pick up sharp

lateral variations needed to identify fault systems, and the fact that the field work can be conducted rapidly with relatively low cost.

Relevant limitations of the ERT method include: suppression, which is the difficulty to clearly resolve thin bodies of a slightly higher resistivity below thicker low resistivity surface layers such as saprolite; non-uniqueness, which, for this study, could occur from saline seepage zones or clay rich saprolite zones both showing similar resistivities; and accurate resolution of smaller anomalies at greater depths, which for this study may affect the resolution of deeper faults.

The ERT sections were taken on the ground around the tailings facility and to the north and south of the tailings facility, perpendicular to structural trends. The lines were placed to avoid known structures with potential interference effects such as power lines, metallic fencing or pipes and active roads. Parallel sections were taken in some areas to aid structural interpretation. A dipole to dipole array of 96 electrodes was used with an electrode spacing of 10m to provide a maximum investigation depth of approximately 100m.

Geotechnical logging

Diamond-core drill holes were carried out directly along the ERT sections primarily to verify lithology and weathering against resistivity. Core was logged for lithology, weathering description, foliation, joints and fractures. Fracture parameters included dip, fill, aperture and roughness.

Hydraulic tests

Instability in the weathered zone required that core holes were immediately converted to piezometers without the opportunity to carry out spinner tests (impeller flow logging) as originally planned. Hydraulic tests were carried out in a later DTHH drilling programme designed to identify suitable well locations. The majority of these rotary boreholes were located using favourable geophysics results, whilst others were based on client preference and historic water quality data. Hydraulic measurements comprised drill-stem airlift (or blow yield), constant rate airlift tests and rising head tests; and in wells with sufficient flows, constant rate pumping tests.

RESULTS AND ANALYSIS

Interpretation of weathered layers

Core holes in the investigation area showed that the foliation of the rock mass was steeply dipping at between 60° and 70°. The dip of open joint planes in the weathered zone included both sub-horizontal and sub-vertical joint sets in both units due to the high angle foliation. A stronger foliation and therefore more foliation jointing was found in the volcaniclastics.

The relationship between resistivity measurements and weathering zone was principally determined through comparison with weathering logs and open joint count for both the saprolite and the fractured layer. The correlation between the base of the saprolite layer and resistivity data was generally clearer for both lithologies. In contrast, the transitional base of the fractured layer was less clear, particularly in the volcaniclastics. This is partly due to the variability in foliation within the unit. The correlation of the fractured base level to resistivity data was improved by comparison to hydraulic data, as discussed below.

Figure 2 shows an example of the lithological, weathering and joint count logs for a core hole in basalt superimposed on resistivity data. At this location the saprolite was logged to a depth equivalent to ~11Ω.m (ohm-meter), whereas open joints were recorded in the resistivity range of ~11to 30Ω.m.

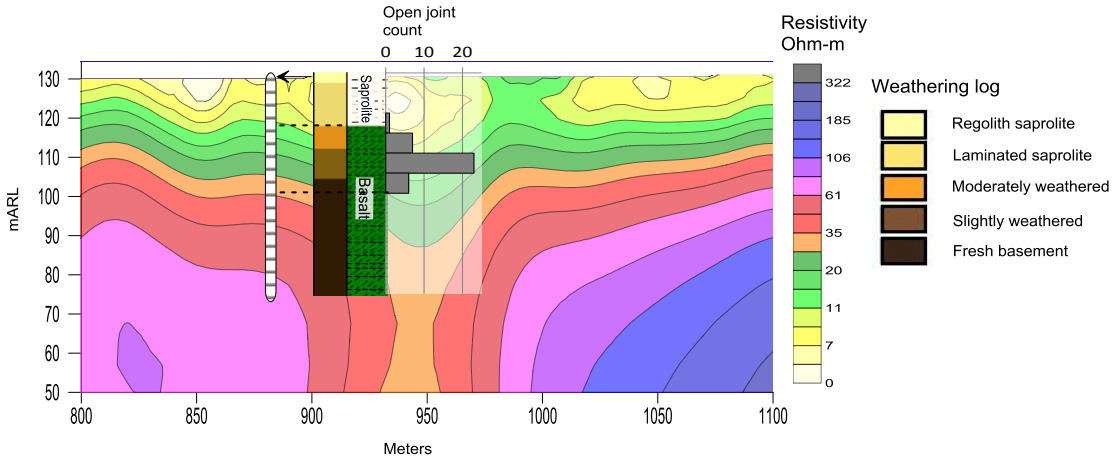

Figure 2 An example of the comparison between ERT results and the weathering log, lithology log and open joint count for an along-section vertical core hole in the basalt.

The initial interpretation of the weathered layers was compared with vertical airlift flows during drilling to identify permeable fractures and to refine the depth of the weathered fractured zone. The interpolated static piezometric groundwater level was used to identify locations where the base of the fractured zone was likely to be below saturated pressure. An example of this comparison is shown in Figure 3. Although airlift yields during drilling have limited accuracy, they can provide useful quantitative data for interpreting inflow zones. For example, in well GW02 the rapid drop-off in airlift yield to zero following water strike, indicates a shallow perched lens of limited capacity. Subsequent water quality analysis showed that this was undiluted leakage from the tailings facility (See Figure 3). Airlift yield measurements showed a good relationship between inflows and areas of interpreted fractured weathered rock below the piezometric level (e.g. wells GW01, GW03, GW04 and GW11 in Figure 3). Conversely, little or no groundwater yield was recorded for some well locations that were selected purely based on site preferences without the use of the geophysical data. These wells were typically located in areas where fresh rock had been interpreted above piezometric level (e.g. wells GW12a and GW02).

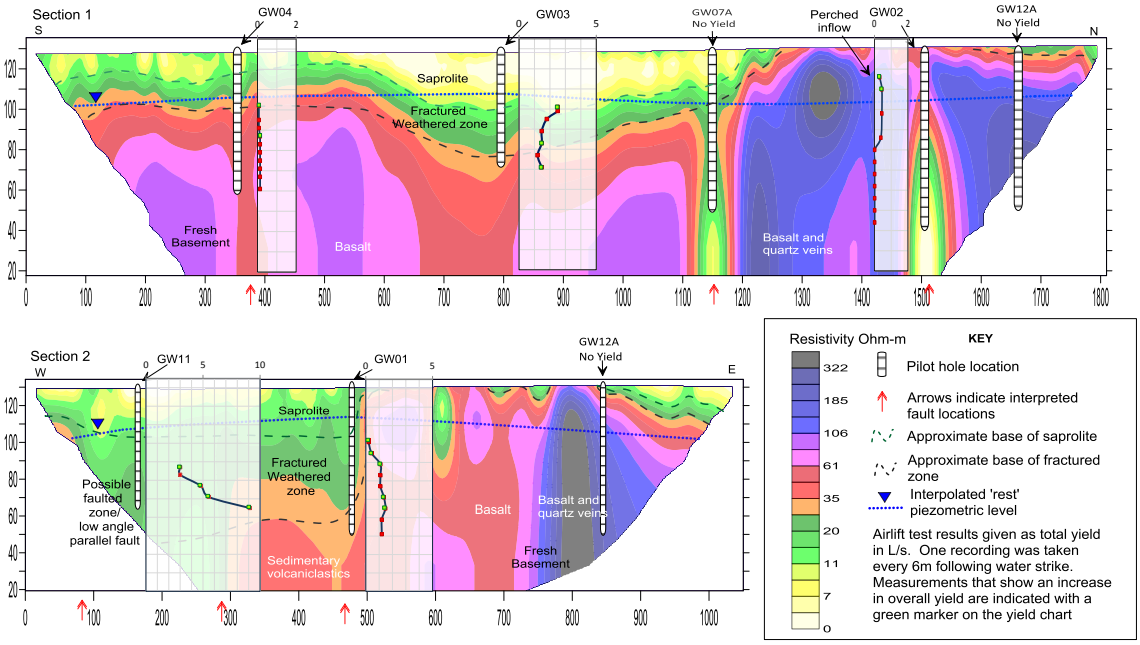

Figure 3 ERT sections with interpreted base of weathered saprolite and the fractured zone overlain by pilot hole locations, graphs of recorded airlift yields (L/sec) for yielding wells and interpolated piezometric level of the groundwater. Section 1 is a north to south section in basalt. Section 2 is a west to east section in sedimentary volcaniclastics and basalt. Both sections suggest that the weathered fractured zone is only present below the piezometric level in parts of the site.

A very deep, low resistivity zone in the ERT originally thought to be anomalous (as shown between 200m and 300m in Section 2, Figure 3) was partly verified through comparison of yield data. Well GW11 passed through a thick saprolite layer before striking water at ~44mbgl and showed water gains until the hole was stopped due to the collapsing nature of the shattered zone intercepted below ~70maRL. It should be noted that the resistivity results may show some depth inaccuracy in this area due to the thick layer of very low resistivity material at the surface.

A number of results can be drawn from the comparison of hydraulic and geotechnical data with ERT sections:

- Consistent with the classic crystalline weathered model significant increases in pilot hole yield were found in the saturated upper fractured zone (e.g. as seen in pilot holes GW11, GW03 and GW01 in Figure 3). Subsequent pumping test analysis confirmed well inflows were likely to originate from only a few principal fractures in most wells and these depths matched well with the inflow depths observed from airlift tests during drilling. In the lower part of the fractured zone there was generally no noticeable additional yield and the fresh basement generally exhibited no noticeable additional yield;
- The depth and thickness of weathering is variable across the site with the base of the fractured zone showing considerable variation. Visually this compares better to the 'multiphase weathered model' presented by Dewandel et al (2006). However, this is likely to be due to the increased variability in metamorphic rocks, particularly in folitation strength;

- Due to this weathered depth variability the base of the fractured zone is only below the piezometric level in certain parts of the site including beneath and around the tailings facility where groundwater levels were locally mounded due to seepage;
- Owing to the salinity of the water fault structures were visible on ERT sections as near vertical, thin, low resistivity zones (See Section 1, Figure 3). Based on core data and fault mapping in the pits it is expected that the majority of fault structures are permeable. These structures were not intercepted in any of the test wells (despite attempts e.g. GW02, GW07a). However, in some cases subsequent pumping test analysis has indicated permeable boundary structures consistent with the locations of these fault structures.

Table 1 Approximate resistivity ranges attributed to geological formations

Weathering Layer	**Approximate Resistivity (Ω.m)**	
	Meta-Basalt	**Meta-volcaniclastics**
Saprolite	0-10	0-25
Fractured layer	~10-45	~26-100
Fresh rock	>45	>100

Table 1 summarises the resistivity measurements for the different weathered zones deduced from comparing the ERT data to fracture logging, weathering logging and hydrogeological data. The resistivities are lower than would typically be expected for these lithologies due to the salinity of the groundwater and the high clay content of the weathered rock.

Saturated fractured layer and fault mapping

The results of the ERT surveys indicate that only parts of the upper fractured layer are below groundwater level. 'Channels' of higher permeability are formed where this layer is below groundwater level. As the majority of groundwater and solute flow would occur along these zones of higher permeability, as well as along the faults, mapping the channels and faults was an important part of the conceptual model development.

Resistivity sections were compiled into Leapfrog™ 3D geological modelling software for cross comparison (Figure 4). The interpreted base of the weathered fractured layer was interpolated between the resistivity sections with drill data used where larger gaps were present between sections. The area below the tailings facility, together with other zones of limited data, represents areas of considerable uncertainty in terms weathering depth, fault location and water.

For the interpolation of vertical structures dikes were separated from faults by overlaying aerial magnetic survey data and comparing with the ERT sections (the mafic dikes are clearly defined in the magnetic results). The fault structures were then interpolated with a confidence rating of 1 to 5 applied to the interpolations. The interpolated north to south trending faults (Figure 4) are consistent with structural mapping and some show good correlation with surface fault mapping.

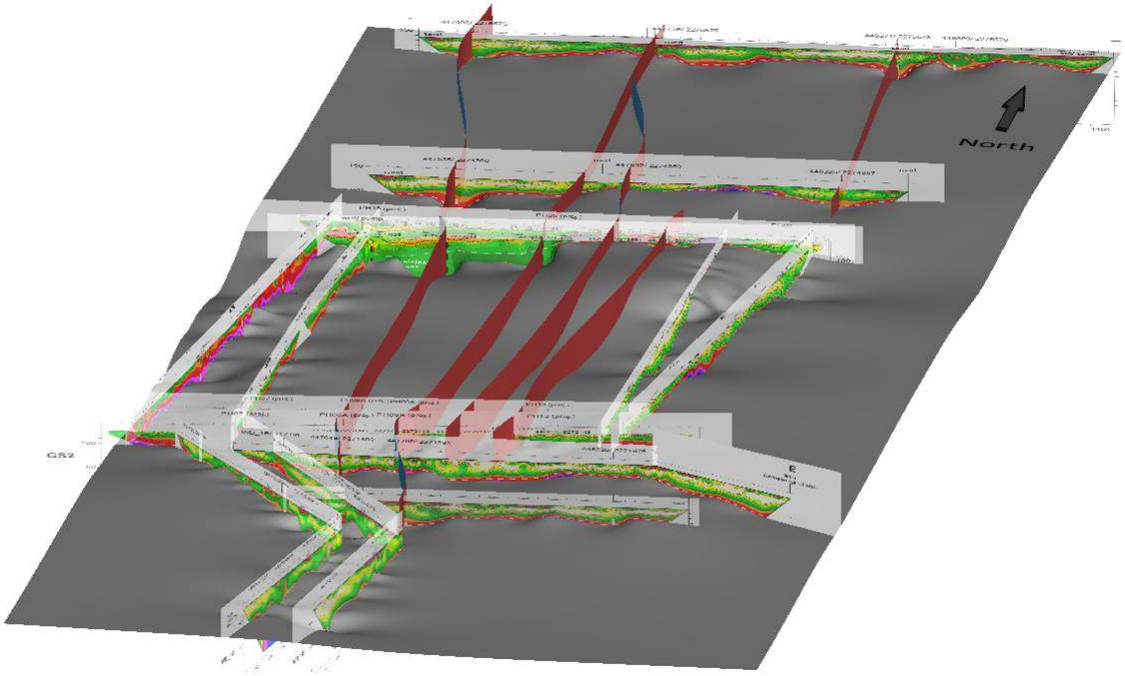

Figure 4 Compilation of ERT sections with the interpolation of the base of fractured layer (grey) and major north to south trending fault interpolations (burgundy and blue).

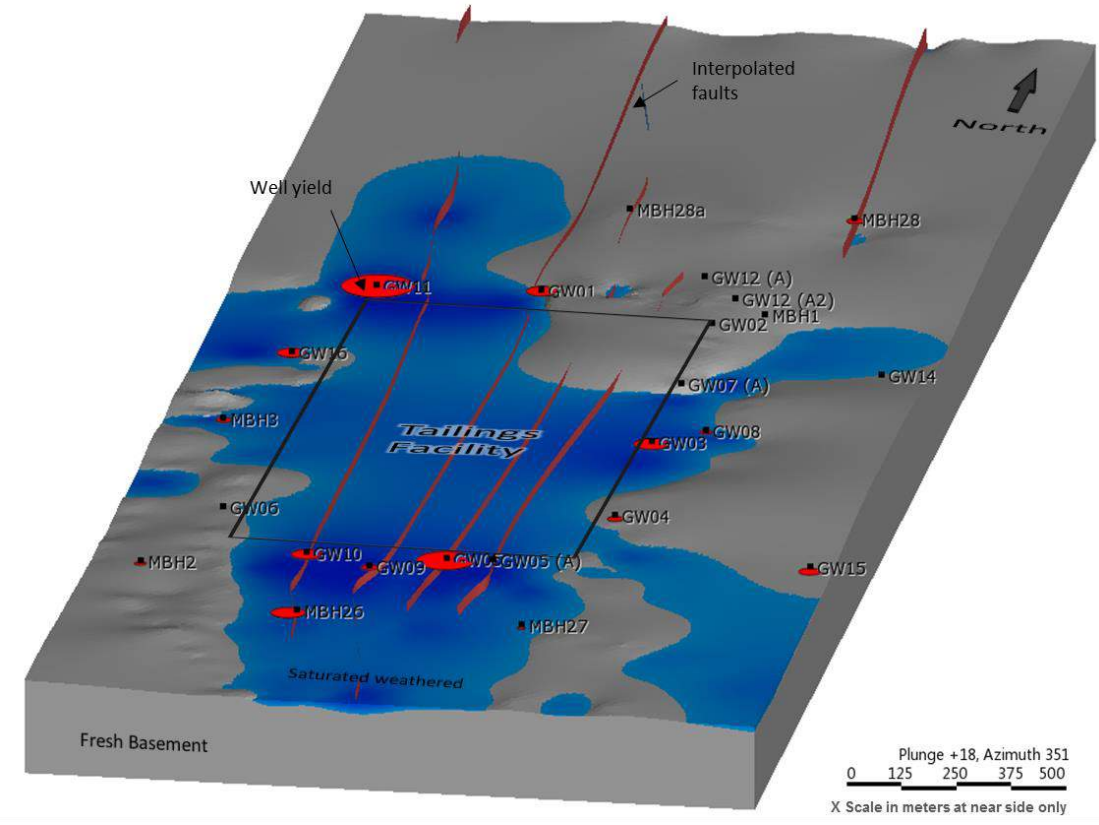

Figure 5 Interpolated base of the fractured weathered layer with a colour flood showing areas below the piezometric surface. Darker blue shading indicates an increased thickness of saturated weathered layer. Black

dots mark DTHH boreholes where water yield was measured. The relative yields from the boreholes are indicate by the size of red circles

Overlaying the groundwater level with the interpolated base of the fractured weathered layer shows a roughly north northwest to south southeast orientated channel that represents the 'saturated fractured weathered layer' material beneath the site and the tailings facility (blue area Figure 5). A deepening of the weathered layer is also seen to the east of the tailings facility (as evident in Section 1 Figure 3). Total yields from airlift tests indicate a good correlation between high borehole yield and the boreholes' positions relative to the weathered channels. Conversely there is a good correlation with zones of elevated fresh basement and boreholes which were drilled with no yield recorded (e.g. in the area North of GW07[A] in Figure 5) with only some minor exceptions (e.g. MBH02, GW04 and GW15).

Furthermore, the channel area mapped around the tailings facility was found to be consistent with groundwater quality samples containing tailings solute, indicating that solute migration was likely to be preferentially occurring along these weathered channels. Long-duration pumping at some of the wells has since established drawdown relationships between wells to the north and south of the tailings facility, which may be a result of hydrogeological connection within the weathered channels or the north – south oriented faults.

CONCLUSIONS

An ERT survey supported with lithological, geotechnical and hydrological data was used to characterise the shallow weathered zone and fault locations for a hydrogeological conceptual model in weathered metamorphic rock as part of a tailings seepage study. In the comparative analysis the open joint locations generally correlated well to inflow zones, which in-turn could be broadly correlated to a range of resistivities. However, the depth of the fractured layer itself was not apparent from the resistivity results alone. Therefore, the combination of both geotechnical and vertical hydrogeological data was found to be indispensible when interpreting the ERT measurements, leading to improved confidence in the overall interpretation of the system.

Despite some limitations to the method, the ERT measurements helped to show that weathered zone thickness at the site is considerably variable. The variable weathering depth differs to the classic single phase weathered model, which is considered to be a result of increased anisotropic structure of metamorphic rocks (particularly foliation). The weathered fractured zone is only present below the piezometric surface in certain parts of the site, with mapping of the fractured layer revealing a channel system where the fractured zone is saturated. This compares well with elevated hydraulic test results and water quality data showing that tailings water is migrating along these higher permeability channels. A number of faults were also determined from mapping of the ERT data, with locations that are supported by existing structural data. Some of these faults have since been evidenced hydraulically by pumping test analysis.

ERT integrated with geotechnical and hydrological data proved to be an invaluable tool in the refinement of the conceptual model for this hydrogeological study. It has led to important changes in our understanding of shallow flow and potential flow barriers, and, in turn, the potential for solute transport. The conceptual model has assisted with the siting of subsequent groundwater monitoring wells, the development of a numerical flow and solute model as well as the interpretation of hydraulic and water quality test data at the site.

Acknowledgments

The authors would like to thank the client for the use of their data in this paper, Terratec for the resistivity field work, and the SRK structural geologists and geotechnical engineers involved in the project for their input.

Alberta Oil Sands Cover System Field Trial: Development, Construction, and Results Two Years In

Larisa Barber, David Christensen, and Lindsay Tallon
O'Kane Consultants, Canada

ABSTRACT

Syncrude Canada Ltd. (SCL) has developed a field scale cover system trial at the Aurora North mine operations in Fort McMurray, Alberta, Canada. O'Kane Consultants Inc. (OKC) is part of the multi-discipline team that includes university researchers and industrial partners. The overall objective of the trial is to determine appropriate soil cover system designs and capping depth(s) for reclamation using available surface soil materials, while understanding and addressing the risk and uncertainty associated with the presence of oil sand (naturally occurring hydrocarbons) in the overburden and soil reclamation materials. The field scale cover system trial consisted of 36 one hectare cells, made up of 12 treatment options constructed in triplicate. The research cells were instrumented and planted with three native boreal forest tree species in varying densities.

OKC's primary research objective of the field trial was to investigate internal overburden disposal area dynamics, and develop an understanding for the key mechanisms and processes that influence the performance of various soil cover system prescriptions. Instrumentation was installed to monitor water balance parameters and groundwater, and to collect pore-water. Of the cells examined, the treatments with peat as a surface material had the lowest net percolation, due to higher water storage capacity. Groundwater levels revealed small, dynamic hydraulic gradients across the trial, and groundwater chemistry was generally typical of mine affected groundwater elsewhere at the Aurora North mine. Results from the study will serve to identify optimal cover system configurations and will be used by SCL to guide future reclamation operations.

Keywords: cover system, net percolation, overburden

INTRODUCTION

Syncrude Canada Ltd. (Syncrude) has developed a field-scale soil capping study at their Aurora North mine operations in Fort McMurray, Alberta, Canada. The overall research objective of the Aurora soil capping study (ASCS) is to determine appropriate soil cover system designs and capping depth(s) for reclamation using readily available surface materials, while understanding the risks and uncertainties associated with overburden and soil reclamation materials containing naturally occurring oil sand (petroleum hydrocarbons).

Syncrude has undertaken the study to examine alternatives for rehabilitation of their overburden areas. Rehabilitation practices must optimize the available reclamation materials to provide the foundation for re-emergence of sustainable, productive ecosystems. It is the research team's expectation that a wide range of land capability will be required within reclaimed areas and, as a result, reclamation treatments might change from one area to the next within the final landform. Consequently, the differences in performance between different surface materials, the thickness of the surface material, and the influence of the underlying subsoil materials need to be defined.

Indicators of cover system performance include net percolation and health of vegetation. OKC's contribution to the multi-disciplinary study is to examine the hydrological performance of the treatment alternatives. As soil moisture dynamics and vegetation health are interrelated, indirect indicators of vegetation performance such as plant available water and soil temperature are also considered. Further conclusions on vegetation health are within the scope of other researchers on site and are supported by data collected by OKC.

BACKGROUND

Oil sands mining is an open-pit mine operation. It involves removal of surficial geologic materials within the mine footprint that are suitable for use later in reclamation. This primarily includes discrete salvage of upland surface topsoil and subsoil materials and peat materials from lowland bogs and fens. Following reclamation soil salvage, overburden is removed to the oil sand ore body. The overburden is transported to a designated disposal area (generally above-grade or out of pit) where it is landform graded to defined elevation and grade specifications and capped with previously salvaged soil reclamation materials.

The appropriate soil reclamation capping design and depth is dependent on the underlying overburden quality and risk. For Syncrude's Aurora North mine, there are a number of risks and uncertainties associated with their overburden reclamation. Due to the geologic processes that took place at the end of the last glaciation, naturally occurring sand material which contains petroleum hydrocarbons have been mixed in the overburden and the soil reclamation materials in the region. Naturally occurring hydrocarbons are present in the entire matrix of the overburden, while they are present as discrete bands or chunks of varying size and proportion within the soil matrix. The removal, disruption, and spreading of these materials in a new setting poses a risk to the closure landscape, and the appropriate soil cover design and thickness is also uncertain.

A second issue Syncrude faces with overburden reclamation at the Aurora North mine is the large abundance of sandy (coarse textured) mineral reclamation materials. Although Syncrude has over 30 years of reclamation experience in the region, the Aurora North mine coarse textured surficial geological materials differs from previous mining locations. The appropriate use of available soil

reclamation materials to re-establish similar vegetation that was present prior to the disturbance has not been determined.

The ASCS has been constructed to address the risks and uncertainties with overburden reclamation at the Aurora North mine. The objective is evaluate the risks present and provide an appropriate soil cover system design and depth that will mitigate these risks. It is a large-scale, replicated multi-disciplinary study that spans key disciplines such as soil physics, soil chemistry, geochemistry, hydrology, plant growth and soil microbiology.

METHODOLOGY

Twelve treatment options (Figure 1) were constructed in triplicate to facilitate scientifically rigorous comparisons, resulting in a total of 36 cells (Figure 2). Surface layer materials include peat (a material of high organic content, salvaged from bogs), LFH (forest floor material), and Centre pit Bm (sandy subsoil material). Instrumentation for measurement of groundwater and various parameters of the water balance was installed in the cells (Figure 2). The research cells were planted with three native tree species in varying densities.

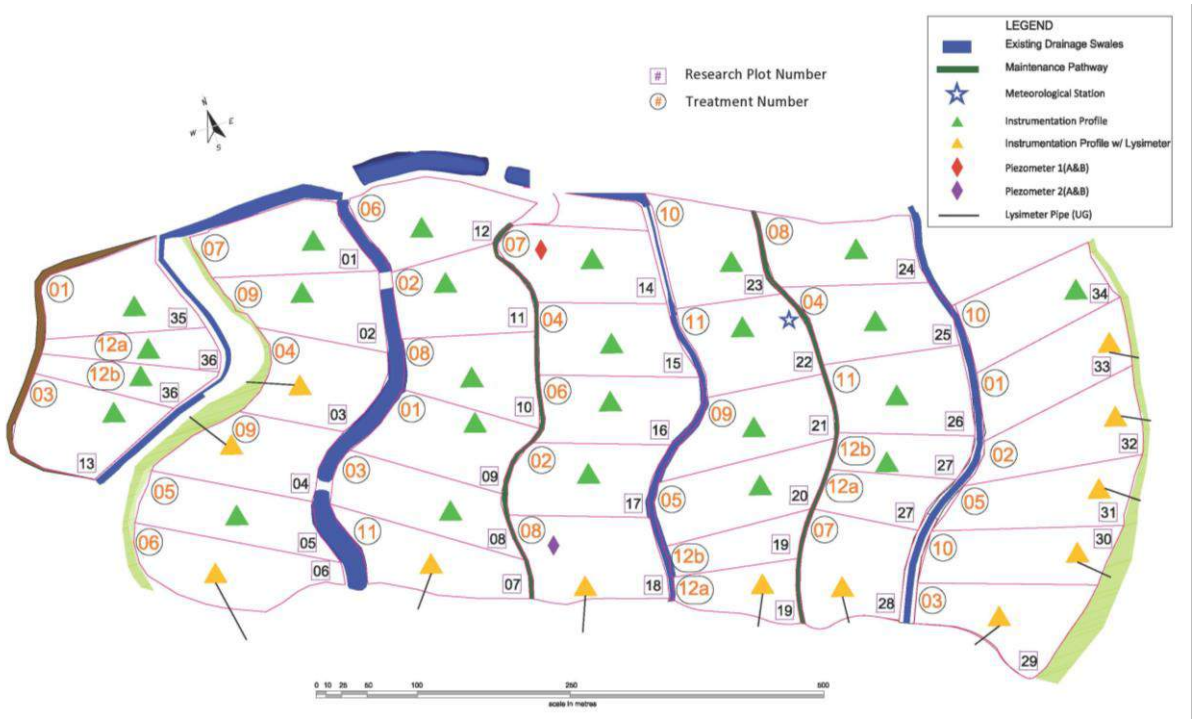

Figure 2 Study layout and instrumentation installed at the ASCS.

Water balance method

Analytical water balances were performed for cells on the perimeter of the ASCS to quantify the volume of water percolating through the cover systems in the 2012 - 2013 water year (November 1, 2012 to October 31, 2013). Water balances use calculated, estimated and field measured components as inputs to solve the water balance equation [1] on a daily basis during frost-free periods. In this way, the water dynamics of the various cover system treatments, and the hydrology of the system as a whole, can be characterized.

$$PPT = RO/S + AET + NP + dS \quad [1]$$

PPT = precipitation (rainfall plus snow water equivalent (SWE)),

RO/S = runoff and sublimation,

AET = actual evapotranspiration,

NP = net percolation, and

dS = change in moisture storage.

A meteorological station was erected at the ASCS on Cell#22 to measure site-specific climatic parameters (Figure 2). The station included instrumentation to monitor air temperature, relative humidity, net radiation, wind speed and direction, rainfall, snow depth, and air pressure.

Potential evapotranspiration (PE) was estimated using the modified Penman-Monteith method (Vanderborght et. al, 2010) and site meteorological data collected by the meteorological station. AET was calculated based on climate data and rates of PE, while AET/PE ratios were based upon

soil saturation levels, and field capacity and wilting point values, and adjusted to match the calculated storage to the measured storage in the water balance.

Vadose zone water dynamics in the cover systems and overburden at the ASCS were monitored by Campbell Scientific (CS) model 616-L volumetric water content sensors and CS229-L matric suction sensors. Data from these sensors was used to determine measured change in storage for the water balance. Pairs of soil water sensors were installed by hand in all layers of cover materials and in overburden, with focus on material interfaces.

CS229-L matric suction sensors also recorded soil temperatures. Soil temperature data was used to determine the frost-free period, and assist with the interpretation of water content data. In addition, the season when vegetation on the test cells is active is heavily influenced by soil temperatures.

Net percolation through the cover system treatments was monitored by large-scale lysimeters (Figure 2). The large-scale lysimeters were installed in the upper overburden profile of 12 of the perimeter test cells. Smaller scale Gee drain gauges were installed to assist in the characterization of water flow dynamics. Water balance net percolation was estimated using lysimeter and Gee gauge data, and the change in water storage at the base of the cover system.

Runoff is not directly measured at the site. Runoff and sublimation from the snowpack were estimated from the water balance.

Groundwater monitoring instrumentation

Four standpipe piezometers were installed at the ASCS (Figure 2) to measure groundwater levels and facilitate groundwater sampling, using Barber Dual Rotary and Coring Rigs. SP-1A and SP-2A are deep standpipes, while SP-1B and SP-2B are shallow standpipes. Groundwater levels were manually recorded in August and September of 2013, and samples taken using an inertial pump.

RESULTS AND DISCUSSION

Two cells with the surface treatment types of 20 cm LFH (top 15 cm of soil which consists of litter layer plus a portion of the immediately underlying mineral material) (Cell#18) and 30 cm peat (surface peat salvaged from bogs and fens) (Cell#30) were selected for presentation of results, but trends for research cells with large scale lysimeters and located on the perimeter of the study area are also discussed.

Temperature

Cells with peat as a surface material had dampened freezing penetration, in that they did not freeze as deep or as quickly as cells with LFH as a surface material. Freezing penetration occurred to approximately 90 cm for Cell #30 (Figure 3), versus approximately 200 cm for Cell #18 (Figure 4). In addition, freezing was more gradual for Cell#30 than for Cell#18 which showed an immediate spike of freezing to approximately 50 cm depth.

The number of days that soil temperatures at 10 cm depth exceeded 5°C was determined for the four major surface treatment types (Figure 5). The criteria of 5°C at 10 cm depth was used as an approximate indicator for when vegetation becomes active (Novak, 2005). The cells with 20 cm LFH at the surface had a greater number of days with active vegetation than cells with 30 cm of surface peat. Peat is an excellent insulator and more easily transmits energy from the material surface to the atmosphere relative to the sandy textured LFH. If soil-water is present to meet vegetation demand, increased soil temperature (more active vegetation days) in the boreal forest will likely translate into increased tree growth.

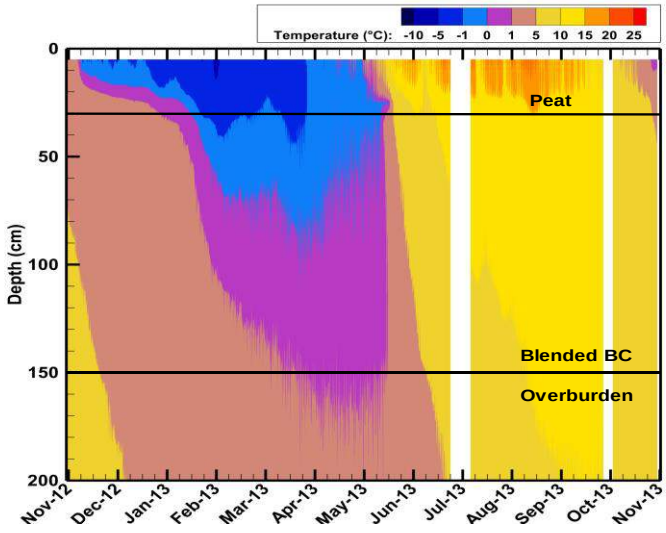

Figure 3 *In situ* soil temperature contours measured at Cell#30 (30 cm peat cover treatment) during the 2012-2013 water year.

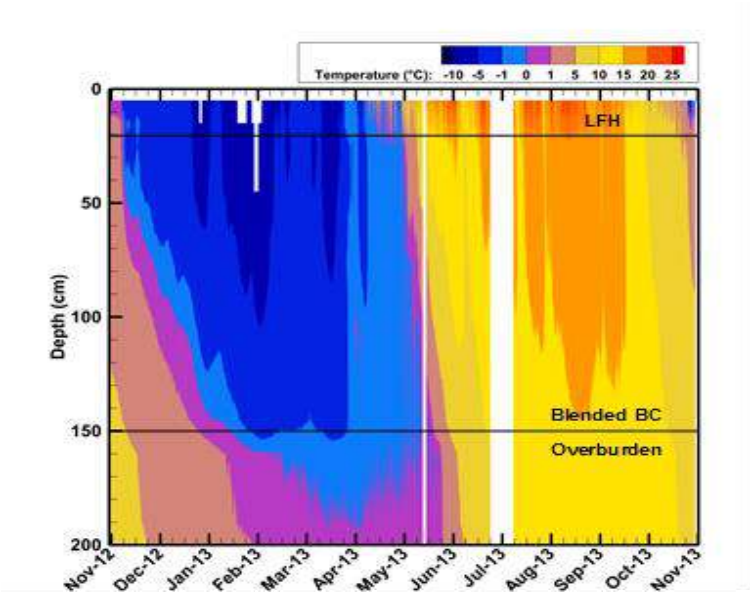

Figure 4 *In situ* soil temperature contours measured at Cell#18 (20 cm LFH cover treatment) during the 2012-2013 water year.

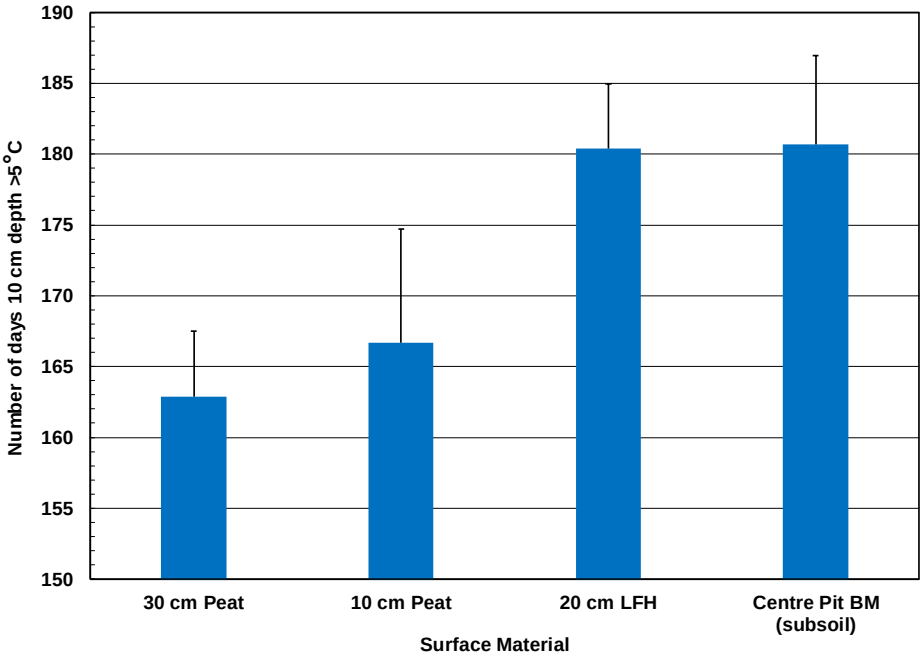

Figure 5 Number of days soil temperature at 10 cm depth was greater than 5°C for surface materials during the 2012 - 2013 water year.

Water balances

Water balances were completed for all research cells with large scale lysimeters and located on the perimeter of the study area. Calculated and measured storages matched well for Cell #30 (Figure 6) and Cell#18 (Figure 7) for the 2012 – 2013 water year, and for all water balances. Runoff and sublimation were higher for Cell#30, as well as for the majority of cells with peat as a surface material. AET rates were similar for Cell#18 and Cell#30, and ranged between 61% and 76% for all water balances constructed. AET rates did not have a discernible pattern based on material type. Rainfall for the year was above average, with two major rainfall events resulting in the majority of net percolation through the cover systems.

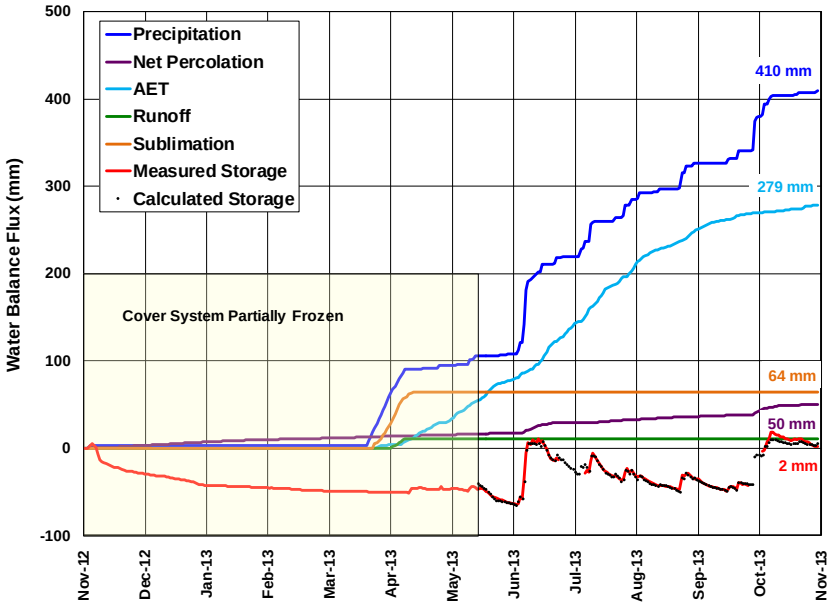

Figure 6 Cumulative water balance fluxes for the Cell#30 (30 cm peat cover treatment) for the 2012 - 2013 water year.

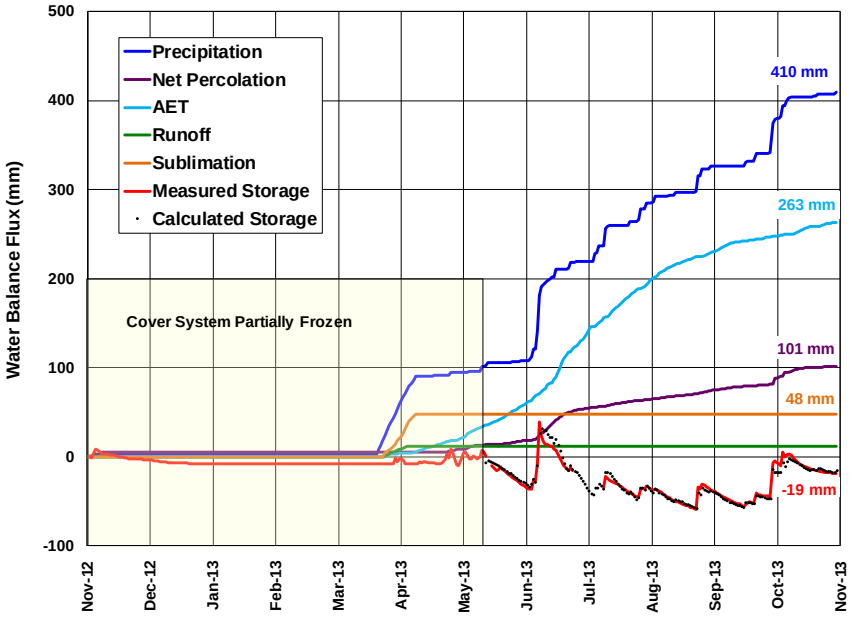

Figure 7 Cumulative water balance fluxes for the Cell#18 (20 cm LFH cover treatment) for the 2012 - 2013 water year.

Net percolation is an indicator of storage water potential of the cover system treatments,which can have implications on soil-water availability for vegetation growth and groundwater recharge rates. The net percolation rate for Cell#30 for the 2012 – 2013 water year, at 12% of annual precipitation was lower than the rate for Cell#18, at 25%. Following this trend, on average, cells with 30 cm of peat as a surface material had lower net percolation rates, at 14%, than cells with LFH as a surface material, at 23% (Figure 8). This is attributed to the higher storage capacity of peat, which improves the water store and release mechanism of the cover systems. In addition, it is possible that textural discontinuity between peat and subsurface materials inhibits drainage from peat to subsurface materials.

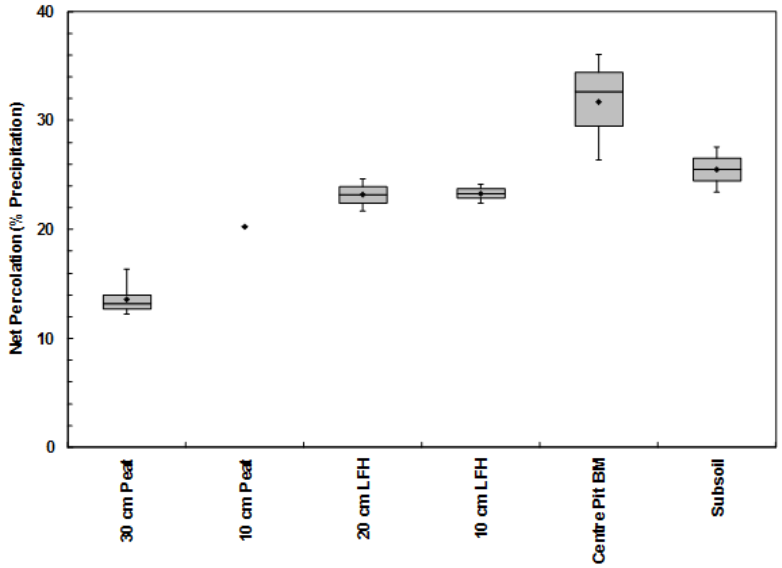

Figure 8 Net percolation box and whisker plot for all surface treatment options.

Groundwater levels and chemistry

Deep and shallow water tables were identified by manual water level measurements at SP-1A and SP-2A, and SP1-B and SP-2B, respectively. The average hydraulic gradient between SP-1A and SP-2A (the deep seated piezometers) in the 2012 - 2013 water year was -0.0098 m/m, translating into a north to south flow. The average hydraulic gradient between SP-1B and SP- 2B (the shallow seated piezometers) for the 2012 - 2013 water year was 0.0027 m/m, which translates to a south to north water flow.

Select results from chemical analyses of groundwater samples taken in standpipes (Table 1) were typical of mine-affected groundwater sampled elsewhere at the Aurora North mine.

Table 1 Select results of groundwater chemistry analyses.

Parameter	SP-2B	SP-1B	SP-1A
pH	7.35	7.89	7.88
EC (uS/cm)	2,760	3,860	2,680
TDS (mg/L)	2,340	3,060	2,240
Organic C (mg/L)	83.6	92.7	21.7
Dissolved Ca (mg/L)	429	205	436
Dissolved Mg (mg/L)	96.1	62.3	93.4
Dissolved Na (mg/L)	276	824	225
Dissolved S04 (mg/L)	955	1,360	1,060
Dissolved V (mg/L)	<0.0002	0.0024	0.0036
Dissolved As (mg/L)	<0.0004	0.001	0.0022
Dissolved Chloride (mg/L)	74.7	241	204

CONCLUSION

The influence of cover system treatments on soil temperature and water content were measured at an oil sands reclamation research study referred to as the Aurora soil capping study. Net percolation rates for the 2012 - 2013 monitoring year for treatments with 30 cm of peat at the surface were 14% of annual precipitation, which was lower than treatments with LFH (23% of annual precipitation) at the surface. The greater soil-water content of the treatments with peat at the surface is attributed to peat having a higher water storage capacity. In addition, textural discontinuity between peat and underlying sandy subsurface materials potentially inhibits drainage. Peat as a surface material also had an influence on soil temperature. Due to its ability to insulate the soil from the atmosphere, the number of active growing days was significantly lower in the peat cover treatments relative to the LFH cover treatment. Although peat may improve vegetation production in terms of water storage, it has the potential to reduce a soils effective growing season. These relative advantages and disadvantages over a range of wet-dry conditions and whether they persist as the site soil and vegetation mature may shape the preferred reclamation soil cover design strategy.

The first full year of monitoring the dynamics of the overburden disposal area at the ASCS have shown the interactions of the vegetation, cover materials, and climate are complex and further study is required to determine the preferred cover system treatment(s) for closure of the area. Data collected so far was sufficient to provide a comparison of cover system performance and identify key trends that will affect long-term performance such as net percolation, and the length of the vegetation growing season.

Rheology and Hydrogeological Behavior of Thickened Tailings Disposal using Field Experimental Cell

Abdelkabir Maqsoud, Mamert Mbonimpa and Bruno Bussière
Université du Québec en Abitibi-Témiscamingue, Canada

ABSTRACT

Due to the current global context of the mining industry, many open pit mine projects are being developed. In the cases where the dimensions of the open pits are very important (order of km), the mining industry faces many challenges, particularly the management of mine tailings produced during mineral extractions. For that, different surface disposal technologies can be used such as dry, paste and thickened tailings disposals. These methods allow reducing the deposition area covered by the tailings and limit the environmental footprint. The rheological behavior of the tailings influences their flow distance, which in turn can affect the segregation behavior. The hydrogeological behavior of these types of deposition is mainly related to soil-atmosphere exchange.

To evaluate the geotechnical properties of thickened tailings and their hydrogeological behavior during their deposition, an experimental cell was constructed with three instrumented monitoring stations. The tailings thickness was included between 28 and 40 cm. These monitoring stations allowed to measure changes in volumetric water contents, suctions and pore pressures. Also, before tailings deposition in cell, grain-size distribution and % solids were analyzed. The % solids, rheological yield stress used as the initial design criterion correspond to 68 % and 16 Pa, respectively. During deposition, tailings samplings were performed and these samples were used to evaluate the grain size distribution and rheological properties.

The grain size distributions are typical for hard rock and did not present any segregation during tailings deposition. Rheology properties analysis show that the yield stress values obtained with the Bingham and Herschel-Bulkley models are very close to 8 Pa. The Sicko and Cross models provide similar values for the dynamic viscosity η_∞ (= 0.46 Pa.s) at high shear stress or rate ranges. Volumetric water content (VWC) measurements performed show that after tailings deposition and during drainage, the VWC are higher in the bottom and in middle than in the top tailings layer. These values remain higher in the bottom, whereas in the middle and top layer there is a rapid decrease indicating that the tailings materials drain relatively well. Finally pore pressure measurements showed that the pressure dissipation takes about 10 days to reach the initial state. These results allow concluding that these materials can be used as thickened tailings and allow to manage properly the wastes tailings and to limit the environment impact.

Keywords: Mine tailings, Experimental cell, Rheological properties, Hydrogeological

INTRODUCTION

The extraction of mineral resources plays an important role in the Canadian economy. However, ore extraction generates large amount of wastes. In Canada, about 650 Mt of solid wastes are generated each year by mining operations (*in* Winfield et al. 2002). These wastes include overburden, fine-grained mill tailings produced by the ore processing plant and waste rock extracted to reach the orebody.

Due to the current global context of the mining industry, many open pit mine projects are being developed. In the cases where the dimensions of the open pits are very important (order of km), the mining industry faces many challenges, particularly the management of mine tailings generated during mineral extractions (Oxenford & Lord 2006; Fourie 2009). Over the last few years, new and modified approaches have been proposed to increase the geotechnical and geochemical stability of mine tailings to better insure environmental protection (Bussière 2007). For the surface disposal, different technologies can be used such as 1) thickened (Robinsky 1999, Oxenford and lord 2006), 2) slurry, 3) paste (Hassani and Archibald, 1998; Benzaazoua et al. 2004), and 4) dry tailings disposals (Devies and Rice 2001, Kemp 2005). These technologies allow reducing the deposition area covered by the tailings and limit the environmental footprint.

The thickened paste technology offers significant economic incentives and environmental benefits (Meggys and Jefferies, 2012) because particle segregation cannot occurs during process, the paste material exhibits much greater stability than conventional tailings; there is no need for a pond on top of the deposit; which itself forms a gently sloping surface promoting runoff of rain water; and the overall costs are lower than for conventional slurry technologies

To evaluate the hydrogeological behavior of thickened tailings during and after deposition, an experimental cell was constructed and instrumented using monitoring stations. The main objectives of this paper are to evaluate in first the possible segregation of tailings during deposition and their rheological properties and in second the drainage behavior of the thickened tailings after deposition.

This article starts by field experimental cell description and its instrumentation followed by material characterization and rheological properties. Then hydrogeological behavior using volumetric water content and water pressure are presented. Finally this paper ends by a conclusion

FIELD EXPERIMENTAL CELL AND MATERIALS CHARACTERISATION

Experimental cell and monitoring stations

The field experimental cell was constructed using three dykes in the north, east and west side (see Fig. 1). Then three monitoring stations were installed in the thickened tailings flow direction, station 1 being closest to the discharge point. Each station is equipped with 1) 5TM sensors for volumetric water content and temperature measurements; 2) MPS sensors for the suction measurement (see Figure 1). Volumetric water content and suction sensors are connected to data logger for continuous measurements (see Maqsoud et al. 2007). The location of different sensors from the bottom, corresponding to the initial surface before deposition of tailings cell, is shown in Table 1 where one can observe that the average spacing between sensors is about 10 cm.

At each monitoring station, a well point was installed prior to the tailing depositions and it is equipped with a mini-Diver logger for continuous measurement of water pressure (see Figure 1).

Table 1 Sensor locations from the bottom surface installed at different monitoring stations

	Bottom sensors	Middle sensors	Top sensors
Station 1	10 cm	20 cm	35 cm
Station 2	7 cm	21 cm	32 cm
Station 3	9 cm	18 cm	28 cm

Figure 1 Experimental cell: a) Location of the different monitoring stations; b) details of instrumentation

After installation of monitoring stations, solid percent were verified using different methods then tailings deposition occurred in the experimental cell. Two layers were deposited in the experimental cell and during deposition 5 tailings samples were collected for each layer (see Fig. 2 for sampling locations).

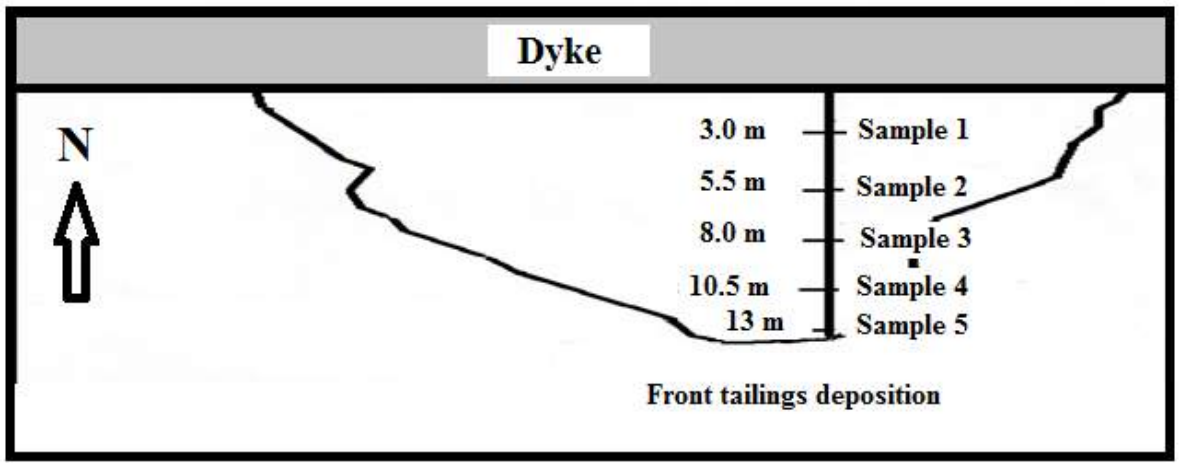

Figure 2 Samples location during tailings depositions

Grain size distribution and rheological properties

The grain-size distribution of the tailings was measured with a particle size analyzer based on laser diffraction. The apparatus used is a Mastersizer Standard Type S from Malvern Instrument (Merkus

2008; ASTM D 6913-04, 2009). The grain size measured with this equipment is included between 0.01 and 1000 μm.

The rheological properties of tailings were studied using an AR 2000 apparatus from TA Instruments. The tests were performed following the protocol:

- Preparation of a small pastefill batch (50 ml) at a given solid content;
- Pastefill mixing for 2 minutes;
- Rheological testing on a specimen of 28 mL at times t = 10 min (t =0 corresponds to the beginning of pastefill mixing);
- Each tests series was triplicated to ensure reproducibility of the results.

The rheological tests were performed at 20°C using a 14 -diameter by 42 mm-high vane geometry. The gap between the rotating vane and the wall of the stationary cylinder was 1 mm. This geometry gap must be at least 10 times higher than the largest grain size of the tested mixture. The following shear protocol was used:

- Conditioning step: a pre-shear stage of 30 s at a shear rate of 800 s^{-1} is performed;
- Flow procedures: the specimen was sheared from 800 to 0 s^{-1} using a continuous shear ramp test, stepped flow step and a steady state flow step.

The down flow and viscosity curves obtained were fitted using 4 models available in *TA instruments* data analysis software to obtain some rheological parameters such as the yield stress, etc.:

- Bingham and Herschel-Buckley models for flow curves;
- Cross and Cisko models for viscosity curves.

The Herschell–Bulkley and Bingham models are described with equations (1) and (2), respectively.

$$\tau = \tau_{0HB} + K_{HB}\dot{\gamma}^{n_{HB}} \quad [1]$$

$$\tau = \tau_{0B} + \eta_B\dot{\gamma} \quad [2]$$

The Sisko and Cross equations are defined with equations (3) and (4), respectively.

$$\eta = \eta_\infty + K_S\dot{\gamma}^{n_S-1} \quad [3]$$

$$\eta = \eta_\infty + \frac{(\eta_0-\eta_\infty)}{1+K_C\dot{\gamma}^{n_C}} \quad [4]$$

In equations (1) to (4),τ is the shear stress, $(\dot{\gamma})$ is the shear rate, and η is the dynamic viscosity. ($=\tau/\dot{\gamma}$). In eq. (1), τ_{oHB}, K_{HB} and n_{HB} represent the Herschell–Bulkley yield stress, viscosity (or consistency) and flow rate index, respectively. The following behavior applies: $n_{HB} < 1$ for shear-thinning, $n_{HB} > 1$ for shear-thickening and $n_{HB} = 1$ for Binghamn behavior (see eq. 2). In eq.(2), τ_{oB}, η_B correspond the Bingham yield stress and viscosity. In eqs. (3) and (4), η_0 and η_∞ are dynamic zero-rate ($\dot{\gamma} = 0$) and infinity-rate ($\dot{\gamma} \to \infty$) viscosities, respectively. K_s and K_c are consistency parameters and n_s and n_c are viscosity rate indexes. The performance of the different models can be compared using the standard error (SE) defined with equation (5). SE is deemed acceptable when it is less than 20 ‰ (TA Instrument manual).

$$SE = \left[\frac{\left(\frac{\sum(x_m - x_c)^2}{(N-2)}\right)^{1/2}}{\text{Range}} \times 1000\right] \quad [5]$$

where Range = difference between the maximum and minimum value measured, N is the number of points, x_m and x_c represent measured and calculated (with the fitting model) values, respectively.

MAIN RESULTS

In this paragraph, one can find results of the grain-size characterization, rheological properties and hydrogeological behavior of tailings during and after deposition.

Grain size distribution

The grain size distributions of different sampled materials are presented in figure 3 where one can observe that grain size range included between 2 and 74 µm (corresponding to silt fraction) corresponds to percent included between 65 and 69. The other percent corresponds to sand fraction. These different curves were used for determination of the geotechnical parameters D_{10}, D_{60} *and coefficient of uniformity* ($Cu = D_{60} / D_{10}$). These values are presented in Table 2, where one can observe that D_{10} is included between 6.47 and 7.16 (mean = 6.84) µm; D_{60} is included between 53.47 and 61.94 (mean = 59.84) µm and Cu, is included between 7.97 and 9.13 (mean = 8.75). These values are typical for hard rock tailings (see Aubertin et al. 2002).

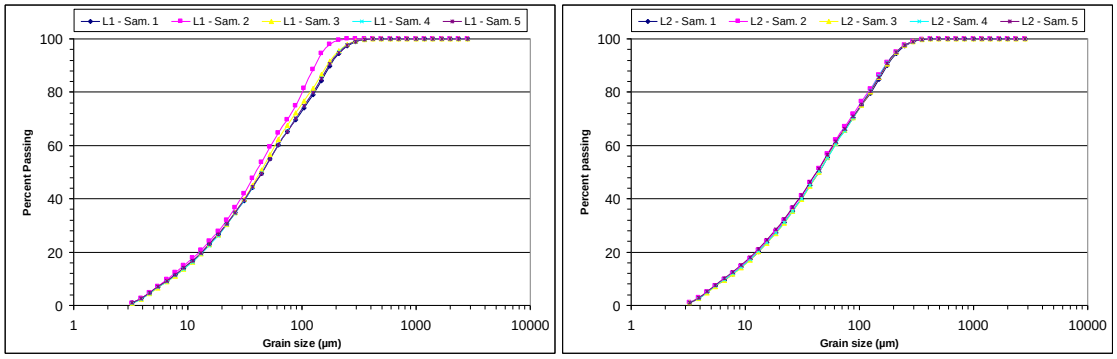

Figure 3 Grain-size distribution of tailings sampled during deposition (L1: layer 1, L2: layer 2, Sam: sample)

Tableau 2 Geotechnical parameters of tailings (Sam: sample)

	Layer 1					Layer 2				
	Sam 1	**Sam 2**	**Sam 3**	**Sam4**	**Sam 5**	**Sam 1**	**Sam 2**	**Sam 3**	**Sam 4**	**Sam 5**
D_{10} (µm)	6.96	6.71	7.16	7.11	6.93	6.77	6.66	6.93	6.74	6.47
D_{60} (µm)	61.8	53.47	58.23	61.55	61.93	60.81	58.28	61.94	61.33	59.06
Cu	8.89	7.97	8.13	8.66	8.94	8.99	8.76	8.94	910	9.13

Rheological properties

Figures 4 shows typical flow and viscosity curves obtained from the tests made following the three flow procedures. These figures show that all obtained results using different procedures are very

close. These triplicated results were merged using built-in rheological data analysis software to obtain one representative flow curve and viscosity curve. The merged flow and viscosity curves were fitted with the rheological models described above by applying the best fitting option available in the software (See Figure 5).

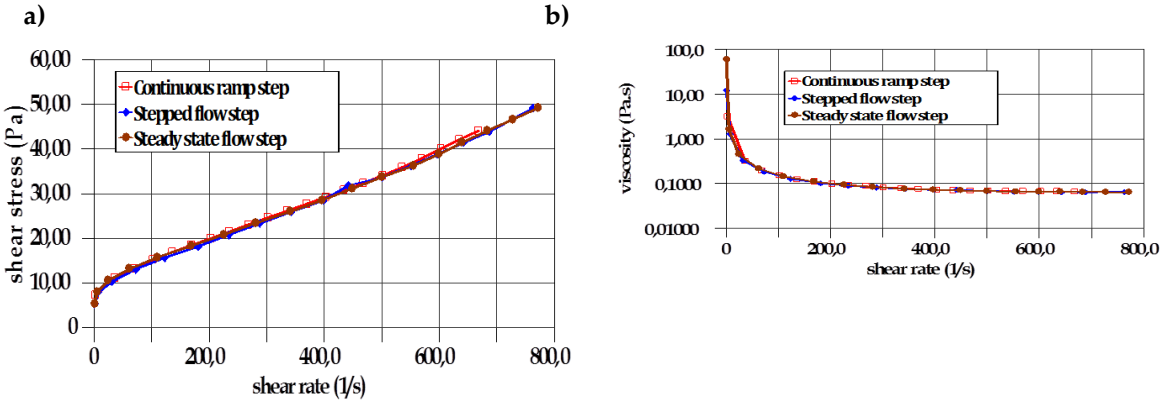

Figure 4 Flow (a) and viscosity (b) curves obtained for different flow procedures

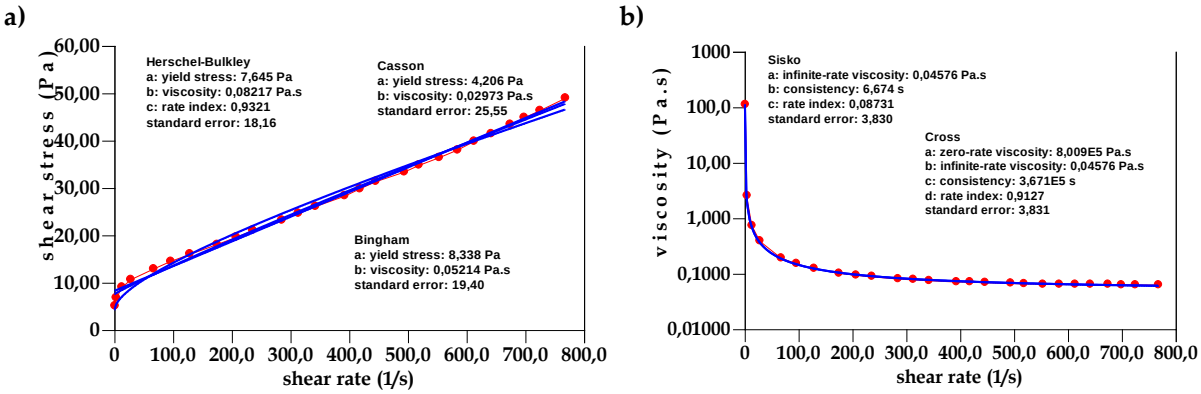

Figure 5 Merged flow (a) and viscosity (b) curves fitted with differents models

Table 3 summarizes the model parameters obtained. The yield stress values obtained with the Bingham and Herschel-Bulkley models are very close about 8 Pa.

Table 3 Rheological parameters obtained by fitting the merged flow and viscosity curves with different rheological models

Parameters	Models			
	Bingham	Herschel-Buckley	Cross	Sisko
Yield stress τ_{0B} or τ_{0HB} (Pa)	8.3	7.6	/	/
Viscosity η_B (Pa.s)	0.052	/	/	/
Consistency K_{HB} (Pa.s)	/	0.082		6.7
Rate index		0.93	0.91	0.87
Zero-rate viscosity η_0 (Pa.s)	/	/	$8x10^5$	
Infinite-rate viscosity η_∞ (Pa.s)	/	/	0.046	0.046

The Sicko and Cross models provide similar values for the dynamic viscosity η_∞ (= 0.46 Pa.s) at high shear stress or rate ranges.

Hydrogeological behavior of tailings

Volumetric water content measurement

Volumetric water content (VWC) measurements performed at stations 1, 2 and 3 (see Fig. 1 for location) are presented in Figures 6 a, b and c. Due to the experimental cell configuration (tilt from north to south) and the limited volume of deposited tailings, sensors placed at the top (see table 1 for location) were not completely covered at stations 2 and 3. For these raisons, measurements results from these sensors are not presented.

Figures 6a, b and c show that VWC at saturation is about 0.44. Also, one can observe that after tailings deposition and during drainage, the VWC are higher in the bottom and in middle than in the top tailings layer. These values remain higher in the bottom, whereas in the middle and top layer there is a rapid decrease indicating that the tailings materials drain relatively well.

It is important to recall that after tailings deposition, different fluctuations were observed in the VWC. Some of these changes are related to precipitations, such as those that took place during November 23, that induce an increase in the volumetric water content. Other fluctuations are induced by temperatures decrease (below the freezing point) causing the water freezing and therefore reducing the amount of liquid water that can be measured by the equipment (figure 6d). This effect is illustrated by the lower VWC (close to residual volumetric water content) observed at the top of the layer at stations 1 (figure 6d)

Suction measurements

Suction measurements were performed in the top and bottom at the station 1 and 3. However, for the station 2, suction measurements were performed in the bottom and middle of the layer. Due to the limited volume of tailings deposition, sensor installed in the top of station 3 was not completely covered by tailings; consequently measurements results at this level will not be presented.

Suctions measurements results (not shown here due to space limitations) indicate that there is a good agreement between volumetric water contents and suctions measurements at different tailings layers: when volumetric water contents increase, there is a drop in the suction values while when volumetric water contents fall, suction value increase. Also, in the bottom layer suction remain constant at about 10 kPa, and this until November 24. After November 24, the measured suctions value show different fluctuations (exception for station 1). It is important to recall that the observed fluctuations and particularly the suction increases are related to freeze effect. Also, in the top and in middle the tailings layer, the measured suctions show many variations that are related to drying effect during water distribution and to wetting effect of tailings by precipitations.

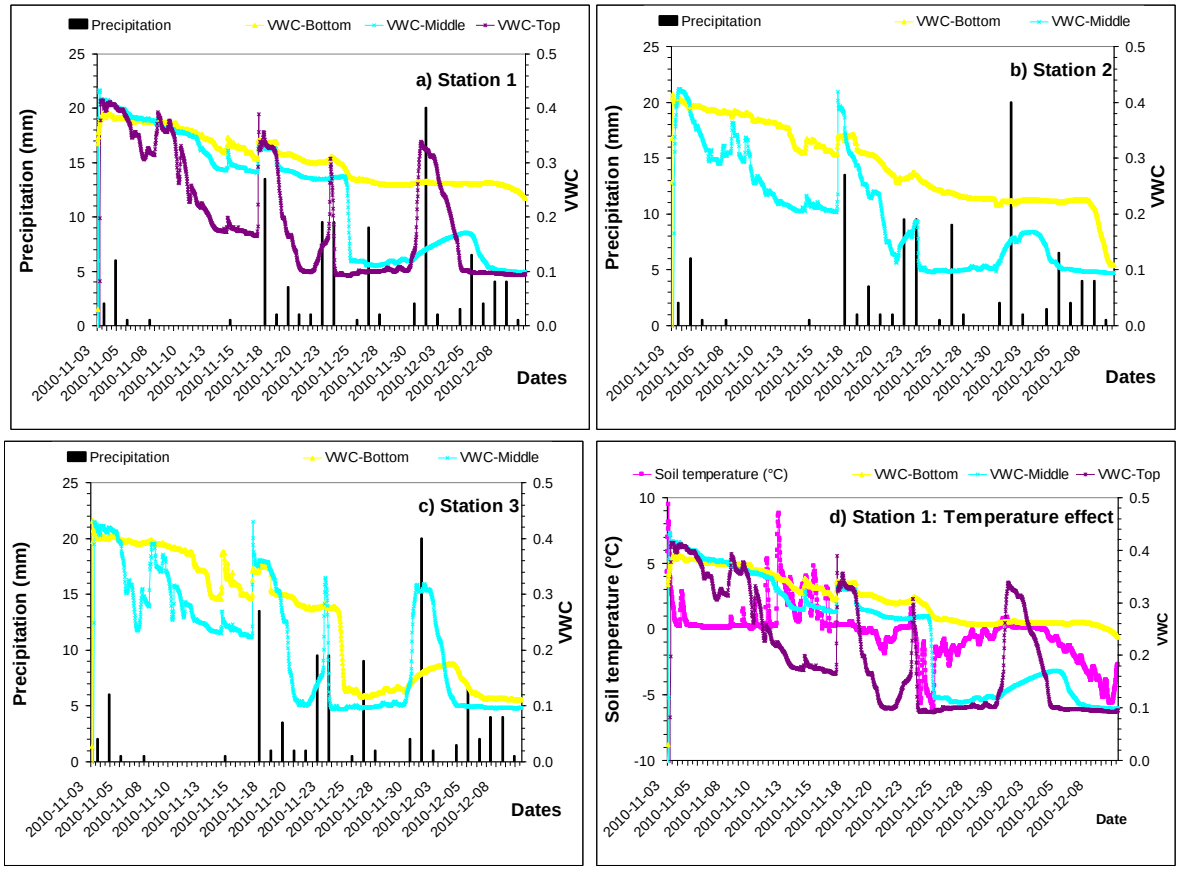

Figure 6 Volumetric water content measurements: a) station 1, b) station 2, c) station 3 and d) temperature effect

Well point pressure

Water pressures measured in the three well points are presented in Figure 7. Thus, in the three well points, one can observe in first an increase in water pressure during tailings depositions (2 and 3 November). Then there is a drop in the water pressure to reach the initial level after about 10 days (see Figure 7). Then one can observe that water pressure increases, especially during the 14, 17 and 23 November; these increases in water pressure are related to the precipitation that occurred in the region. As final remark, it is important to note that the water pressure decreases from the well point P1 (near the deposition area) to the well point P3 (at the bottom of the cell). The tailings thickness being greater near P1, it is fitting that the pore pressure is greater than that P2 and P3.

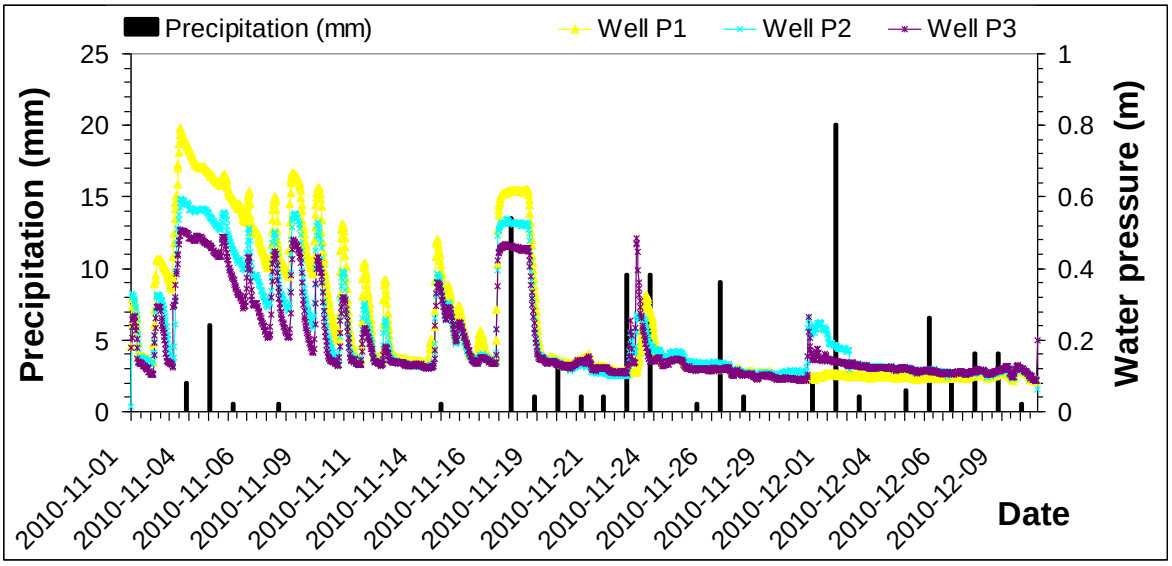

Figure 7 Water pressures measured in the three well points: P1, P2 et P3

CONCLUSION

An experimental field cell was constructed to evaluate the drainage behavior of the thickened tailings during and after deposition. Three monitoring stations were installed for volumetric water content, suction and water pressure measurements. During deposition, 10 thickened tailings samples were collected for analysis of grain size distributions and rheological properties.

Analysis results show that the grain size distributions are typical for hard rock where silt fraction corresponds to percent included between 65 and 69. Also, grain size analyzes show that there is no particle segregation during thickened tailings deposition. Rheology properties analyses show that the yield stress values, obtained with the Bingham and Herschel-Bulkley models, are very close about 8 Pa. The Sicko and Cross models provide similar values for the dynamic viscosity η_∞ (= 0.46 Pa.s) at high shear stress or rate ranges. Measurements show that after tailings deposition and during drainage, the VWC decrease from the bottom to the top layer. These VWC values remain higher at the bottom, whereas in the middle and top layer there is a rapid decrease indicating that the tailings materials drain relatively well. After tailings deposition, different fluctuations were observed in the VWC. Some of these changes are related to precipitations but others are related to freezing effect. Finally pore pressure measurements showed that the pressure dissipation takes about 10 days to reach the initial state. These results allow concluding that these materials can be used as thickened tailings and all to manage properly the wastes tailings and limit the environment impact.

Experimental Analysis on Soil-Water Characteristic Curve of CH_3COO^- Contaminated Clay

Liwen Cao, Tianyu Xu, Yong Wang and Pan Huo
School of Resource and Earth Science, China University of Mining and Technology

ABSTRACT

Based on the soil-water characteristic curve (SWCC) of CH_3COO^- contaminated clay determined by test, SWCC parameters and equations, as well as SWCC factors and its application of forecasting on permeability and shear strength of the CH_3COO^- contaminated clay are confirmed.

Comparative study on CH_3COO^- contaminated clay and non-contaminating clay are carried out, and the fitting parameters are gotten. It is found that Van Genuchten model and Fredlund-Xing model are suitable for CH_3COO^- contaminated clay. Then, such factors as concentration, initial moisture content and initial dry density influence on the soil-water characteristic curve of the CH_3COO^- contaminated clay are explored. Specially, the SWCC of CH_3COO^- contaminated clay is used to predict the permeability coefficient and shear strength of the CH_3COO^- contaminated clay in this article. The researches show as follows: with the increase of concentration of CH_3COO^-, value of air-entry suction and residual water content are reducing gradually; meanwhile, saturation moisture content is increasing, and the SWCC curve slope is rising, which indicate that water-holding capacity is declining with CH_3COO^- concentration increase. When the initial water content is equal to plastic limit, such parameters as saturation moisture content, value of air-entry suction and residual water content reach to maximum, at the same time, the soil-water characteristic curve becomes flat, which represents the maximum water-holding capacity. With the increase of initial dry density, the value of air-entry suction and residual water content are increasing, and saturation moisture content is declining. Additionally, with increasing matric suction, the permeability coefficient of the CH_3COO^- contaminated clay declines and the shear strength increases, but the changing rate becomes slower and slower.

INTRODUCTION

The soil contaminated by leachate is a common type of contaminated soil in the nature. CH_3COO^-, a common composition in the organic acid, influences the physical-mechanical properties of soil greatly. For example, the compression coefficient and deformation value of the foundation soil increasing obviously due to contamination will induce the buildings to crack. The determination of Soil-water characteristic curve is a premise of the study on physical-mechanical properties of soils. Thus, it is important to research contaminated soil and its soil-water characteristic curve (SWCC).

The researches on contaminated unsaturated soils are performed widely at home and abroad. A migration model on heavy metal in unsaturated soil was established (Chen W *et al*., 2010). The component and physical property of clay before and after the contamination of hydrochloric acid and sodium hydrate were analyzed (Zhang X.L. 2007). Bo researched the physical-mechanical properties and structure as well as corrosion mechanism of hydrochloric acid contaminated red clay (Bo T.Z. 2012), and Cao researched the influence of concentration of sulphuric acid and corrosion time on the physical-mechanical properties of clay (Cao H.R. 2012). Additionally, some researchers focused on salt contaminated soils, for example, physical-mechanical properties of clay change with the concentration of salt solution (Niu X.L. 2009). In the aspects of soil-water characteristic curve of unsaturated soil, the relationship between void ratio and soil-water characteristic curve of unsaturated soil, as well as the prediction of soil-water characteristic curve through any initial void ratio was involved (Chen G.F. *et al*., 2008.Cai G.Q. *et al*.,2010).

However, the leachate contaminated clay, especially CH_3COO^- contaminated clay, is scarcely touched upon. Based on theory of the unsaturated soil mechanics, the author investigates the soil-water characteristic curve of CH_3COO^- contaminated clay, and its influence factors, and then the parameters and equations of CH_3COO^- contaminated clay are confirmed.

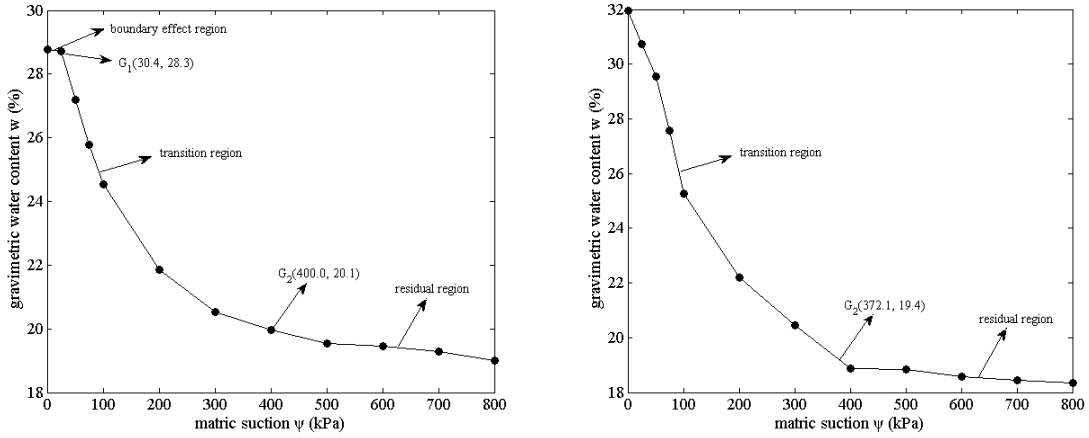
THE SOIL-WATER CHARACTERISTIC CURVE OF CH_3COO^- CONTAMINATED CLAY

The SWCC feature of CH_3COO^- contaminated clay

The CH_3COO^- contaminated clay sample was prepared through soaking in 10% of acetic acid solution. According to the test data, soil-water characteristic curve of CH_3COO^- contaminated clay is obtained.

As is illustrated in Figure 1, the SWCC of CH_3COO^- contaminated clay shows the same tendency with that of uncontaminated clay. With increasing matric suction, the water content is declining, specially, the water loss rate declines obviously in high matric suction stage. Furthermore, the SWCC of uncontaminated clay can be divided into three sections named as boundary effect region, transition region and residual region by two inflection points G_1 and G_2. Similarly, the SWCC of CH_3COO^- contaminated clay can be divided into two sections named as transition region and residual region by one inflection point G_2 without boundary effect region. The same feature is

presented in CH_3COO^- contaminated clay and non-contaminated clay in the transition region and residual region.



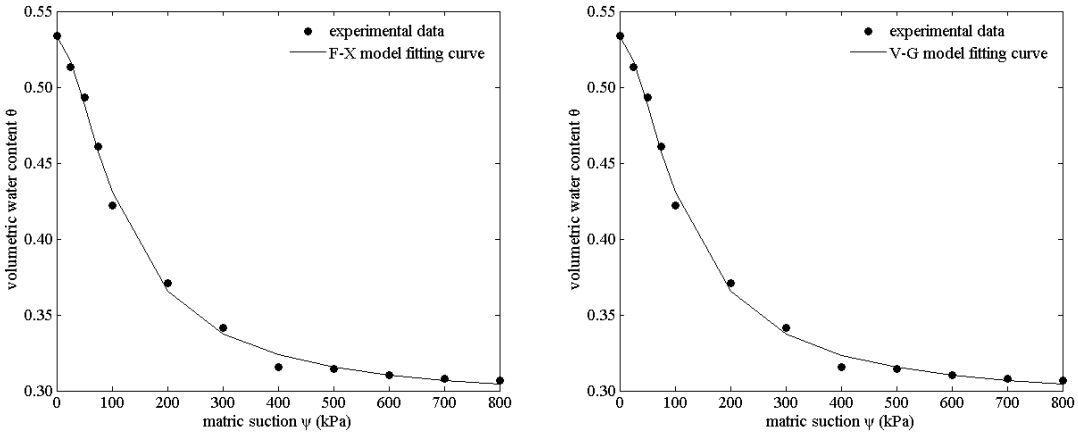
(a) SWCC of uncontaminated clay (b) SWCC of 10% of CH_3COO^- contaminated clay

Figure 1 SWCC of uncontaminated and 10% of CH3COO- contaminated clay

Meanwhile, the saturation moisture content of CH_3COO^- contaminated clay is greater than that of uncontaminated clay; however, the residual moisture content shows a contrary trend. Additionally, the gradient of soil-water characteristic curve of CH_3COO^- contaminated clay is larger than that of uncontaminated clay, which indicates the moisture holding capacity of the clay declines due to CH_3COO^- contamination.

The SWCC model of CH_3COO^- contaminated clay

Among the soil-water characteristic curve models, Van Genuchten model and Fredlund-Xing model are frequently used with characteristic of considering more factors and higher representative (Guo *et al.*, 2013).



(a) V-G model fitting (b) F-X model fitting

Figure 2 The fitting curves of 10% CH_3COO^- contaminated clay

In this paper, the scatter diagram on soil-water characteristic curve of CH_3COO^- contaminated clay is drawn from experimental data, then, Van Genuchten model (V-G model) and Fredlund-Xing model (F-X model) are used for fitting, as showed in Figure 2.

The soil-water characteristic curve model equations are demonstrated as follows:

$$\theta_w = 0.279 + \frac{0.255}{\left[1+\left(0.23\varphi\right)^{1.72}\right]^{0.88}} \quad (1)$$

$$\theta_w = 0.281 + \frac{0.253}{\left\{\ln\left[e+\left(0.13\varphi\right)\right]^{1.66}\right\}^{1.97}} \quad (2)$$

THE EFFECT FACTORS ON SWCC OF CH_3COO^- CONTAMINATED CLAY

The effect of acetic acid concentration on SWCC of CH3COO- contaminated clay

The CH_3COO^- contaminated clay samples with four concentrations: 1%, 4%, 7% and 10% of acetic acid were prepared. The SWCCs of the clay samples are tested as shown in Figure 3 with the corresponding relation between volumetric water content and matric suction displayed in Table 1.

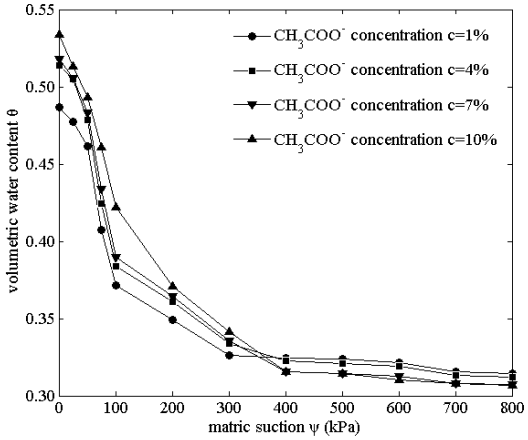


Figure 3 The SWCC of contaminated clay with different acetic acid concentrations

With increasing acetic acid concentration, the saturation moisture content of CH_3COO^- contaminated clay is rising. In the stage of lower matric suction (0-350kPa), the corresponding moisture content is increasing gradually with the acetic acid concentration rising as to the same matric suction, on the other hand, the SWCCs in the stage of higher matric suction (>350kPa) show a contrary trend.

Suffered from acetic acid pollution, the clay mineral compositions change significantly. For instance, mental salts are dissolved. High valence ions such as Al, Si and Fe, as well as Na, Mg, K, Ca and other elements content reduce significantly. With the increase of acetic acid concentration,

the dissolution increases obviously, while the adsorption capacity of soil particles to water and water holding capacity gradually decreases. Meanwhile, with the increase of acetic acid concentration, the clay porosity and pore size increase, thus inducing the decrease of value of air entry, water holding capacity and residual water content.

Table 1 The volumetric water content and matric suction of contaminated clay with different concentrations

The effect of initial water content on SWCC of CH_3COO^- contaminated clay

The CH_3COO^- contaminated clay samples with three initial water contents: 15%, 21% and 27% were prepared. The SWCCs of the clay samples are tested as shown in Figure 4 with the corresponding relation between volumetric water content and matric suction displayed in Table 2.

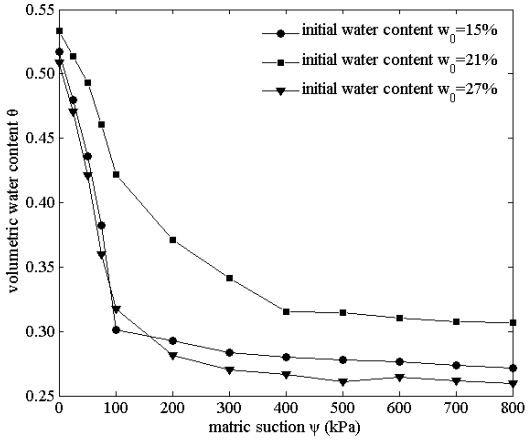

Figure 4 The SWCC of contaminated clay with different initial water contents

Table 2 The matric suction and volumetric water content under different initial water content of CH_3COO^- contaminated clay

matric suction kPa	w_0=15%	w_0=21%	w_0=27%
0	0.5172	0.5337	0.5086
25	0.4796	0.5135	0.4703
50	0.4357	0.4932	0.4215
75	0.3825	0.4607	0.3597
100	0.3013	0.4218	0.3173
200	0.2928	0.3710	0.2812
300	0.2837	0.3414	0.2701
400	0.2801	0.3154	0.2668
500	0.2778	0.3145	0.2610
600	0.2765	0.3105	0.2648
700	0.2733	0.3078	0.2617
800	0.2714	0.3065	0.2598

When the initial water content is equal to plastic limit 21%, such parameters as saturation moisture content, value of air-entry suction and residual water content reach the maxima, at the same time, the soil-water characteristic curve becomes flat, which represents the maximum water-holding capacity.

The initial water content has important effect on clay pore structure. When initial water content is small, the clay possesses lower value of air entry and the water holding capacity. When the water content increases to plastic limit, the clay possesses optimal pore arrangement, inducing the water holding capacity, saturated moisture content and residual water content reached the maxima. When the water content increases continually, the adsorption ability of clay particles decrease, causing the water holding capacity, saturated moisture content and residual water content declines as well.

The effect of initial dry density on SWCC of CH_3COO^- contaminated clay

CH_3COO^- contaminated clay samples with three initial dry densities: 1.64g/cm^3, 1.72g/cm^3 and 1.78g/cm^3 were prepared. The SWCCs of the clay samples are tested as shown in Figure 5 with the corresponding relation between volumetric water content and matric suction displayed in Table 3.

With the increase of the initial dry density, the CH_3COO^- contaminated remolded clay has the smaller saturation moisture content, but the bigger value of air-entry suction and residual water content. The curve slope increasing represents the water holding capacity rising.

The influence of initial dry density on SWCC of CH_3COO^- contaminated clay is realized by changing clay pore structure. With increasing initial dry density, the clay pore space decline gradually, thus decreasing the water storage space and saturated water content of the clay. With the increase of dry density and the decrease of pore space, the specific surface area of clay particles

increases, enhancing the adsorption to water, water holding capacity, air entry value and residual water content greatly under the same matric suction.

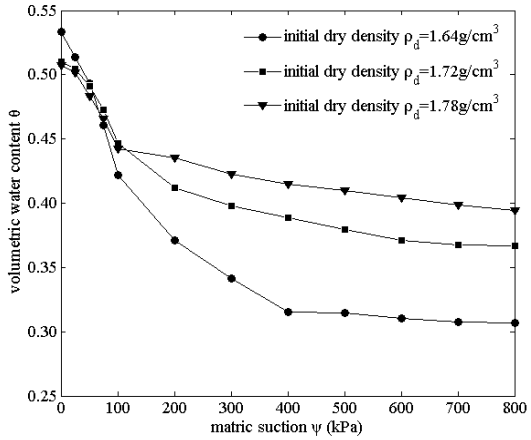

Figure 5 The SWCC of CH_3COO^- contaminated clay with different initial dry densities

Table 3 Matric suction and volumetric water content under different initial dry density

matric suction kPa	ρ_d=1.64g/cm^3	ρ_d=1.72g/cm^3	ρ_d=1.78g/cm^3
0	0.5337	0.5102	0.5075
25	0.5135	0.5043	0.5018
50	0.4932	0.4911	0.4832
75	0.4607	0.4725	0.4653
100	0.4218	0.4468	0.4424
200	0.371	0.4117	0.4356
300	0.3414	0.3981	0.4223
400	0.3154	0.3885	0.4148
500	0.3145	0.3793	0.4096
600	0.3105	0.3713	0.4045
700	0.3078	0.3674	0.3989
800	0.3065	0.3668	0.3944

Additionally, with the matric suction increasing, the permeability coefficient of the CH_3COO^- contaminated clay declines and the shear strength increases, but the changing rate becomes slower and slower.

FORECASTING ON PERMEABILITY COEFFICIENT AND SHEAR STRENGTH OF THE CH_3COO^- CONTAMINATED CLAY

In this paper, SWCC was used to predict the permeability coefficient and shear strength of the CH_3COO^- contaminated clay. Jackson equation and Vanapalli equation are used to predict the

permeability coefficient and shear strength of the CH_3COO^- contaminated clay as to the same permeability coefficient and shear strength of the CH_3COO^- contaminated clay sample. The relevant forecasting equations show as follows:

$$k = 6.38\times10^{-13}\times\left(2.76\times10^{15}\right)^{\theta} \tag{3}$$

$$k = e^{-8.8-0.04\varphi+6.16\times10^{-5}\psi^2} \tag{4}$$

$$\tau = 4.3\times10^{5} - 3.3\times10^{-5}e^{25\theta} - 4.3\times10^{5}e^{7.69\times10^{-6}\theta} \tag{5}$$

$$\tau = 5.4\times10^{5} - 19e^{-0.02\psi} - 5.4\times10^{5}e^{1.43\times10^{-6}\theta} \tag{6}$$

The above equations can be used to forecast the permeability coefficient and shear strength of the CH_3COO^- contaminated clay.

CONCLUSIONS

Based on the experiment of the CH_3COO^- contaminated clay, the soil-water characteristic curve (SWCC) of CH_3COO^- contaminated clay and their SWCC parameters as well as equations are obtained, meanwhile, SWCC factors and its application of forecasting on permeability and shear strength of the CH_3COO^- contaminated clay are confirmed.

(1) It is found that Van Genuchten model and Fredlund & Xing model are suitable for CH_3COO^- contaminated clay.

(2) Such factors as concentration, initial moisture content and initial dry density influence on the soil-water characteristic curve of the CH_3COO^- contaminated clay are explored, meanwhile, their influence mechanism are touched upon.

With the increase of concentration of CH_3COO^-, value of air-entry suction and residual water content are reducing gradually; meanwhile, saturation moisture content is increasing, and the SWCC curve slope is rising, which indicate that water-holding capacity is declining with CH_3COO^- concentration increase. When the initial water content is equal to plastic limit, such parameters as saturation moisture content, value of air-entry suction and residual water content reach the maxima, at the same time, the soil-water characteristic curve becomes flat, which represents the maximum water-holding capacity. With the increase of initial dry density, the value of air-entry suction and residual water content are increasing, and saturation moisture content is declining. The shape of the water content curve is more sensitive to the initial dry density value than the concentration of acetic acid.

(3) The SWCC of CH_3COO^- contaminated clay is used to predict the permeability coefficient and shear strength of the CH_3COO^- contaminated clay, and the related forecasting equation are obtained.

Simulation of Contaminant Transportation in Saturated Transparent Rock Fractures

Wanghua Sui and Hao Qu
School of Resources and Geosciences, China University of Mining and Technology

ABSTRACT

This paper presents an experimental investigation of flow of contaminated water in saturated rock fractures by using a transparent fractured rock replica for visualizing contaminant transport. The transparent fractured rock model is composed of transparent silica blocks and matched refractive index pore fluids. A dyed fluid is used for simulating contaminants. The experimental setup consists of a Plexiglas container, a contamination injection system and three CCD cameras. The transport images during testing are captured by the three cameras in orthogonal directions. Digital image processing is applied to analyze the greyscale to detect the edge of the transportation front and to calculate penetration length and area at different times. A roughly circular plume is found when the fractures filled with transparent silica grains. The results indicate a square relationship between the penetration length and the cubic root of injection time, and a square relationship between the propagation area and the injection time in the fractures. The results also verified the possibility for simulation of contaminant transport in a fractured rock mass by using a transparent rock replica.

Keywords: Contaminant transport; rock fracture; digital image correlation; transparent rock replica; transparent soil

INTRODUCTION

In recent years, transparent models have been successfully applied to investigate contaminant transport in porous media (Mannheimer and Oswald 1993; Iskander et al. 2003; Liu et al. 2005; Lo et al. 2008; Fernandez et al. 2011; Liu et al. 2013). However, the transparent model has not been used to study contaminant transport in fractured rock mass. The difficulty of the visualization inside a rock mass limits the understanding of contaminant transport during water drainage due to mining. This paper presents a preliminary extension of the transparent soil modelling techniques to simulate contaminant transport in rock fractures. A transparent rock replica is constructed to document contaminant propagation in saturated fractures filled with fused silica grains.

EXPERIMENTAL SET UP AND PROCEDURE

Experimental setup and transparent model preparation

The experimental setup consists of a transparent fractured rock replica, an injection system, an optical detecting system and data collectors. All of the experimental devices were built on a vibration isolation optical platform.

Transparent fractured rock model

Silica blocks that were 2 cm (length) × 2 cm (width) × 2 cm (depth) in size were used to replicate fractured rock in this experimental investigation. The apertures between silica blocks were considered as rock fractures. A regular fracture network could be built when the silica blocks were placed in order. The fractures in the blocks were filled with fused silica grains with a particle size between 0.1 to 1 mm. The refractive index (RI) of the fused silica was 1.4585. The related physical properties of the fused silica can be found in Liu et al. (2013) and were generally similar to those of Chinese standard sand. Calcium bromide solution was applied as pore fluid, which can be made the same RI as the fused silica and can be completely mixed with the fused silica. $CaBr_2$ which is white powder or crystals with a purity of more than 96% was used to prepare the calcium bromide solution. A series of trial and error tests shows that the RI of calcium bromide solution reached 1.4585 at a concentration of approximately 65% thus the best transparency achieved. An ink-dyed calcium bromide solution was used to simulate the contaminant. When the contaminant propagates among the fractures, the position of the contaminant front in every fracture could be easily observed and recorded since the fractured rock replica is transparent.

The injection system and the optical detecting system

Fig. 1 shows an overall schematic of experiment set up. A similar drip injection method was used by Hayashi, et al. (2006). The injection pressure was about 1500 mm high which approximates a pressure of 15 kPa. An injection needle with an inner diameter of 1.2 mm was inserted into the model at a depth of 25 mm below the sample surface. The injection system was connected with transparent pneumatic tubes. A point contaminant source was then simulated by the injection at the end of the needle.

The optical system was a modified particle image velocimetry (PIV) system. Three black and white Charge Coupled Device (CCD) cameras were connected to a computer for image capturing and collecting. The CCD cameras had a resolution of 1024 × 768 pixels and a maximum frame rate of 30

frames per second (fps). The CCD cameras were controlled by a computer through the MV Capture 2.0 program.

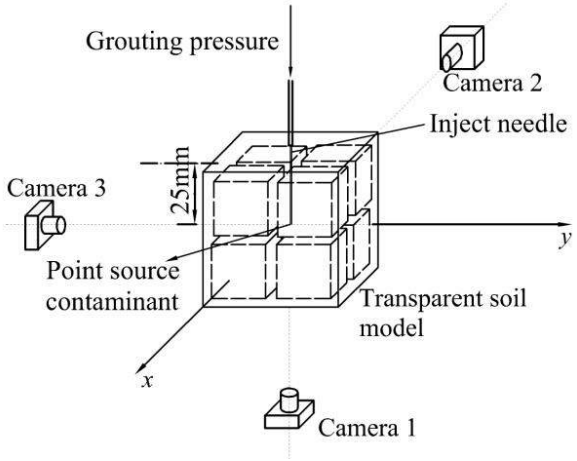

Figure 1 Schematic of experimental set up

Transparent model preparation

The transparent model was constructed in a transparent Plexiglas mold with an inner size of 5 cm (length) × 5 cm (width) × 5 cm (depth). Four silica blocks were evenly and symmetrically packed in blocks of 2 × 2 to form a layer of the rock replica. The fractures with an aperture of about 3 mm were filled with fused silica grains and pore fluid. The model was then de-aerated by using a vacuum pump to achieve the best transparency. Fig. 2 shows the transparent replica and its transparent effect.

Test procedure

A background image was taken before the injection. Once the injection pipe was turned on, a series of images were then captured during the injection at a frame rate of 30 fps until the test stopped after 22 s of contaminant injection.

RESULTS AND ANALYSIS

Propagation characteristics of contaminant front

Fig. 3 shows some images captured by Camera 2 at different times during the experiment, in which the contaminant transport process lasted for about 22 s and approximately 2000 images were captured. The contaminant propagates almost symmetrically. The contaminant first penetrates in a nearly circular shape inside the fractures; see Figs. 3(a) to 3(e). However, the contaminant did not propagate in an entirely circular shape; see Figs. 3(f) to 3(j). The contaminant front appeared inside the fractures where the penetration was faster. With a longer time, the propagation boundary became more irregular. The pore structure of the fused silica sands themselves caused the plume-shaped edges of the propagation front.

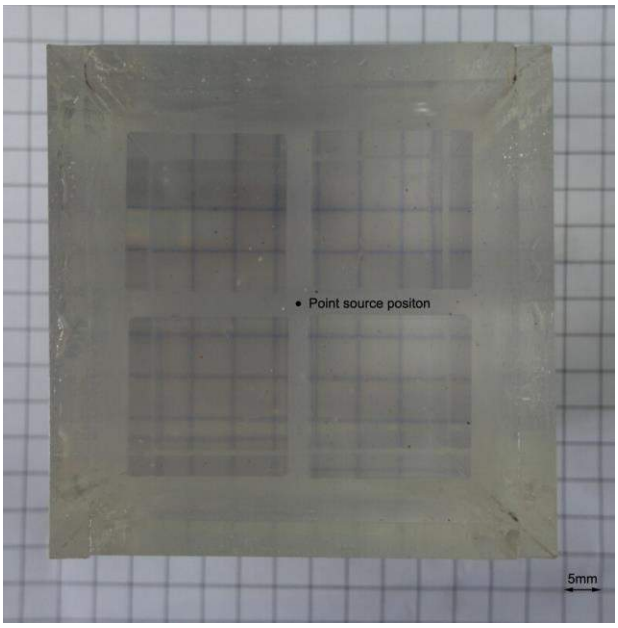

Figure 2 Transparent silica rock replica

Contaminant penetration length and propagation area

The images captured in the test were analyzed by digital image process software. The propagation front was traced to acquire perimeter. The propagation area was calculated according to the traced data. Table 1 lists the image scale coefficients calculated in accordance with the pixel value and real size of the silica blocks.

Table1 Scale coefficients of images in accordance with size of silica block

Location	Pixel value	Real size (cm)	Length scale coefficient (cm^{-1})	Area scale coefficient (cm^{-2})
Camera1, underneath the model	256	2	128	16384
Camera 2, behind the model	233	2	116.5	13572
Camera 3, on the left of the model	233	2	116.5	13572

Fig.4 shows the maximum penetration length of the contaminant in the images. The equations are as follows

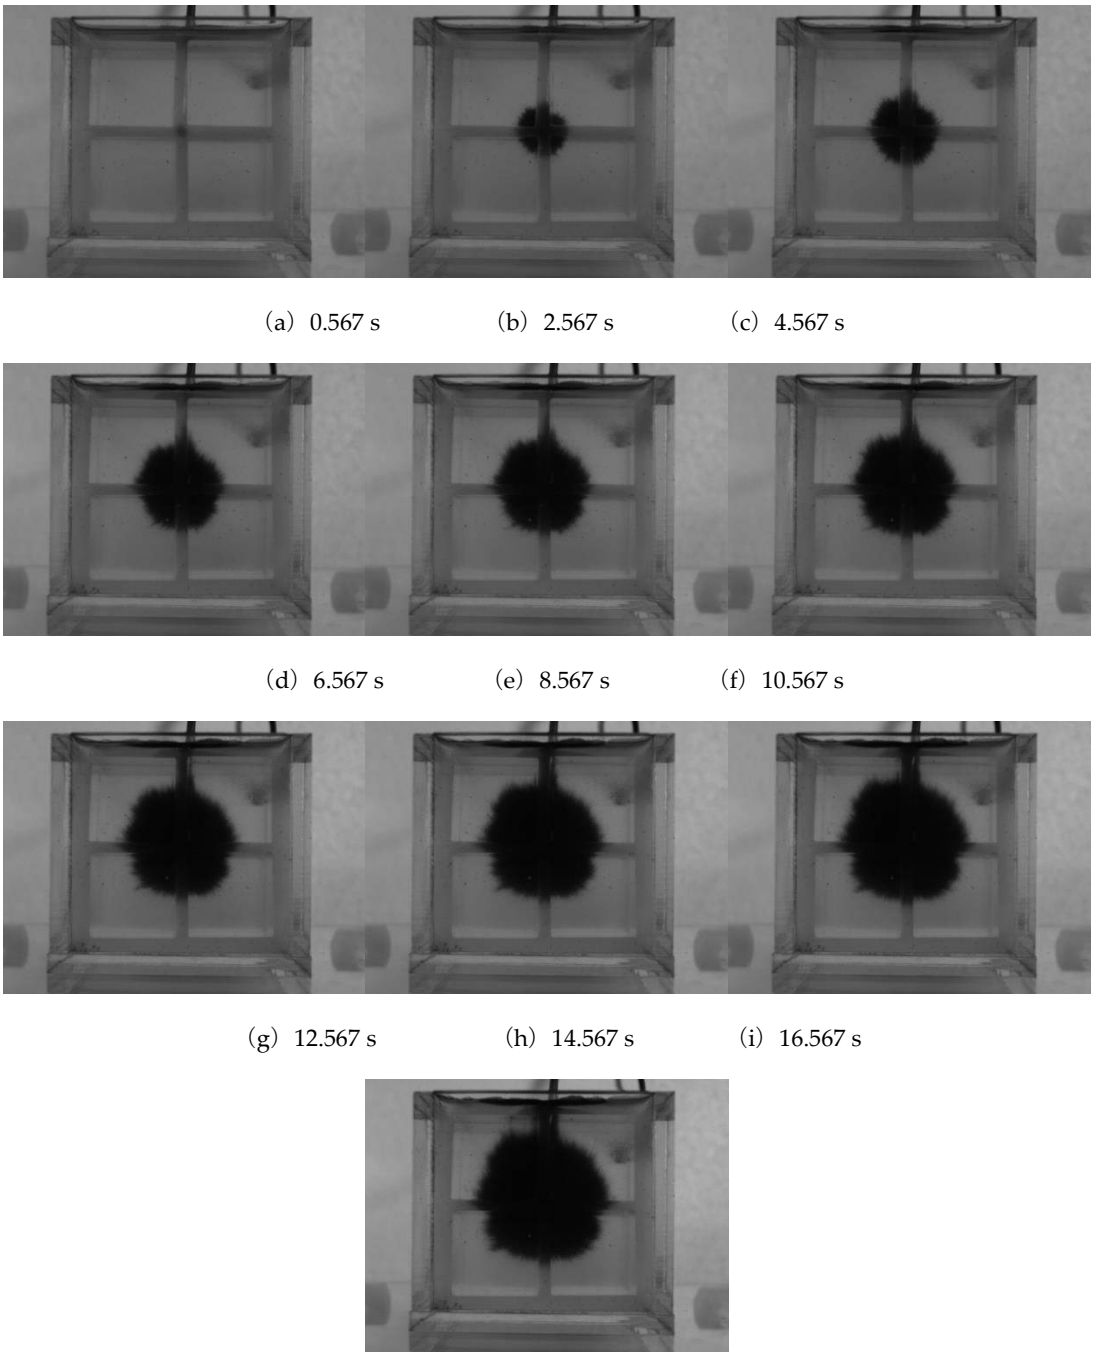
$$L_N = -2.31t^{2/3} + 18.01t^{1/3} - 13.16 \quad (1)$$

$$L_B = -1.18t^{2/3} + 11.52t^{1/3} - 7.96 \quad (2)$$

$$L_L = -1.23t^{2/3} + 12.76t^{1/3} - 8.71 \quad (3)$$

Where L_N = contaminant penetration diameter taken from underneath the model, mm; L_B = contaminant penetration diameter taken behind the model, mm; L_L = contaminant penetration

diameter taken on the left side of the model, mm; and t = injection time, s. The start times of contaminant propagation in three locations were 0.412 s, 0.456 s and 0.535 s, respectively.



(a) 0.567 s (b) 2.567 s (c) 4.567 s

(d) 6.567 s (e) 8.567 s (f) 10.567 s

(g) 12.567 s (h) 14.567 s (i) 16.567 s

(j) 18.567 s

Figure 3 Contaminant propagation images captured by Camera 2 at different times

The border of the propagation for every image was approximately traced, and the propagation area was calculated. Fig. 5 shows the variation in the contaminant propagation area with time. The equations are as follows

$$A_N = -0.020t^2 + 0.892t - 0.758 \quad (4)$$

$$A_B = -0.006t^2 + 0.532t - 0.120 \quad (5)$$

$$A_L = -0.005t^2 + 0.550t - 0.199 \quad (6)$$

Where A_N = contaminant propagation area taken from underneath the model, cm²; A_B = contaminant propagation area taken behind the model, cm²; A_L = contaminant propagation area taken on the left side of the model, cm²; and t = injection time, s. The start times are 0.332 s, 0.455 s and 0.590 s, respectively.

CONCLUSIONS

This paper has presented an experimental investigation in which contaminant transportation phenomena were observed in a saturated transparent fracture replica filled with sand grains by using three CCD cameras. A series of images during contaminant transport have been captured and analyzed to identify the plume boundary, penetration length, and propagation area.

The results indicate that there is a square relationship between the maximum penetration length and the cubic root of injection time, and also a square relationship between the contaminant transport area and injection time when the pressure head is constant.

This paper is a very preliminary attempt to investigate the possibility of real-time observation of contaminant transport in a rock fracture replica. There are still many factors that need to be taken into consideration in further studies for more real and complicated geological conditions, such as different fracture shapes, dip angles, groundwater pressures. Furthermore, physical and chemical interactions should also be considered in future investigation.

Reactive Transport Model of the Carbonate-Evaporite Elk Point Group Underlying the Athabasca Oil Sands

Matt Neuner and Skya Fawcett
Golder Associates, Canada

ABSTRACT

A reactive transport model was constructed to investigative how the carbonate-evaporite aquifer system within the Devonian Elk Point Group in northeast Alberta has evolved over geologic time and to evaluate connectivity in the present system. The mineable area of the Athabasca Oil Sands overlies the Elk Point Group where regional dissolution of halite and anhydrite has eroded the Prairie Evaporite Formation from a thickness of approximately 260 m to as thin as 20 m. Groundwater chemistry changes along the flowpath towards the Athabasca River, reflecting the evaporite distribution. Water types change from bicarbonate- to sulphate- to chloride-types, and salinities increase exponentially toward saturation with respect to halite. The model was constructed as a 1-D domain in PHREEQC to simulate the regional dissolution of the evaporites, using hydraulic testing results, isotopic data, and the measured hydrochemistry to constrain the transport parameters. The dual porosity function in PHREEQC was needed to calibrate the model to the measured chloride distribution over the 90 km-long model domain, indicating the role of mass transfer from poorly-connected regions of the aquifer system. The simulated duration of the regional dissolution was on the order of 50,000 to 500,000 years, suggesting that the phases of dissolution postulated from geologic evidence from the pre-Cretaceous to the Holocene (Stoakes et al. 2014a) may have consisted of relatively shorter pulses of dissolution. Two types of accelerated anhydrite dissolution and dedolomitization are identified for the current conditions: anhydrite/gypsum removal by low-TDS, bicarbonate-dominated waters and increased anhydrite/gypsum solubility with higher salinity. Both of these processes appear to be occurring within approximately 20 km east of the Athabasca River. Reactive transport modelling of the regional system may help to identify local areas of karst development and vertical connection to open-pit mines in the overlying McMurray Formation.

Keywords: Reactive transport carbonate evaporite karst

INTRODUCTION

The mineable Athabasca Oil Sands Area (AOSA; Figure 1) is underlain by a carbonate-evaporite aquifer system with hydraulic heads >50 m above the planned base of the open-pit mines. A karst-type inflow of saline water to one of the mines in 2010 demonstrated the high degree of vertical connectivity to this aquifer system where hydraulic windows exist (Wozniewicz et al. 2014). Characterization of the Devonian strata and specifically the aquifer system within the Elk Point Group in the region has increased significantly since the 2010 karst inflow event.

This study presents a reactive transport model that provides an investigative tool to aid in attempts to identify regions with highly-transmissive karst and potential vertical connectivity between the Elk Point Group and overlying McMurray Formation. The model was also used to explore the evolution of the Elk Point aquifer system over geologic time and to postulate a mechanism for the present-day hydrochemical distribution. Data from previously published studies were used to calibrate the model, as the geochemical interpretation from recent field programs at several operating mines is ongoing. Dedolomitization is assessed at a regional scale, as it has been recognized as a key process resulting in enhanced permeability laterally within the Elk Point aquifer system and potentially also enhancing vertical connectivity (Wozniewicz et al. 2014).

BACKGROUND

Geologic Setting

The mineable AOSA is near the northeast edge of the Western Canadian Sedimentary Basin (Figure 1), where the Phanerozoic strata form a wedge over the Canadian Shield with maximum thickness of approximately 700 m. Devonian strata consisting primarily of marine carbonates regionally dip to the southwest (Figure 2) due to subsidence associated with formation of the Rocky Mountains. Cretaceous sediments including the McMurray Formation, which hosts the oil sands deposit, overlie a 200 million year gap in the geologic record referred to as the Pre-Cretaceous unconformity.

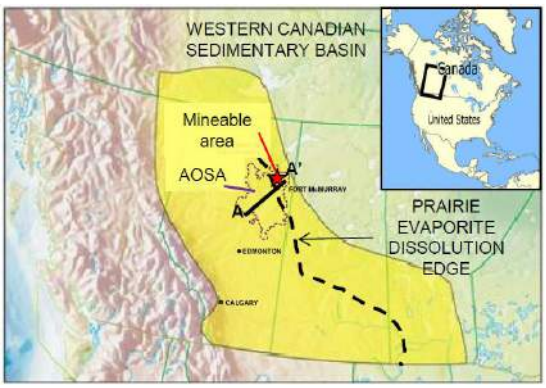

Figure 1 The mineable Athabasca Oil Sands Area

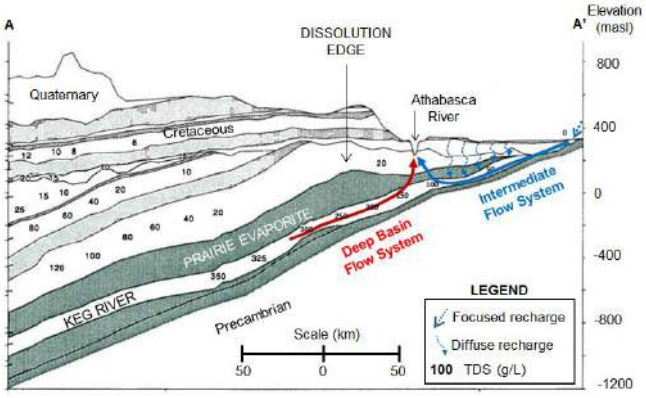

Figure 2 Cross section through Northeast Alberta

The Devonian Elk Point Group includes porous reef buildups of the Keg River Formation and an evaporative sequence in the Prairie Evaporite Formation, which on-laps the reefs. The Prairie Evaporite Formation was deposited as brining-upward sequences of dololaminites, anhydrite, and halite (Stoakes et

al. 2014b). These two formations are overlain by approximately 60 m of primarily marine carbonates and shales, which are referred to here as the Upper Devonian.

Infiltrating meteoric waters to the eastern edge of the basin have dissolved the Prairie Evaporite Formation from an initial thickness of approximately 260 m west of the dissolution edge (Figure 1) to as thin as 20 m near the basin edge. This dissolution resulted in extensive collapse of the overlying strata and enhanced permeability within the Prairie Evaporite Formation.

Physical Hydrogeology

Dololaminites in the lower Prairie Evaporite Formation form a highly transmissive (10^{-3} to 10^{0} m^2/s) aquifer where they have been more extensively dedolomitized, as evident in regional responses to the 2010 inflow event (Wozniewicz et al. 2014). This event provided direct evidence of karst in the Devonian strata and of good connection in places between the Elk Point and the overlying McMurray Formation, neither of which had previously been unequivocally accepted (e.g., Alsands 1981). Reefs in the Keg River Formation form aquifers capable of sustained wastewater injection (1,733,000 m^3 over ten years; Husky 2011). Most multi-day hydraulic tests in the region have been conducted over both of these formations and have yielded transmissivities on the order of 10^{-5} m^2/s. The Prairie Evaporite Formation on-laps to the sides of reefs suggesting some degree of connection; hence, the two aquifers are collectively referred to as the Elk Point aquifer system.

The Elk Point aquifer system is highly heterogeneous, and flow paths at the sub-lease scale are thought to follow complex fracture networks with a wide range of connectivity. At the regional scale, the subcrop of the Elk Point Group beneath Quaternary sediments near the provincial border (Figure 3) provides focused recharge to the aquifer system. Groundwater flows from the subcrop generally westward toward the discharge zone at the Athabasca River, and the system also receives more diffuse vertical recharge through the overlying units (Figure 2).

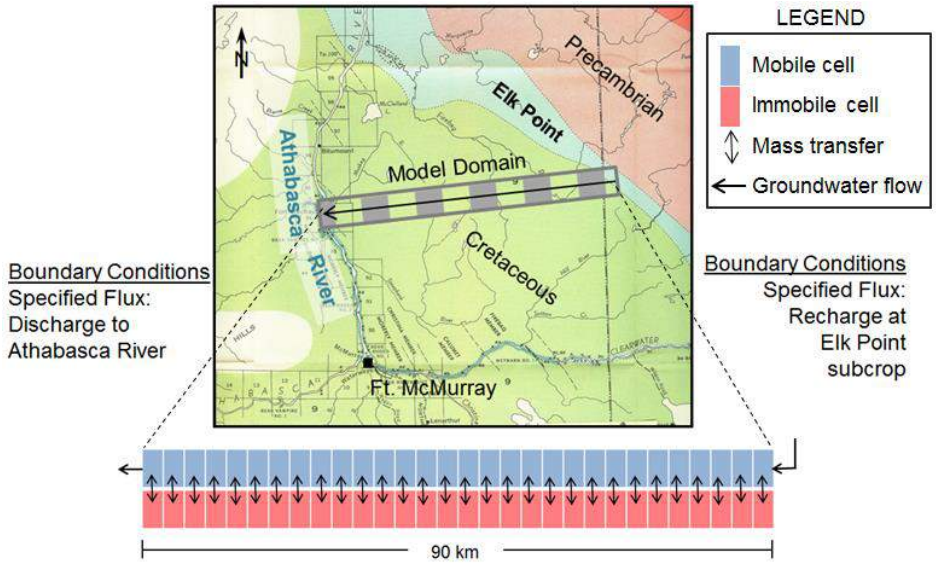

Figure 3 Geologic map: units subcropping beneath Quaternary sediments (Norris 1963), adapted with regional flow directions in the Elk Point and the 1-D domain for the reactive transport model.

GEOCHEMISTRY OF THE ELK POINT AQUIFER SYSTEM

The regional distribution of evaporite minerals in the Prairie Evaporite Formation (Figure 4) provides a primary control on the hydrochemistry within the Elk Point aquifer system. Generally in the region, halite is still present and dissolving between the dissolution edge and the Athabasca River. Within approximately 20 km to 30 km east of the Athabasca River halite has been removed and anhydrite is dissolving, while in the eastern part of the region both halite and anhydrite have been removed leaving an extensively collapsed region with dolomite the primary mineral (Figure 4; Schneider and Grobe 2013).

A preliminary model was constructed in PHREEQC (v. 3.06; Parkhust and Appelo 2013) to begin investigating the relationship between dissolution of the Prairie Evaporite over geologic time and the present day hydrochemistry. A batch model domain of one litre was filled with an approximate composition of Prairie Evaporite Formation prior to dissolution, based on publically-available geologic logs: 40% dolomite ($CaMg(CO_3)_2$), 20% halite (NaCl), 20% anhydrite ($CaSO_4$), 20% calcite ($CaCO_3$), and 10% porosity. The model domain was then successively flushed with pure water equilibrated with atmospheric CO_2 (pCO_2 10^{-2} atmospheres [atm]) and allowed to equilibrate to these minerals and CO_2 at 10°C at each step. The results of this preliminary modelling exercise are shown in Figure 5.

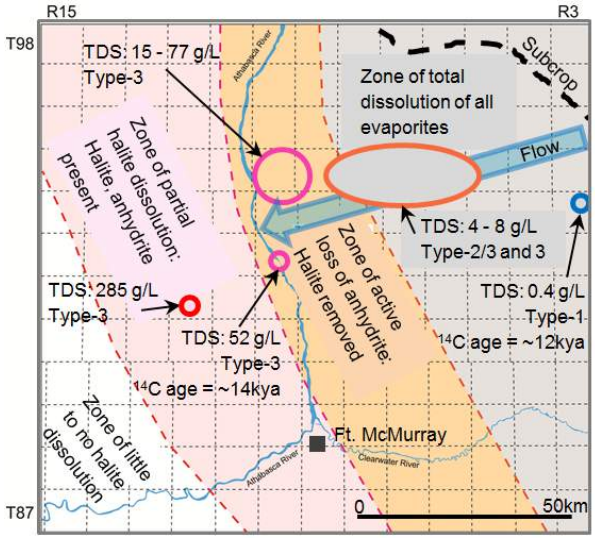

Figure 4 Prairie Evaporite dissolution map (adapted from Schneider and Grobe 2013); samples from Elk Point wells and saline a saline spring (1 to 9 wells per oval).

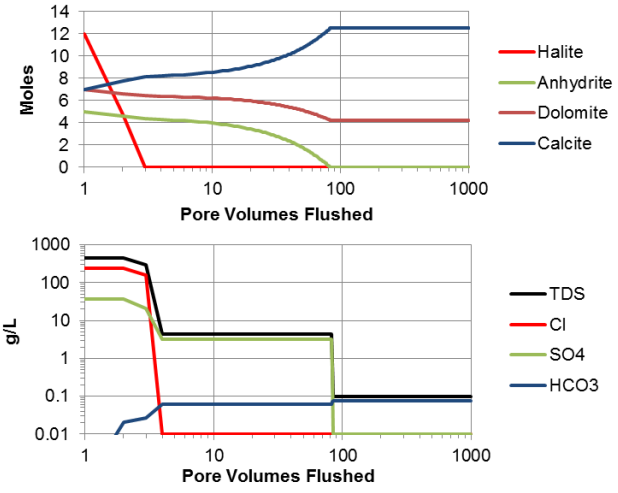

Figure 5 Results from a preliminary modelling exercise: successive flushing with fresh waters of a one litre domain representing the Prairie Evaporite Formation.

Three distinct zones were simulated with the preliminary model, similar to the regional dissolution map (Figure 4). The simulation illustrates that halite in the Elk Point Group was dissolved after only a few pore volumes had been flushed by infiltrating fresh recharge waters, such that regions with halite remaining and salinity of >300 g/L TDS can be assumed to have had little contact with fresh waters. An intermediate region was simulated having anhydrite remaining but halite removed and waters dominated by sulphate and salinity of approximately 5 g/L TDS (Figure 5). Where on the order of one hundred pore volumes or more had been flushed in the preliminary model, the anhydrite was removed leaving only dolomite, calcite, and bicarbonate-dominated waters with salinity on the order of 0.1 g/L.

Water types and salinities in samples collected from the Elk Point aquifer system in the region are shown on Figure 4 (Alsands 1981, ARC 1975, Cenovus 2011, Golder 2002, Gue 2012, and Husky 2011). Water type classifications developed here are listed in Table 1. The samples exhibit an evolution along the east to west flowpath that reflects the mineralogy and is generally similar to the results from the preliminary modelling exercise. Near the focused recharge zone at the Elk Point subcrop, a sample had salinity of 0.4 g/L TDS and was dominated by bicarbonate. Approximately 45 km to 60 km downgradient of the subcrop, salinities range from 6 g/L to 8 g/L TDS with dominant anions of sulphate and chloride. Within 15 km of the Athabasca River, salinities in the Elk Point increase to 77 g/L TDS with chloride the dominant anion (Figure 4). West of the river a chloride-dominated sample with salinity of 285 g/L TDS has been collected, and similar samples have been collected from wells farther to the west.

Table 1 Water types in the Elk Point aquifer system, northeast Alberta

Water Type	Dominant Anion	Origin of Water	Salinity	Residence (m=million; k=thousand)	Occurrence
Type 1	Bicarbonate	Meteoric	< 2 g/L	< 10k yrs	Near subcrop
Type 2	Sulphate	Meteoric	3 to 5 g/L	< 10k yrs	~20 to ~50 km east of Athabasca R.
Type 3	Chloride	Meteoric	5 to 300 g/L	5k to 40k yrs	East of dissolution edge
		Connate	> 250 g/L	> 1m yrs (?)	West of dissolution edge
Intermediates	HCO_3, SO_4, Cl	Meteoric	1 to 10 g/L	< 40k yrs	East of Athabasca R.

The main geochemical processes, based on the mineralogy, hydrochemistry, and preliminary modelling, are: halite (NaCl) dissolution, anhydrite ($CaSO_4$) dissolution, dolomite ($CaMg(CO_3)_2$) dissolution, and calcite ($CaCO_3$) dissolution/precipitation. Ion exchange in the Elk Point in the region is thought to be less significant than the main mineral interactions listed above, but is significant enough to characterize the samples east of the dissolution edge as having meteoric origin, using the Index of Bases Exchange (IBE) formulation of Collins (1975). Samples west of the dissolution edge have IBE greater than the diagnostic cut-off for connate water defined by Collins (1975) of 0.129, indicating deep basin water with residence time of millions of years or more.

Isotopic signatures further characterize origins of waters in the Elk Point. Deep basin waters sampled in the Edmonton area have $\delta^{18}O$ and $\delta^{2}H$ signatures of warm recharge and a high degree of water-rock interaction (Simpson 1999). Samples from Elk Point wells and saline springs east of the dissolution edge in the region have meteoric $\delta^{18}O$ and $\delta^{2}H$ signatures of cold water recharge, with $\delta^{18}O$ values ranging from -19.2‰ to -24.6‰ (Cenovus 2011, Gue 2012, Wallick and Dabrowski 1982). These values and ^{14}C groundwater age estimates of approximately 10,000 to 30,000 years indicate that Elk Point waters east of the dissolution edge represent a mixture of meltwater from the Laurentide ice sheet, which melted in the region approximately 10,000 years ago and has a $\delta^{18}O$ signature of -25‰ to -28‰, and warmer water similar to present-day recharge (-17.7‰ to -19‰) (Grasby and Chen 2005; Gue 2012).

Karst development in the region is caused by halite dissolution, anhydrite/gypsum dissolution, and dedolomitization. These processes accelerate carbonate dissolution, which is otherwise controlled by pH of the water and specifically carbonic acid sourced from atmospheric CO_2. Dedolomitization causes a large increase in the dolomite dissolution rate (e.g., Palmer 2007; Escoria et al. 2013) due to dissolution of both dolomite and anhydrite. It causes a process referred to as the common-ion effect, with ideal stoichiometry (Appelo and Postma 2005):

$1.8CaSO_4 + 0.8CaMg(CO_3)_2 \rightarrow 1.6CaCO_3 + Ca^{2+} + 0.8Mg^{2+} + 1.8SO_4^{2-}$.

Anhydrite and dolomite dissolution both produce calcium ions, driving precipitation of calcite.

1-D REACTIVE TRANSPORT MODEL

A 1-D reactive transport model was constructed in PHREEQC to attempt to simulate salinities above 5 g/L TDS where halite has been completely or almost completely removed, and to provide an investigative tool to potentially identify areas with higher dissolution rates. The model domain represents a 90 km flow path from the Elk Point subcrop to the Athabasca River, using 30 mobile and 30 immobile cells (Figure 3).

The initial conditions represent the Elk Point prior to dissolution, based on publically-available logs from the region: 40% halite, 40% dolomite, 10% anhydrite, and 10% calcite; 6% porosity; and 1 mol/L dissolved organic carbon (oil and bitumen). Boundary conditions are specified flux into the east end of the domain yielding a groundwater velocity of 10 m/yr through the model domain, and an equivalent discharge rate at the west end. Recharge was simulated as pure water equilibrated to atmospheric CO_2 with pCO_2 of 10^{-2} atm. No transverse flow boundaries are necessitated by the 1-D model geometry: an important limitation, which assumes zero vertical recharge through the overlying Cretaceous sediments and Upper Devonian into the Elk Point aquifer system. This limitation is discussed further below.

A high degree of simulated heterogeneity was required to approximately match the hydrochemistry in samples along the flow path. Dispersion was simulated using a dispersivity of 1000 m for the regional flowpath. The dual-porosity function in PHREEQC was also required: the domain was divided into 30 cells through which the simulated groundwater flows laterally, referred to as mobile cells, and 30 adjacent cells referred to as immobile cells (Figure 3). Rate-limited mass transfer between immobile and mobile cells is allowed, simulating a store-and-release function in the poorly-connected regions of the domain similar to the concept of Harvey and Gorelick (2000). The mobile and immobile cells initially have very high salinity due to equilibration with halite; as the mobile cells are flushed with meteoric recharge, Na and Cl in particular diffuse from the immobile cells into the mobile cells.

The simulated flow velocity of 10 m/yr was chosen based on corrected radiocarbon ages (Figure 4; Cenovus 2011, Gue 2012) and 1-D Darcy flux using hydraulic conductivity from multiple-day hydraulic tests (Alsands 1981, Golder 2002, Husky 2011), average hydraulic gradient of 0.002, and porosity of 10%. Both approaches yielded flow velocity estimates ranging from 1 to 10 m/yr. Flow velocities may have been lower at early stages of the dissolution of the Prairie Evaporite Formation. During the later glacially-driven stages of dissolution, flow velocities could have been an order of magnitude higher or more due to an increased pressure gradient imposed by the receding glacier.

Reactive transport is simulated in PHREEQC by solving equilibrium equations and shifting reaction products from each cell to the next cell along the flowpath, as calculated according to the flow velocity. At each time step in the model (representing approximately 300 yr), the water in each cell (3,000 m length) equilibrates with aqueous and mineral phases using the ThermoChimie database in PHREEQC, which utilizes the specific ion interaction theory (SIT) approach. The SIT approach estimates ion activities based on ionic strength and is hence suitable for solutions with high salinity; the Pitzer approach was not used due to its limited database in PHREEQC. Flow and transport of the reaction products are then simulated by input of the recharge to the eastern-most mobile cell and shifting the water in each mobile cell to the next mobile cell, followed by dispersion, rate-limited mass transfer from the immobile cells, and re-equilibration.

MODEL RESULTS

Dissolution Fronts and Simulation of Present Conditions

A halite dissolution front was simulated advancing from east to west over geologic time, followed by an anhydrite dissolution front (Figure 6). Dissolution fronts were delayed in the immobile model cells, which represent poorly-connected regions in or adjacent to the Elk Point aquifer system.

Figure 7 shows the simulated distribution of salinity and major ions along the flowpath for the present conditions, compared to concentrations in samples (Alsands 1981, ARC 1975, Cenovus 2011, Golder 2002, Gue 2012, and Husky 2011). Present conditions were simulated by 50,000 years of active freshwater recharge. At that time in the simulation, halite was completely removed from the mobile cells and partially remained in immobile cells within 10 km of the Athabasca River. The dissolution front for anhydrite, modelled as gypsum, is simulated to have advanced approximately 15 km (Figure 6), with anhydrite still present in the rest of the model domain.

The modelled concentrations of major ions and TDS in the Elk Point aquifer system (solid lines in Figure 7) approximately match the majority of the concentrations from samples, where available along the regional flowpath. The modelled distribution of water types generally matches those measured in samples: Type-1 in the east, Type-2/3 in the central part of the region, and Type-3 in the western part of the flowpath near the Athabasca River.

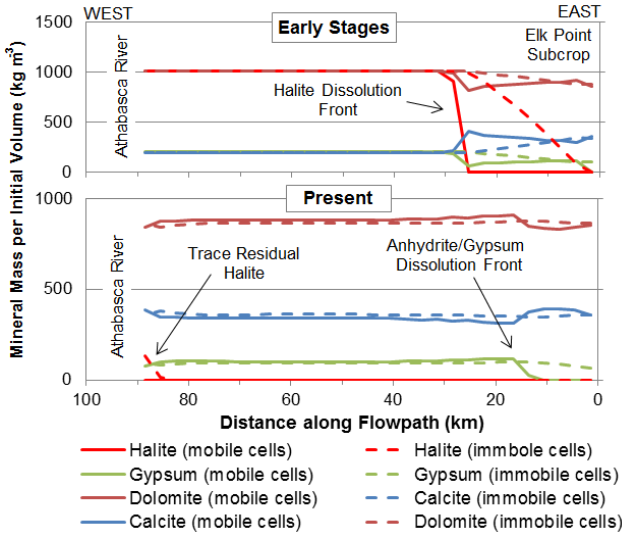

Figure 6 Model results: mineral mass and dissolution fronts along the flowpath, at early stages in the evolution and for the simulated present conditions.

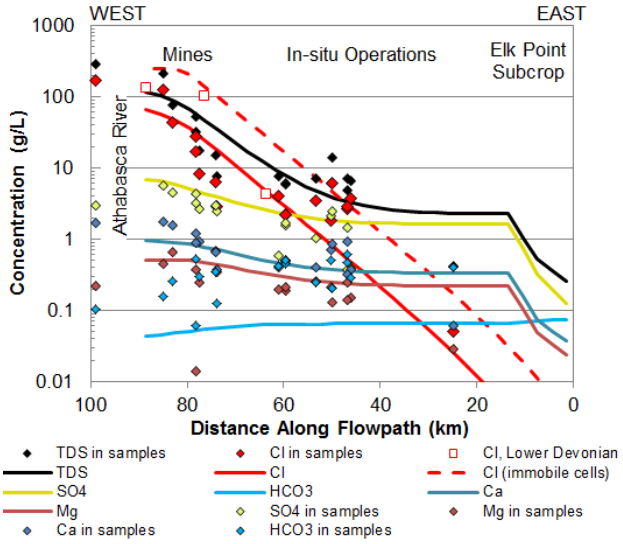

Figure 7 Model results for present conditions, as the 50,000 year simulation: major ions modelled (lines) and in Elk Point (◇) and Lower Devonian (□) samples.

Halite dissolution resulted in removal of more than half of the mass in the model. This large loss in volume was accommodated by regional collapse (not modelled). Anhydrite dissolution and dedolomitization resulted in increases in porosity of <1% to approximately 5%, based on the reactive transport model results.

Areas with Higher Degree of Connectivity

Rates of dissolution of halite, anhydrite, and dolomite were examined with the reactive transport model. Simulated rates of dissolution were highest as the halite dissolution front moved through the region: on

the order of 1,000 g m^{-3} yr^{-1} for halite and in excess of 100 g m^{-3} yr^{-1} for anhydrite and dolomite. As the evolution of flow velocities over geologic time is unknown, modelled dissolution rates are presented for comparison only. The flow rate in the model assumes the halite dissolution products are advanced forward. In the actual system, the halite forms an aquiclude that was being dissolved entirely at the eastern edge and would likely have forced the dissolution products upward, possibly along collapse features at the dissolution front, further enhancing these vertical connections.

Dissolution rates for anhydrite and dolomite at the anhydrite dissolution front (Figure 6) were on the order of 10 g m^{-3} yr^{-1}. Dissolution rates were lower over much of the model domain, except within 20 km of the Athabasca River where they ranged from 0.5 g m^{-3} yr^{-1} to 10 g m^{-3} yr^{-1}. Simulated dissolution rates indicate two types of enhanced anhydrite/gypsum dissolution and dedolomitization: input of Type-1 water (~15 km on Figure 6) and where gypsum solubility is higher due to increased salinity (elevated SO_4 at ~70 to 90 km on Figure 7).

A minority of samples in the area of the mines have Cl concentrations an order of magnitude lower than the regional trend simulated with the model (Figure 6). These low Cl concentrations, which correspond with lower SO_4 and higher HCO_3, indicate greater vertical recharge in those areas. Input of vertical recharge in the eastern area of the mines could provide a driver for circulation of freshwater to development of karst. Mine operators should carry out geochemical modelling at the scale of the lease to further investigate higher dissolution rates.

Model Sensitivity

Model sensitivity was investigated for these parameters:

- Groundwater velocity;
- Mass transfer rate;
- Initial mineral composition; and
- Initial and boundary pH.

Simulations were run with flow velocity one order of magnitude lower and higher than the base case of 10 m/yr by varying the number of shifts as an analogue to flow rate. The higher velocity (100 m/yr), possible during glacial melt, corresponded with a reasonable match to the major ions in samples at a duration of 3,000 years, with dissolution fronts travelling an order of magnitude faster, and dissolution rates approximately 30% faster. Isotopic values and geologic evidence, however, necessitate a longer duration such that a high velocity could have occurred only for a relatively short time. With the lower velocity (1 m/yr), the match to major ions in samples was poor except when a reduced mass transfer rate was used. Dissolution fronts moved an order of magnitude slower, but peak dissolution rates were approximately the same as for the base case. While this slower velocity may have prevailed at earlier phases of the geologic evolution, an average velocity at this rate would necessitate a high proportion of vertical recharge to result in detection of modern carbon. Such a case may result in decreasing groundwater ages along the flowpath, which is not measured in samples.

The distribution of sodium and chloride, in particular, were sensitive to the mass transfer rate. A change of less than half an order of magnitude from the base case $5x10^{-13}$ mol s^{-1} yielded poor matches. The model results were not sensitive to the initial halite, dolomite, or calcite amounts (within +/- 50% of base case), but the timing of the anhydrite/gypsum dissolution front was sensitive to the initial anhydrite amount. Although carbonate reactions can be highly sensitive to pH, changing the recharge boundary pH or the initial conditions from pH 7 to either 6 or 8 yielded essentially no change in the results. The model also

was not sensitive to the initial pCO2 value, and was not equilibrated with CO_2 (although the preliminary model was).

The simulated duration of active groundwater flow through the Elk Point and movement of dissolution fronts are sensitive to the selection of present-day groundwater velocity, and hence represents a lower estimate on the duration and an upper bound on dissolution front velocity, each with uncertainty of approximately an order of magnitude. Dissolution rates at the regional scale were less sensitive to the flow velocity. The model was not sensitive to whether halite was remaining in the poorly-connected model cells or completely removed: elevated chloride can be explained by either diffusion or active interaction with residual halite.

CONCLUSIONS

Karst inflow from the carbonate-evaporite Elk Point aquifer system to the overlying mines of the Athabasca Oil Sands Area is a major geohazard for the operators in the region. The following conclusions from investigative geochemical modelling with a 1-D reactive transport model are highlighted:

- The hydrochemistry within the Elk Point is directly related to mineral dissolution.
- Poorly-connected regions provide an important store-and-release function affecting the regional distribution of salinity in the Elk Point.
- Removal of anhydrite by Type-1 (TDS <1 g/L, HCO_3-dominated) water is associated with accelerated dedolomitization occurring in the eastern part of the region and possibly in areas of increased vertical recharge.
- Anhydrite dissolution and dedolomitization are also accelerated within approximately 20 km of the Athabasca River where salinity is greater than approximately 10 g/L, yielding increased anhydrite and gypsum solubility.
- The modelled dissolution rates suggest that dissolution of the Prairie Evaporite appears to have occurred as shorter periods of active dissolution (total duration 50,000 to 500,000 years) within phases of karst development in the Jurassic, Cretaceous, Tertiary, and Quaternary (Stoakes et al. 2014a).

The modelling approach used in this regional study has several limitations: the 1-D domain assumes zero or constant vertical recharge such that focused vertical recharge was only identified by mismatch to the model; mineral dissolution rates may not be applicable to shorter time scales, as kinetics were not included; an aggregate flow system was simulated rather than realistic geometries of flowpaths; and geologic information at the lease-scale to sub-lease scale were not included. This modelling approach is used as an investigative tool to improve the understanding of the evolution of the aquifer system and to aid in identification of areas of higher connectivity, rather than comprehensively modelling the system.

Using Instrumentation Data to Develop Detailed Conceptual Models for Waste Rock Geohydrology

Steven Pearce[1] and Bonnie Dobchuk[2]

1. *O'Kane Consultants, Australia*
2. *O'Kane Consultants, Canada*

ABSTRACT

The installation of instruments within waste rock dumps (WRD) enables the conceptual understanding of unsaturated zone hydrology using recorded data. Instrumentation has been used for many years as part of the assessment and monitoring of cover systems on WRDs. Conversely, the installation of instrumentation at greater depths within WRDs is less common (with the exception of tailings dams). The general understanding of unsaturated zone hydrogeology and geochemistry deeper in WRDs is typically based on academic theory and conjecture, rather than being derived from measured field data.

O'Kane Consultants Pty. Ltd. has completed the installation of over 150 instruments in WRD landforms in the Pilbara, WA. The instruments were installed to depths of 100 m as part of a long term monitoring and assessment program.

Data from the instrumentation installed to date has been used to develop some fundamental concepts for a detailed conceptual model for the geohydrology of WRDs within a semi-arid environment. The concept of advective drying for example has been determined as a significant factor in the process of wetting up of the waste rock. The analysis of matric potential and temperature sensor data indicates that significant moisture cycling through the waste rock dumps occurs as a result of advection forced drying. A key consequence of advective drying is to increase theoretical timeframes for "wetting up" of waste rock to occur as the overall water balance for the waste rock dump is significantly impacted by this process that is not commonly included as part of traditional water balance calculations. The process also results in transfer of oxygen and moisture through waste dumps in the vapour phase that stimulates oxidation reactions in material buried deep within the waste dump that would be considered as being "oxygen and moisture limited" based on theoretical understanding of waste dump geohydrology.

2. Enviromin, USA
3. Colorado School of Mines, USA
4. U. S. Geological Survey (retired), USA

ABSTRACT

Techniques for Predicting Metal Mining Influenced Water, which addresses the prediction and management of mine-affected water, is Volume 5 in the series of collaborative publications between the Acid Drainage Technology Initiative (ADTI), and the Society for Mining, Metallurgy and Exploration (SME),. Other volumes in the ADTI/SME series have included: Volume 1, *Basics of Metal Mining Influenced Water*, Volume 2, *Mitigation of Metal Mining Influenced Water*, Volume 3, *Mine Pit Lakes, Characteristics, Predictive Modeling, and Sustainability*, and Volume 4, *Sampling and Monitoring for the Mine Life Cycle.* A final volume addressing methods for modeling future water quality is in preparation.

Acidic and metal-enriched mine-affected water is a worldwide environmental problem resulting from weathering of mine-tailings and waste-rock. Management of mined materials is necessary to control impacts on surface and groundwater. The Prediction Volume summarizes the status of acid drainage and metal leaching prediction methods within the context of current best management practice. The volume repeatedly stresses the importance of a detailed understanding of geology including lithology, mineralogy and alteration history to interpret both static and kinetic acid drainage test results. The volume also proposes flexibility for kinetic test duration through the development of a site-specific objective-based framework that can be developed and modified to address project specific objectives.

INTRODUCTION

ADTI and the partnership with SME (after Hornberger, et al., 2000)

In 2014, the Acid Drainage Technology Initiative (ADTI)/Society of Mining, Metallurgy and Exploration (SME) published their prediction volume*: Techniques for Predicting Metal Mining Influenced Water (Prediction)*, one of several guidance documents being prepared by ADTI. The ADTI was initiated in 1995 by federal agencies, the National Mining Association, and the Interstate Mining Compact Commission to identify, evaluate and develop cost-effective and practical acid drainage management technologies. A founding team of regulatory, academic, and industry scientific experts envisioned that a consensus could be developed on reliable, standard static and kinetic test methods and other aspects of mine drainage prediction in the Appalachian Coal Basin. The name ADTI was also selected to emphasize the organization's central focus on technology development and transfer, rather than regulatory or policy issues. Early meetings of the Working Groups demonstrated the great value of coal-mining and metal-mining representatives working together on common objectives to address acid drainage problems confronting both sectors of the mining industry. Although initial efforts at developing various ADTI guidance went well, significant differences between coal mining and metal mining suggested the need for a Metal Mining Sector of ADTI (ADTI-MMS) to more effectively represent the interests of the metal-mining industry and the agencies involved in regulating and remediating metal mine sites. A more detailed historical review of the foundation of ADTI is provided by Hornberger et al., 2000.

The ADTI mission is to use the consensus process to refine prediction methods and management technology for the prevention, treatment and abatement of AMD/ARD pollution in an effective and economical manner. ADTI members believe that it is more productive to solve differences of opinion through the application of good science and consensus process rather than litigation.

Five technical focus areas were identified: (1) Sampling/Monitoring, (2) Prediction, (3) Mitigation, (4) Pit Lakes, and (5) Modeling. In 2007 the ADTI-MMS entered into an agreement with the Society for Mining, Metallurgy and Exploration (SME) to publish the workbooks noted above. The first of these workbooks was published in 2008: *Basics of Metal Mining Influenced Water*. Subsequent volumes include: *Mitigation of Metal Mining Influenced Water* (2009), *Mine Pit Lakes Characteristics, Predictive Modeling and Sustainability* (2009), and in most recently, in 2014, the volume described here, *Techniques for Predicting Metal Mine Influenced Water* and another, *Sampling and Monitoring for the Mine Life Cycle*. The last of the five volumes, on the subject of modeling, is anticipated in 2015.

Prediction Volume

Work on the ADTI prediction volume, began shortly after SME and ADTI agreed to coordinate on the series of workbooks in 2007. As with all the workbooks, volunteer collaboration within the consensus process has proceeded somewhat slowly. Initial drafts of the volume prepared with input from multiple authors were circulated in 2010. Following extensive reviews and edits, a final version was delivered to SME in the fall of 2013 for more detailed editing by SME. The volume was released in March of 2014.

Much of the volume's topics will look familiar to anyone working with rock characterization and acid drainage prediction:

- Chapter 1: Introduction
- Chapter 2: Acid Rock Drainage, Sulfide Mineral Geochemistry Affecting Drainage
- Chapter 3: Prediction: Background
- Chapter 4: Overview of Predictive Methods (Tools)
- Chapter 5: Evaluation
- Chapter 6: Application and Conclusion
- Appendices of Test Methods

Chapter 2, taken largely from Lapakko et al. (2004), focuses on mineral dissolution reactions that influence mine-waste drainage quality. The reactions presented result in acid generation, acid neutralization, and trace metal release. Within the chapter, soluble and insoluble ferrous and ferric solid phases of interest in mine and process waste characterization are identified.

Chapter 3 focuses on geology, lithology, and alteration, and includes a discussion of geoenvironmental models which can provide an initial assessment of potential water quality impacts based on characteristics of a mineral deposit. The chapter also includes a discussion of analytical techniques used to identify sample mineralogy, a critical need for interpreting both static and kinetic tests as noted below.

Chapter 4 includes a more detailed discussion than the GARD Guide (INAP, 2011) of the various static tests, short term and field leach tests, and kinetic tests, including field test methods that are, or have been used to, characterize materials. The strengths and limitations of the tests are discussed here and some examples of their use are also in Chapter 5, Evaluation.

Prediction of the acid-generating material at mine sites is now recognized as a crucial element of mine feasibility, permitting, and environmental review. Predictive technology has advanced considerably in recent years but still requires a detailed understanding of the entire range of complexities in the various units at a mine site needing evaluation. The ADTI/SME Prediction volume attempts to present a thorough discussion of the variety of predictive tests that might be considered for evaluating material that has the potential to be acid-generating:

- Will the material to be mined produce acid?
- Will the properties of the material change as mining proceeds?
- Are there units to be mined that can be used to neutralize or isolate acidic units?
- Will any acid produced impact ground- or surface water(s)?
- What series of test protocols accurately characterizes the material?
- Of these tests, which can be used to operationally segregate material that might need special handling or storage?
- Can any of the tests be interpreted to supplement geochemical modeling?
- Can any of the tests be used to develop field-scale tests that may help to confirm the laboratory tests?
- Can field-scale tests be interpreted to confirm geochemical predictions and modeling?

Together this iterative process should lead to a waste characterization system that enables a mine to accurately characterize and manage material at operational scales and timeframes. This system must incorporate all the information from all the testing and it must be both continuous and flexible enough to allow for the recognition and management of changed conditions.

The volume highlights the importance of a detailed understanding of sample mineralogy. The mineralogy of rock mined from ore deposits may host many generations of minerals, with many associated elements. Mineral composition and surface area, habit, encapsulation, and solubility direct influence reactivity, and therefore control sulfide oxidation and metal/metalloid release potential. A detailed evaluation of the minerals and their composition thus may be required, not only for the purpose of ARD potential and waste characterization but also for efficient recovery of the desired economic products. The choice of methods used for mineral and/or element analysis will depend on the questions that need to be answered. For example, is it more important to know the bulk concentration of an element of interest, or the mineralogical residence of that element? A number of analytical methods used for these purposes, such as XRD and SEM-EDX, are reviewed and discussed in the volume. Regardless of the technology or evaluation method selected, it is critical to remember that an understanding of the mineralogy is essential to understanding and interpreting any of the various predictive tests, not the other way around.

Evaluation

Where the ADTI/SME prediction volume differs from the GARD guide (INAP, 2011) and other guidance documents describing ARD testing methods is the discussion of evaluation provided in Chapter 5. Because these materials require: (1) subjective judgement in deciding when HC tests should be terminated, (2) may be used to answer multiple questions, and (3) are complex to interpret, the ADTI-MMS Steering Committee requested that the editors of the prediction volume examine this issue and include a discussion of humidity cell duration and provide a recommended framework that might aid in clarifying HC test objectives and termination criteria.

Although many have attempted to standardize the methods used to evaluate and predict the geochemistry of mined materials, the application of the individual analytical methods within testing programs continues to vary between jurisdictions and mine localities. One reflection of this is the varied duration of humidity cell (HC) tests during mine permitting baseline studies, which was raised as an issue during the preparation of this volume. Early work on HC method development indicated the potential need for extended run times (Lapakko, 1988, 1990; White and Jeffers, 1994), yet the initial ASTM standard developed in 1996 mentioned a minimum run time of 20 weeks (ASTM, 1996). Though other sections of the ASTM clarified that this was meant to be a minimum, this 20-week duration nevertheless became the "standard" run time. This led, inevitably, to arguments over humidity cell tests not being run long enough to accurately represent the potential for material to produce problematic drainage in a real world setting. It also, of course, led to the over-testing of some types of materials. Examples include samples with obvious potential to produce acidity in the short term being run longer than necessary to make an accurate determination of the material's need for special handling. Another, and particularly interesting example of this are inert materials, which have both low sulphide and low neutralization potential, which may appear to have uncertain potential for acid generation when they have little if any potential to produce acidity at all.

This framework/guidance is complicated by the fact that HC tests are often asked to answer two separate questions, neither of which the test is specifically designed to do:

1) How will the material perform in a real world setting and
2) What short term tests can be linked to the HC test results and then be used to accurately characterize the material so it can be managed and handled in a real time setting at a minesite?

Results generated during HC tests are not known in advance, so it is not possible to establish a specific test duration prior to test initiation. This makes it all the more important to develop rational objectives and criteria for test duration.

An understanding of the detailed objectives and rational criteria for test duration is necessary and should include a discussion of which samples are being collected and why samples are tested and evaluated: Why do we run these tests and what is it we're trying to accomplish? A mining company may use HC tests for internal environmental management programs or tests may be run as part of a larger, public permitting program. Tests may be run to identify material for selective handling, and terminated as soon as their character relative to that selective handling strategy (e.g., impoundment or encapsulation) has been identified (i.e., acid material in an HC test terminated at 10 weeks). Tests may also be run to predict the long term water quality of a material and therefore merit longer testing duration to evaluate metal release potential. The intended use, applicable regulatory guidelines, and relevant management scenarios identify the key stakeholders who define the objectives and criteria.

The objectives and rationale developed envision the involvement of knowledgeable stakeholders to develop site specific criteria for the following different possible objectives:

- Confirmation of Static Testing Results

    a) For strongly acidic or basic samples
    b) For neutral/inert or slightly basic samples

- Evaluation of Reactivity and Leachate Quality for Segregating Mine Waste

    a) For neutral/inert samples
    b) For inert/non-reacive

Each of the above possible objectives can involve criteria, which includes pH trends, sulfate release rates, Ca/Mg:S ratios, or ANP/AGP ratios among other possibilities. These criteria must be developed on a site/project-specific basis based on the site-specific lithology, mineralogy, trace-metal characteristics, and potential environmental risks.

- Evaluation of Quantity of Neutralization Potential (NP) Available to React with Produced Acid

In the event detailed information on the actual availability and timing of neutralization is critical to developing a comprehensive waste management plan, the following factors must be considered

    a) Duration will be based on when NP of carbonate or other neutralizing minerals has been consumed. Tests based on this objective can be expected to have extended durations, potentially years rather than weeks.
    b) Mine-waste constituents that are mobilized during weathering need to be identified and characterized.

- Prediction of leachate quality (metals/metalloids)

Given the potential duration of HC tests, the importance of early test initiation cannot be overstated. Other considerations include: (1) ongoing field pilot study tests, which can be used to

supplement HC results and support detailed geochemical modeling; (2) geoenvironmental comparisons with closely related deposits; and (3) the possible need for duplicate cells for lithologies with complex mineralogy or conflicted static test results as an alternative to restarting humidity cells with disputed termination decisions.

Once the objectives and criteria for HC tests have been satisfied, this information can then, hopefully be used to develop a sequence of testing that can be used at an operational scale to effectively segregate and manage material at the mine site to meet environmental requirements.

CONCLUSION

The volume describes an iterative process characterizing and classifying mined material. One of five guidance documents developed through a unique consensus process within the ADTI, this volume addresses some key elements of management practice which include the perspective of regulators, corporations, and other stakeholders. While any waste characterization program should be based on clear set of sampling and testing objectives, criteria for terminating kinetic tests which are appropriate to the goals of the overall program (e.g., selective handling vs. use of material for construction, for example). In developing criteria for test duration, a thorough understanding of the following is needed:

- The petrology, mineralogy, alteration, and sequential mineralization history of material.
- The actual procedures used in the static and kinetic tests of the material

This detailed understanding will allow correct evaluation of results from both the static and kinetic tests performed on samples. Characterization of large tonnages of mining and processing waste requires complex and geostatistically sound sampling and characterization programs throughout the mine life to assure that relevant environmental standards can be met both throughout the mine life and beyond as the mine is closed and reclaimed.

The ADTI/SME Prediction volume also presents some ideas on a possible framework that might be used by stakeholders to develop rational objectives and criteria for the duration of HC tests that will contribute to reducing uncertainty and level of risk associated with mineral development.

Collectively this information will help assure that mines identify and manage materials that might adversely affect the environment if not handled appropriately.

ADTI-MMS continues to work towards its goals through coordination with the International Network for Acid Prevention (INAP) and its partners in the Global Alliance; South Africa's WRC (Water Research Commission), MEND (Mine Environment Neutral Drainage) in Canada, PADRE (Partnership for Acid Drainage Remediation in Europe) in the European Union, SANAP (South American Network for Acid Prevention) in South America, SMIKT (Sustainable Minerals Institute, Knowledge Transfer) in Australia, INAD (The Indonesian Network for Acid Drainage), and the CNAMD, The Chinese Network for Acid Mine Drainage in China.

A Risk Assessment of ARD Prediction and Control

Shannon Shaw[1] and Andrew Robertson[2]

1. *pHase Geochemistry Inc., Canada*
2. *Robertson GeoConsultants Inc., Canada*

ABSTRACT

Risk assessments are routinely conducted for many of the specialized aspects or features of a mine site or design, but rarely completed as a focussed evaluation of acid rock drainage and metal leaching, or ARD/ML risk. ARD/ML and water quality impacts however are often one of the most significant risks associated with mining projects in terms of long term environmental impacts, public and regulatory image and closure costs.

Risk assessments are often done via the Failure Modes and Effects Analysis (FMEA) methodology in which potential failure modes are identified, the anticipated effects of those failures are documented and the likelihood of occurrence and consequences of occurrence are rated. Failure modes as they relate to ARD/ML can arise from errors and uncertainties in predictions, as well as errors and uncertainties associated with control measures. The FMEA can be used as a tool to better mitigate and manage these errors and uncertainties.

This paper uses the FMEA approach to classify and share an understanding of relative risks for mines with respect to ARD/ML. By way of case studies and examples, a listing of failure modes that should be considered in ARD/ML prediction programs and management and control plans is provided, as are factors that contribute to each failure mode.

INTRODUCTION

A common risk management tool used by engineers in the mining industry is the failure modes and effects analysis (or FMEA). This analysis tool is meant to identify potential events that could cause a consequence that is unacceptable. In this way, unacceptable risks can be identified and mitigated or managed with the objective of reducing those risks to acceptable levels.

Acid rock drainage and metal leaching (ARD/ML) has been identified and is generally thought of as one of the larger risks associated with mining in sulphide rich deposits, with those risks including not only risks to the receiving environment (water quality, aquatic species, agriculture, livestock and wildlife as well as humans) but also risks to the financial health of mining proponents and their shareholders, tax payers and other stakeholders.

The potential occurrence of ARD/ML is therefore often included as a failure mode in a more encompassing risk assessment at any one project or site with the consequence ultimately being an impact to receiving water quality. When ARD/ML occurs, the view is often that there was a fundamental error in one, or more of the following; (1) the identification and characterization of the potential for ARD/ML, (2) the prediction of water quality effects and/or effectiveness of control measures, or (3) the performance of management of waste for the control of ARD/ML. Significant work goes into each of these aspects at considerable cost to a proponent and considerable implication to the overall risk profile for a project. In the authors' experience there are components of each of these aspects (characterization, prediction and management) that can affect the ultimate risk of a project related to ARD/ML. These components can be framed within the context of an FMEA for the purpose of ARD/ML characterization, prediction and management with the objective of better quantifying the overall ARD/ML risk and then applying applicable mitigation measures to lower risk of a project. In other words, what are the failure modes and consequences of ARD/ML evaluation and management programs themselves? What risk do these represent for the project, so that mitigation measures can be applied to reduce risk? This paper attempts to identify and describe those failure modes that are most common and/or have the highest consequences.

METHODOLOGY

The risk assessment approach used in this study was that of a Failure Modes and Effects Analysis (or FMEA), which consists of the quantification of the likelihood and consequence of a failure or event (Robertson, 2012).

A failure mode can be naturally initiated (e.g. 1:500 year flood event) or initiated by a failure of an engineered system (e.g. leakage from a contaminated water storage pond), or by an operational error (e.g. accidental release of contaminant to the receiving environment).

The assessment of the effects or consequences of these failure modes is site specific though in large part based on precedence, experience at other mines (case histories) and professional judgement by experienced personnel. A suggested basis or metric by which the likelihoods and consequences can be quantified is provided, each based on metrics defined in 5-point scales as detailed in Tables 1 and 2 below.

Table 1 provides the likelihoods of an event occurring ranging from not likely to expected. The not likely category is defined here as having a <0.1% chance of occurrence (or one in a thousand) while the expected case has been defined as a >50% chance of occurrence (or a one in two probability of

occurring). The period of consideration may the annual likelihood or the likelihood over the life of the project. Likelihood increases for the period under consideration. The authors have a preference for working with the likelihood of the period of operation of the mine, or in the case of post closure risk, a period of 100 years.

Table 1 Scale used to define the likelihood of a risk.

Likelihood Class	Likelihood of Occurrence of event within the period of consideration
Not Likely (NL)	<0.1% chance of occurrence
Low (L)	0.1 to 1% chance of occurrence
Moderate (M)	1 to 10% chance of occurrence
High (H)	10 to 50% chance of occurrence
Expected (E)	>50% chance of occurrence

Consequences in Table 2 have been categorized or grouped in a manner used commonly for FMEAs in the mining industry; specifically as geochemical impacts (often compared to water quality guidelines or biological metrics), regulatory effects (compliance), social license, health and safety and costs. The example scalars used here to assess the consequences, or the severity of effects should an event occur range from negligible to extreme. A negligible consequence would be one that had no measurable geochemical impacts on the receiving environment, that did not exceed regulated limits, that did not result in social attention or a health and safety concern, and for which repair or mitigate costs less than $10,000. An extreme consequence on the other hand would be an event that resulted in a geochemical impact that was considered very large and irreversible, that resulted in exceedances of regulatory obligations at a level that might shut down an operation or impose severe restrictions on an operation, that resulted in social outcry and the loss of social trust, that may result in fatalities and cost $10 million dollars or more to clean-up or mitigate. This scale can be modified to suit the sensitivities of each mine or project and the site and project specific conditions.

Risk is the product of likelihood and consequence:

Likelihood x Consequence = Risk

The risk rank can be quantified as either a number (the product of the likelihood rank and the consequence rank) or as a colour.

The matrix provided in Figure 1 below illustrates this as a color-coded (or ranked) system with warmer colors representing higher risks (with higher likelihoods and consequences) and colder colors representing lower risks (with lower likelihoods and consequences). A numerical quantification is also provided with the risk value for each failure mode being the multiplication of the likelihood rank times the consequence rank.

A separate risk matrix can be generated for each risk consequence: Geochemical Impacts; Regulatory Effects; Social Licence; Health and Safety; and Costs. This paper addresses geochemical failure modes, likelihood, consequences and risk.

FAILURE MODES

Geochemical failure modes identified in this paper have been organized here into those that are related to (1) prediction of geochemical behaviour, (2) prediction of effectiveness of control measures and (3) performance of control measures. In addition, the dimension of time (or kinetics)

as related to each possible failure mode is discussed. This temporal aspect can relate to prediction of geochemical behaviour (e.g. the rate of neutralization depletion), the prediction of the effectiveness of control measures (e.g. the predicted infiltration rate through covers) and the performance of control measures (e.g. the effect of climatic effects such as a 1 in 1000 year flood on control measure performance).

Table 2 Example of a scale used to define the severity of effects (consequences).

Consequences	Geochemical Impacts	Regulatory Effects	Social License	Health and Safety	Costs
Negligible (N)	No measurable impact	Meet regulatory obligations or expectations	No stakeholder (e.g. locals, NGO) attention	No concern	<$0.01 million
Low (L)	Minor impact on WQ (less than order of magnitude change)	Seldom or marginally exceed regulations. Some loss of regulatory tolerance, increasing reporting	Infrequent local, international and NGO attention addressed by normal public relations and communications	First aid required; or small risk of serious injury	$0.01 to $0.1 million
Moderate (M)	Moderate, temporary, reversible impact on WQ	Occasionally (less than one per year) or moderately fail regulatory obligations or expectations - fined or censured	Occasional local, international and NGO attention requiring minor procedure changes and additional public relations and communications	Lost time or injury likely: or some potential for serious injuries	$0.1 to $1 million
High (H)	Significant, irreversible impact on WQ or large, reversible	Regularly (more than once per year) or severely fail regulatory obligations - large increasing fines and loss of regulatory trust	Local, international activism resulting in political and financial impacts on company 'license to do business' and in major procedure or practice changes	Severe injury or disability likely: or some potential for fatality	$1 to $10 million
Extreme (E)	Catastrophic impact on WQ (irreversible and large)	Unable to meet regulatory obligations or expectations; shut down or severe restriction of operations	Local, international outcry & protests, results in large stock devaluation: severe restrictions of 'licence to practice'; large compensatory payments etc.	Fatality or multiple fatalities expected	>$10 million

Prediction of Geochemical Behaviour

Potential/common failure modes related to prediction programs aimed at characterizing the geochemical behaviour of a material have been identified below.

Failure Mode 1.1: Errors related to geological variability. Geotechnical engineers who use the FMEA tool extensively in the mining industry are used to working with variability in parameters such as shear strength and permeability where variability in values can be substantial but where there is a predictable range for a given rock type. Geochemical variability for a given rock type can result from a number of components that could include variations in the quantity of key minerals, variations in textures and particle sizes, variability in the liberation of key minerals and how each is exposed during blasting etc. Without substantive testing and quantification, geochemical variability for a given rock type therefore is difficult to predict and project specific.

Failure Mode 1.2: Errors related to representativeness of samples. Generally sampling for geochemical characterization is done, at least initially, on the basis of guidelines that suggest a

number of samples be collected for a specific tonnage of waste for each key rock type. Prior to mining, this is further limited by the availability of drill core available to sample. This drill core is generally representative of rock within or close to ore zones and not necessarily encompassing of all likely waste. Uncertainties therefore arise from the frequency and spatial distribution of samples selected. During operations or on closure this uncertainty is often reduced by the fact that sampling can be much more targeted to the material of interest and/or can be done at a higher frequency, with better temporal and spatial certainty.

Failure Mode 1.3: Errors related to representativeness of models. Modelling tools are used extensively in the industry. Often models are used to extrapolate data from the samples collected and characterized spatially in order to forecast the geochemical behaviour of waste rock before it is mined. These models have great value for waste planning particularly on projects where there is waste handling of material with one geochemical characteristic that differs from others. Uncertainties in the models however exist. These uncertainties may be greater for some deposits than for others, for examples extrapolation of a sulphur value from one sample across many meters of rock in a model for a deposit where sulphides are present as veins may have a much higher degree of uncertainty than if the sulphides were evenly disseminated throughout the rock mass.

Failure modes related to the development or utilization of models exist as do failure modes related to the use of the output. Practitioners need to understand the limits of models when making decisions on the basis of those models. Misguided use or over-reliance on model outputs can therefore also lead to failure modes.

Failure Mode 1.4: Errors related to definition of operational waste management. Many projects have waste handling procedures that are intended to segregate one type of rock from another. These programs are often developed to support project licensing prior to obtaining an understanding of how rock will blast, how sulphides and carbonates will partition in blasted rock, how well operations will be able to forecast and identify zones of differing geochemical behaviour, how diligent and dedicated operations will be to segregating rock etc. Predictions of how effective waste handling will be are often optimistic and not practical or conservative and may be unrealistic in estimating effectiveness.

Failure Mode 1.5: Errors in quantification of oxidation rates. Uncertainties that related to the tools and test methods standardly used to quantify oxidation rates (e.g. humidity cell tests, intrinsic oxygen consumption tests etc.) can also lead to failure modes. Because these tests are long in duration they are expensive. Sample selection therefore becomes a critical component of these programs. Inadequate sample representation can therefore lead to failure modes. Additionally, because there are standard methods for this quantification, programs tend to use the standard methods as a default. Adaptation of the methods to better suit site specific needs is rarely done and the duration of testing is often dictated by guidelines (e.g. 20 weeks, 40 weeks) rather than being dictated by each individual sample behaviour.

Failure Mode 1.6: Errors in the extrapolation of lab-based kinetic data to field conditions. Lab-based kinetic tests are typically used to quantify the rate of sulphide oxidation, depletion rates of buffering minerals and release rates of elements of interest. Test conditions seldom represent field conditions and numerical modeling is often inadequate to reliably extrapolate test conditions to field conditions. Data is used to calculate the lag time or delay to the onset of ARD conditions, when they are predicted to occur, as well as using release rates to predict water quality associated with waste facilities. Uncertainties and errors in the way in which lab rates are used in these

calculations and predictions represent another failure mode with potentially significant consequences.

Failure Mode 1.7: Deficiencies in the industry-wide knowledge base. Much of the characterization and predictive work relies in large part on case studies, analogs and the successes and failures experienced at other sites. Our ability to better predict water quality impacts and to better manage or sort waste on the basis of geochemical criteria therefore would have less uncertainties if operations and practitioners were able to, or required to, re-visit predictions and evaluate if there are differences in predictions and observed conditions what may have contributed to those differences. It is recognized that this is only really partially achievable, particularly at locations where there is a lag phase and sometimes decades between the period of time when predictions are made and conditions represented by those predictions occur. Comparing apples to apples therefore becomes a particular challenge when relying on case studies and analogs. However 'calibration' against precedence of other projects or historical behaviour on a given projects are important methods for improving prediction accuracy and risk mitigation.

Prediction of Effectiveness of Control Measures

Control measures most typically evaluated and utilized at mine sites in order to limit the effects of ARD/ML include measures aimed at (1) limiting sulphide oxidation (source control), (2) limiting migration of contaminants generated by sulphide oxidation (migration control), and/or (3) limiting the release of contaminants, if generated, into the receiving environment (collection and treatment). There are a number of potential failure modes related to the prediction of how these control measures may perform that should be considered.

Failure Mode 2.1: Effectiveness of source controls. This failure mode would include potential errors in waste management aimed at controlling ARD/ML which, depending on the waste management at any particular site, could include: ineffective prediction of, or design of, segregation and sorting programs for waste rock; ineffective prediction of or design of blending or layering strategies for waste rock; inaccurate prediction of performance of amendments to lower reaction rates or increase lag times, inaccurate prediction of measures to reduce oxygen ingress, and potentially errors related to the design of sub-aqueous disposal of wastes.

Failure modes could occur where there is inability to, or inadequate planning for, the potential partitioning of the neutralization potential (NP) and acid potential (AP) into different particle size fractions when rock is blasted versus how it is accounted for in samples available prior to mining (i.e. pulverized drill core). This could influence design of segregation and/or blending strategies.

Others could include insufficient planning of amendment application or dosage with the result that reaction rates and/or lag times are faster than anticipated.

Control of ARD/ML by sub-aqueous disposal could also have potential failure modes associated with it. For example, the inability to keep waste submerged resulting from errors in water balance predictions or resulting from severe climatic changes.

Failure Mode 2.2: Effectiveness of migration control measures. In the scenario where ARD/ML generation controls are not considered achievable or are cost prohibitive, control measures aimed at limiting migration are sought and are most often focussed on the design of covers aimed at reducing infiltration into a waste storage facility. Failure modes could occur in the design of appropriate covers for instance if test plots are too shallow or too narrow influencing the parameters which are used to design the most effective covers. Failure modes could also occur by

errors related to assumptions or inaccuracies of modelling relied upon to design covers. Even if designed properly, failure modes can occur during construction and/or as a result of long term changes in cover properties (biotic intrusion, desiccation and settlement cracking etc.).

Failure Mode 2.3: Errors related to collection and treatment measures. If neither oxidation control nor migration control are achievable, the ability to collect and treat impacted waters becomes critical. Failure modes that could occur in the prediction and design stage of collection and treatment control measures might relate again to errors in water balance or site water quality models, inadequate baseline assessments of hydrological or hydrogeological conditions etc. with the potential result that there is either too much water or much less than engineered for and/or that the treatment technology does not treat effectively or for all the parameters of concern.

Performance of Control Measures

Beyond the potential errors involved in characterization of ARD/ML and errors that could occur during the prediction or assessment of control measures for ARD/ML there are failure modes related to the performance of control measures put in place. This could in part be related to a failure to implement a design as planned or a failure to plan and design for implementation challenges.

Failure Mode 3.1: Errors related to operational waste management and deposition. Many projects have waste handling procedures that are intended to segregate one type of rock from another. Operational errors can occur whereby a zone on a pit bench is marked as a non-potentially acid generating zone or domain where in fact it is potentially acid generating and that block gets moved to the wrong disposal area. This could result from blasthole sampling at an inadequate frequency for accurate waste block designation or as a result of operator error where a truck operator who is supposed to take rock to one dump takes it instead to another. Rock management could also be prone to failure modes resulting from other operational constraints (e.g. a road washes out) resulting in all rock going to one area for a period of time. The simple process by which rock is placed can also create variability in a dump. For end-dump waste piles, segregation by rock size can occur down slope, this may result in partitioning of one rock type, perhaps intended to add carbonate buffering to the mix being deposited in one zone and another rock type, perhaps a harder rock that blasts in larger particle sizes, segregating down slope in another zone.

Failure of blending and layering management could result from partitioning of the neutralization potential (NP) and acid potential (AP) into different particle size fractions post blasting whereby neutralization is not effective and the standardized NP/AP ratios are either overly conservative or not protective. Failures could also occur if neutralizing minerals get blinded by secondary mineral precipitation on particle surfaces.

Control of ARD/ML by sub-aqueous disposal could also have potential failure modes associated with it: for example resulting from severe climatic changes; containment structure breaches etc.

Failure Mode 3.2: Migration control failures. Failures in covers due to root action, frost action, erosion and/or deterioration of liners all fall within this failure mode. Often the consequences of these failures occur slowly and gradually over time.

Failure Mode 3.3: Collection and treatment control failures. Failure modes that would occur within the context of collection and treatment systems could include ice and sediment blockages in diversion ditches, landslides blocking water management structures, flood events. Failure modes could also include temporal changes in water quality resulting in changing treatment requirements

and/or changing water quality standards and regulations resulting in changing treatment requirements.

EFFECTS

In the case of the failure modes above, be they related to prediction errors, error in the prediction of control measures or the effectiveness of those measures, the effects can be described as (1) that monitoring detects the failure mode and remediation is taken or (2) monitoring does not detect the failure mode and an impact, perhaps temporarily, to the receiving environment occurs. The likelihood and consequences of geochemical related risks are therefore intimately dependent on the monitoring programs and highlight the importance of appropriate monitoring and response plans. Where monitoring is not adequate and failure modes occur, it may be that emergency response and clean-up plans need to be initiated.

Effects are also tied intimately to the receiving environment in which a project is located, the assimilative capacity, cumulative effects etc. The risk of cover failure in an area of high rainfall may have a much greater effect than if the same failure were to occur over similar waste in a dry environment.

Risks are also cascading. For example, if source control fails – for example if PAG and non-PAG rock segregation or blending is not effectively executed, then migration controls become the primary reliance measure. If migration controls fail, then collection and treatment systems become more important. Collection and treatment controls may have greater assurance where the likelihoods of an event are diminished, however costs are increased.

EVALUATION

This FMEA approach can be illustrated by way of example. For instance, consider a porphyry style open pit project whereby sulphides are both disseminated and structurally controlled and where carbonate content is generally low and present in veinlets. In this example, pre-mining characterization work identified a variable range of both PAG and non-PAG rock that was not strongly lithological-dependent and an operational segregation and sorting plan was developed based on a sulphide value criterion. Waste management in this example is done on the basis of blasthole sampling, on-site testing for sulphur and flagging of dig blocks on the pit face on the basis of those results. Waste planning includes PAG rock disposal in one location and non-PAG rock identified as construction rock and or disposal in a separate facility. The closure plan assumed and allocated closure costs for a cover placement on the PAG rock pile to minimize infiltration and predictions indicated there would be no need for collection and treatment to protect the downstream environment.

Potential failure modes for the characterization program, the prediction of control measures and the performance of the plan are provided in Table 3.

Precedence for this type of deposit would suggest that one possible failure mode is that not all PAG rock is identified or segregated correctly because the original sulphide criteria was not sufficiently protective or due to variability on a scale not adequately represented by sampling etc.. This could result in the PAG rock getting placed in a non-PAG rock pile or used as construction rock. The effects could be very different depending on whether or not monitoring was sufficient to detect and mitigate for this failure mode. Monitoring for this type of failure mode could include a verification

program initiated during construction and early operations aimed to identify whether or not that the criterion be adjusted and/or water quality monitoring detects increased concentrations of indicator parameters.

In the example provided, there were a few failure modes identified related to extrapolation of kinetic data. The first example illustrates a potential error related to oxidation rate expectations. If in a case where control of ARD/ML from a PAG pile is reliant on a cover for infiltration control, the lag phase needs to be sufficient to prevent significant ARD/ML generation until such time as a cover can be placed. Kinetic tests are also relied on for prediction of water chemistry of contact water from non-PAG sources. If the tests or predictions based on those tests are not conservative enough, one effect could be that water chemistry associated with a non-PAG pile is still not of discharge quality and would also potentially require cover placement and/or seepage collection. A robust seepage quality monitoring program becomes a key factor at early identification of these potential failure modes and allowance for early mitigation by additional cover placement in the control plan would reduce risk.

SUMMARY

The FMEA methodology, which has found great utilization in the mining industry particularly in the regard to stability of geotechnical structures (dams, slopes, waste dumps), can also be a valuable tool for risk assessment of ARD/ML control programs and waste planning. In this paper a number of potential failure modes have been identified with greater discussion, by way of example, provided for a subset of these. The importance of consistent, robust and targeted monitoring is illustrated as a key risk mitigation and management tool.

Acid Mine and Metalliferous Drainage (AMD); Sample Selection an Intricate Task

Edgardo Alarcón León, Carel van der Westhuizen and Lucy (Xin) Du
Pendragon Environmental Solutions, Australia

ABSTRACT

Although acid rock drainage (ARD) exists in nature, acid mine and metalliferous drainage (AMD) as a consequence of mining remains one of the most difficult environmental problems to deal with. AMD has the potential to persist long after closure, requiring extensive and expensive on-going remediation and monitoring of local and surrounding downstream environments.

AMD characterization requires in-depth investigations to understand the key processes involved in the oxidation of sulfides and the subsequent release and transport of solutes. Approaches and solutions to mine-waste characterization and management during resource exploitation require accuracy but is site specific. Regulators, miners and scientists have different views on the numbers and types of sample specimens; these differences should be recognised and considered as they play an important role in the overall decision making process. Over time, many different approaches and methodologies to ascertain the number of samples have been developed. These range from a dominant geo-statistical approach, such as the theory of sampling (ToS), to methods inclusive of a combination of statistical, mineralogical, geochemical, environmental and economic analyses.

Despite which approach is followed, sample types and numbers are often subject to unwarranted critique. Regulation may further complicate matters, particularly where decision makers are risk averse. An innovative approach that centres around a risk-based approach and combines geological, mineralogical, geochemical and hydrogeological characteristics of the mine site into a conceptual model, from which the AMD investigator is able to define the type and number of samples and relative amount of material, appears the most appropriate approach to extricate this fundamental problem in investigating and assessing AMD. This global yet site specific approach, will assist during the various stages of mining and will provide assurance that subsequent rehabilitation and closure are achieved with little difficulty and expense.

Keywords: AMD, characterization, sample, selection, number.

INTRODUCTION

Although acid rock drainage (ARD) exists widely in nature, acid mine/metalliferous drainage (AMD) is a significant environmental concern for the mining industry and one that may persist long after closure, often requiring extensive and expensive remediation.

ARD/AMD is caused by the exposure of sulfide minerals to oxygen and water which produces acidity and triggers the dissolution of metals and metalloids, which are harmful to site and neighbouring downstream environments (Alarcón and Anstiss 2002). Owing to the complex physical, chemical and biological processes occurring during the weathering of sulfides, the production of AMD can be severe, or may not occur if the media remains in a reducing condition. This uncertainty adds further complexity to the assessment of a mining project and thus, the characterization of mine wastes becomes fundamental to develop cost effective management approaches including preventive and containment measures.

Regulators, miners and scientists have differing views on the types, number and origins of samples that would fully characterize mine waste. These differences within the various stages of mine development create a complicated paradigm and impact adequate mine-waste identification and management. Responses to these complexities include numerous research investigations and publications that incorporate an all-inclusive approach of statistical, mineralogical, geochemical, environmental and economic analyses. However, these approaches have not fully addressed the intricacies of defining *adequate sampling quality and population*, which remains a paradigm.

With reference to AMD, there are several questions that need to be answered over the life of a mining project, these including but are not limited to:

- Should samples be profiled for AMD characteristics during the exploration stages?
- What constitutes a sample for AMD assessment?
- How many, which kind and what sizes of samples are sufficient to hydrogeochemically characterize the proposed new mine?
- How are we dealing with heterogeneity and how might lithological samples express this complexity?
- How much analysis is required and what parameters need to be investigated?
- How may laboratory analyses be extrapolated to real mine conditions?

SAMPLING PARADIGM

It is accepted that samples for AMD investigations should be *site-specific and depend on the phase of the project, but must be sufficient to adequately represent the variability/heterogeneity within each geological unit and waste type* (DITR 2007). Certain key parameters including the extent of mineral variability, mineralogical alterations and sulfide types/concentrations are often omitted from AMD assessments. These parameters are required to reveal baseline conditions of the overburden/waste rock and ore (high and low grades), and assess the risks that a mining project imposes on the environment.

Whilst numerous sample selection methodologies are used worldwide, the general theory of sampling (ToS, Francis Pitard, 1989) takes into account both technical and statistical aspects of sampling. ToS was developed by the French academic Pierry Gy and addresses all facets of sampling. The main contribution attributed to this theory is the proposition of a mathematical definition of heterogeneity (Rossi *et al*, 2010).

In nature, this concept is paramount as we need to know the lithology, mineralogy, alterations and the variability of the physical, mechanical, hydraulic and chemical properties of the rocks. Alternate sampling strategies range from purely statistical to fixed-frequency approaches. The British Columbia AMD Task Force (1989) proposed that samples be collected in a fixed-frequency approach, based on the mass/volume of waste, and recommends a minimum number of samples expressed as:

$$N = 0.0026M^{0.5}$$

where N is the number of required samples and M is the mass of the geologic unit in tons (M should be > 6×10^3 tons). Based on this approach, a minimum number of 25 samples are required per 1 million tons geologic unit, or one sample for every 40,000 tons (Figure 1). However, as the waste volume increases beyond 1.5E+8 tons, the number of samples decreases. Gene Farmer of the U.S. Forest Service suggested collecting 50 samples for each 1 million tons of waste (USDA Forest Service, 1992). The specifics of Gene Farmers' approach indicate that for each 1 million tons of waste rock, eight to twelve samples of each significant rock type (as a minimum) should be collected (Schafer 1993). Brady and Hornberger (1989) proposed a minimum number of samples per coal seam based solely on acreage, calculated as [acres/(100acres)]+2. A similar approach was suggested by Freeman *et al* (1987), which allowed the areal extent of a coal mine to be used as the basis for determining the number of samples.

In general, fixed-frequency sampling methods imply that each individual sample used to test and classify larger volumes of waste, would allow lithological stratification mixing and sample chemistry blend. Consequences of this approach may be far reaching as information about sample variability could be lost, imposing a degree of liability (British Columbia AMD Task Force, 1990). In addition, sample lithotype mixture may not necessarily be applicable in highly heterogeneous conditions such as at base metal mines (SENES, 1994).

Although the scheme is not specific for AMD, a prominent code on statistical sampling theory and practice has been developed by the Joint Ore Reserve Committee for the mining industry (JORC 2012). Reporting standards on sampling methods, measurements of sampling error and correctness and Public Report transparency regarding exploration results (JORC 2012), are included in this code. The proposed method of sample selection is similar to those used to evaluate recoverable mineral resources (assay samples), which employ estimation variance (ANOVA and variant method) to determine the optimum threshold of parameters (such as total sulfur), as a function of sample density and characterization (Modis and Komnitsas 2007; Kentwell *et al* 2012; Servida *et al* 2013). If the parameter of interest is either well above or below the threshold of interest, the total unit or volume of a rock type can be classified as either potential acid forming (PAF) or non-acid forming (NAF) and managed accordingly. However, the spatial distribution of the element within a rock category may not necessarily be homogeneous across the entire volume of each rock type; this may raise questions pertaining to heterogeneity, sampling intensity and sample density.

CHARACTERIZATION AND ASSESSMENT METHOD

The methodologies used in several AMD studies (Table 1) are inclusive of a global ARD and AMD knowledge base, and experiences gained in different climatic and geological-hydrogeological settings. However, the methodology the authors practice differs slightly as it incorporates the development of a mine hydrogeochemical conceptual model as a first step in the assessment of AMD (Table 2). The conceptual model is developed to account for the potential of overburden, waste rock, and the ore body

(all grades) to possess either acid or base characteristics. Studies incorporated for this assessment include geological, hydrogeochemical, hydrological and hydrogeological data gathered during exploration activities. These parameters are assessed on merits of their natural occurrences and interactions and are subsequently risk assessed with regard to potential short- to long-term social, economic and environmental impacts.

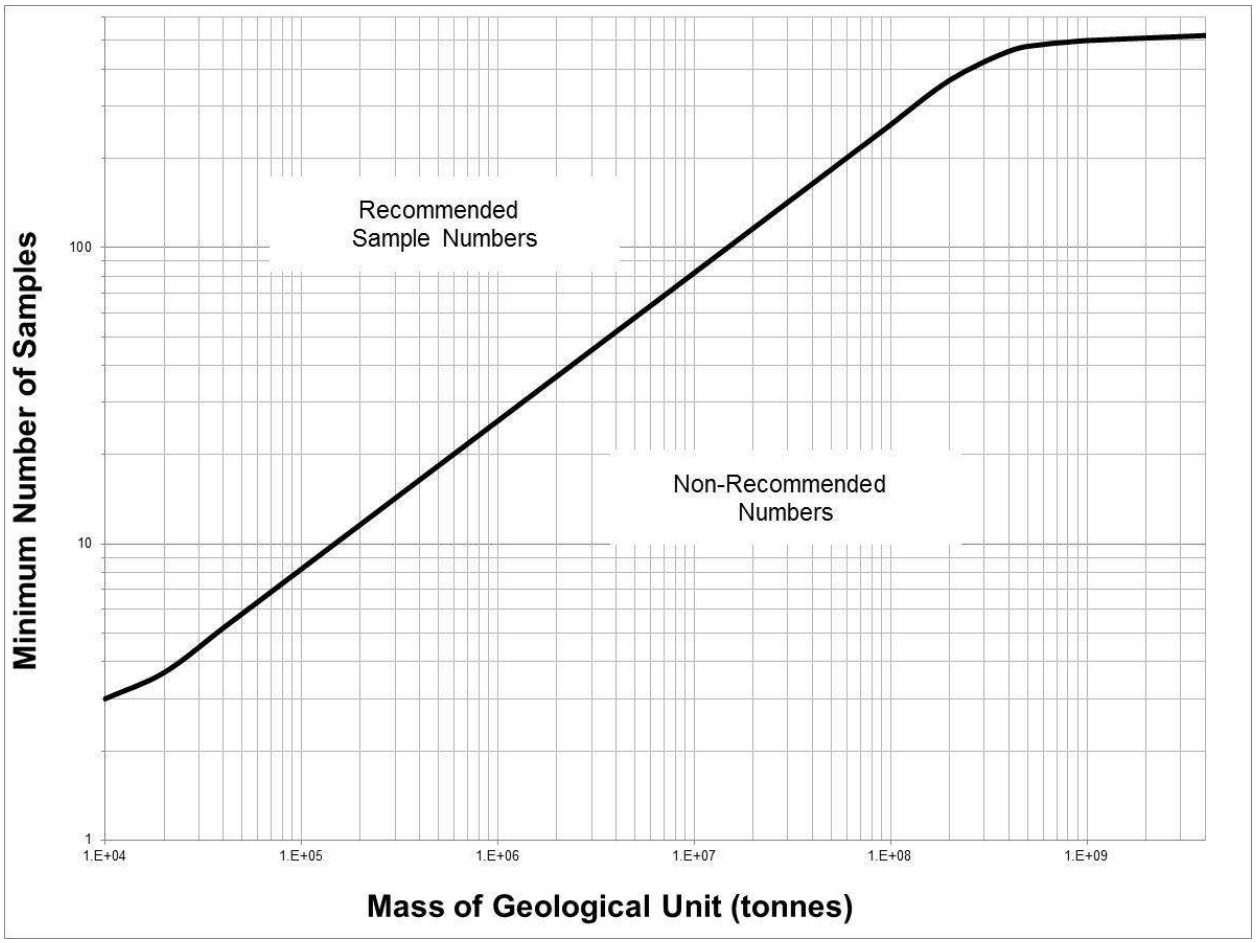

Figure 1 Recommended Minimum Number of Samples as a function of Mass of Each Geologic Unit

The conceptual model becomes a key interpretive AMD framework which provides a basis for the prediction of chemical processes that may develop during operations and post-mining. The derived framework is then tested by limited sampling and analysis which incorporates additional geochemical testing in the form of acid base accounting (ABA) and kinetic testing if required. Although the question of up scaling remains, field kinetic testing is recommended as it fosters the resemblance of actual climatic conditions and can be adapted to investigate new findings arising during the subsequent stages of mining.

Table 1 Selected AMD Investigations

Project Name	Project Location	Client	Characteristic
Area C Iron Project	NT, Australia	Sherwin Iron Pty Ltd.	EIS component
Beatons Creek	Western Australia	Novo Resources Corp.	EIS Component
Frances Creek	NT, Australia	Territory Iron Pty Ltd.	Rehabilitation
Goldsworthy Mine	Western Australia	BHP Billiton	Remediation and Closure
Kapulo Copper Project	Congo	Mawson West Ltd.	EIS component
Old Pirate Mine	NT, Australia	ABM Resources NL	MMP Component
Railway Project, Yandi	Western Australia	United Mineral Corporation	EIS component
RedbankMine Site	NT, Australia	Redbank Cooper Ltd.	EIS component
Western Desert Iron Ore Project	NT, Australia	Western Desert Resources Ltd.	EIS component
Westgold Project	NT, Australia	Westgold Resources Ltd.	EIS component

An example of conclusions reached during the conceptual model stage at one of the projects (Table 1) is presented below.

- Deposit C, due to its mineralogical characteristics and low sulfide concentrations, has a low likelihood of producing acid mine and metalliferous drainage.
- Low sulfur concentrations (<0.25%S) in more than 99% of the samples (Table 2) indicate that potential acid forming (PAF) materials occur sporadically, are highly localised and are confined to about nine locations (RC bores). Four locations (RC bores) contain samples located beneath the direct shipping ore (DSO) body.
- Most PAF materials (84% of samples) occur outside the perimeters of the proposed open pit and/or are beneath the base thereof.
- The ground water level is likely to remain below the base of the open pit. Localised perched waters in shallow highly weathered and/or fracture systems are not a cause for concern.
- Deep ground water may be impacted by infiltrating rain from the open pit (partially backfilled with a large void remaining after closure) migrating through the underlying undisturbed PAF bodies. However, PAF bodies are small and isolated and evaporation exceeds rainfall by several orders of magnitude, which limit the quantity of water that may infiltrate through the base of the open pit. Rain falling into the open pit may also be diverted away from areas where PAF bodies are known to exist.

This preliminary assessment indicated no need for a rigorous AMD evaluation but to comply with regulatory requirements, further assessments were undertaken. Using the fixed-frequency sampling approach a minimum of 404 samples across the different sandstone (Sst), siltstone (Slt), shale (Shl), ferruginous sandstone (Fst) and other layers would have been required. However, a total-S global statistical approach indicated that at a 95% confidence level, a maximum of 50 samples would yield a low global 1.41% margin of error (Table 3).

Table 2 Mine Geochemical Conceptual Models

Project Name	Exploration Geochemistry, Mineralogy and Geology								Interactions	Conceptual Model						AMD Potential
	XRF (No samples; %)				XRD		Petrography	SEM		Perceived Risks:						
	No Samples	<0.25%	0.25% - 0.3%	>0.3%	No Samples	Sulfides				Issue / Cause	Insignificant	Minor	Moderate	Major	Catastrophic	
Redbank Cooper Project	140	*50*	*6*	*44*	40	Yes			Surface / Ground water	Acidic seepages from waste rock dumps (WRD), tailing storage facilities (TSF) and pits.				X		Likely

Westgold Project	115	30	1.2	17	17	17

*Iron and cooper concentrations used for the statistical assessment.

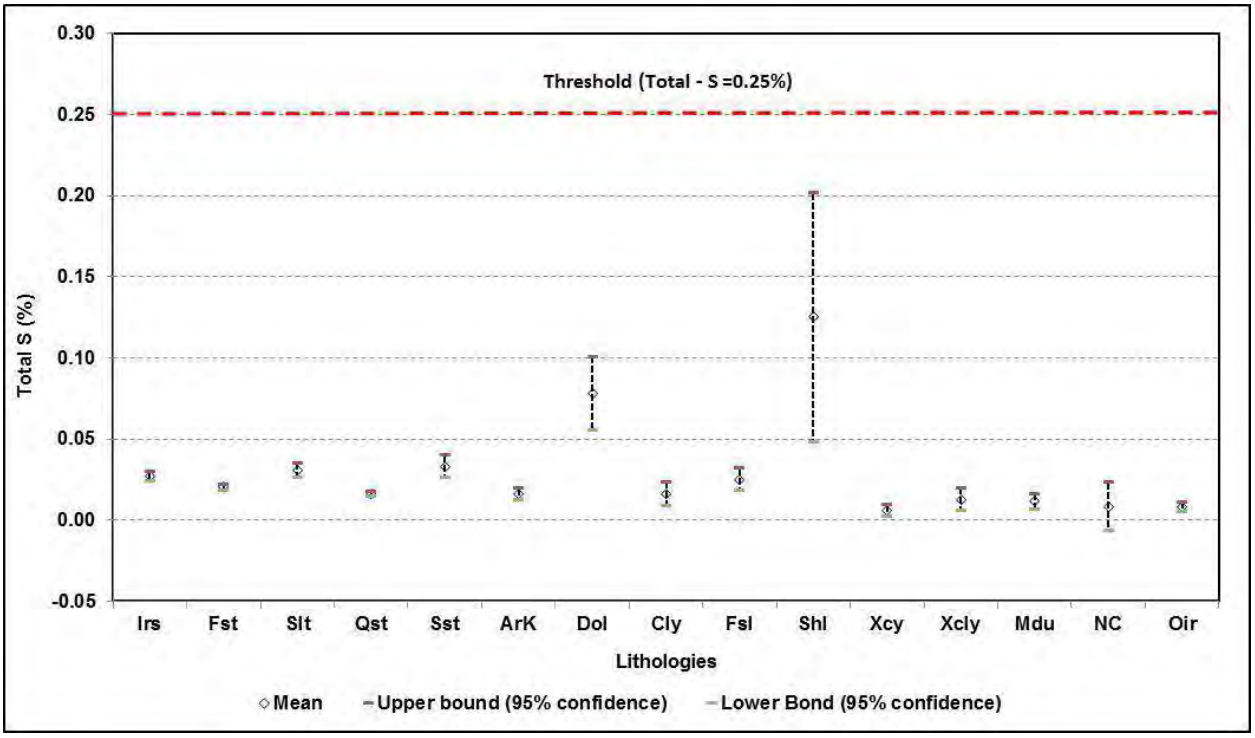

Figure 2 95% Confidence Intervals for Waste Lithologies at Deposit C

A further statistical assessment of the sample population in relation to global lithological distribution based also on total-S concentration (Figure 2) indicated that the threshold sulfur value of 0.25% is well above of the highest mean of 0.13% of the shale (Shl). The 95% confidence level of this highest mean ranges from 0.05% to 0.20% and all rocks may be classified as non-acid forming (NAF) materials.

In summary, the development of the conceptual model assisted with defining the degree of rigour with which the exploration data needed to be assessed, as a first step of sample number definition and

quantification. The statistical assessment, to comply with regulatory requirements, allowed verification of the optimum number of samples (Table 3) submitted for analytical assessment. The highest confidence levels tolerated indicated that the sample population selected would produce high confidence levels and contain the true sample population value which, provided confidence to verify the assumptions made during the development of the geochemical conceptual model.

The conceptual model approach with clearly defined objectives abridged the premise that *samples must be selected to characterize both the type and volume of rock materials and also to account for the variability of materials that will be exposed during the life of the mine* (DITR 2007; DMP 2009). In addition, it assisted with determining the extent of the mine AMD management plan (including sampling methodologies and monitoring requirements) and a site specific standard operation procedure (SoP) for the daily management of PAF/NAF waste materials.

AMD ASSESSMENT APPROACH

Sample qualification and quantification are generally regulated by various authorities and approval agencies, and supplemented by a series of guidelines which despite postulating sample location, quantity and type, are seldom specific in regard to analytical assessment methodology. The use of these guidelines in distinguishing an approach to sampling should not be regarded as a stringent *step-by-step,* but instead be considered in conjunction with a risk-based approach, incorporating interpretation of the wider interactions of site conditions with current ARD and AMD scientific knowledge, and adjusted accordingly. Guidelines, rather than being prescriptive, should aid stakeholders to factor internal and external influences of and for the project. This in essence should set a framework that integrates the processes for identifying and managing risks, strategies and planning for the management of potential acid forming materials.

Included in the development of the hydrogeochemical conceptual model are the environmental risk assessment of AMD and an overall evaluation of social, economic and environmental impacts of the project. The analysis of these parameters primarily assists with defining the potential extent of impacts and perceived value of onsite and offsite environments. These are also considered to ascertain the degree of rigour required by further sampling and help in setting adequate analysis to characterize sources, pathways and receptors. For example, if the mine is located within a sensitive environment with likely downstream impacts by AMD formation, the sample number and sampling frequency are likely to increase as a consequence of the risks coupled with a stricter more detailed assessment by the regulator. However, if the site has no significant potential for AMD and is located in a remote locality with little or no predicted downstream environmental impacts, the AMD assessment may be concluded after finalising the conceptual model, with limited confirmatory sampling and analysis.

In summary, if the analysis of key parameters incorporates a quantifiable risk of the local and regional site conditions, the wider geological and geochemical analysis, qualification and quantification of wastes and a hydrogeochemical assessment, a site specific investigation should provide a good base to evaluate AMD and their implications for mining development (Figure 3).

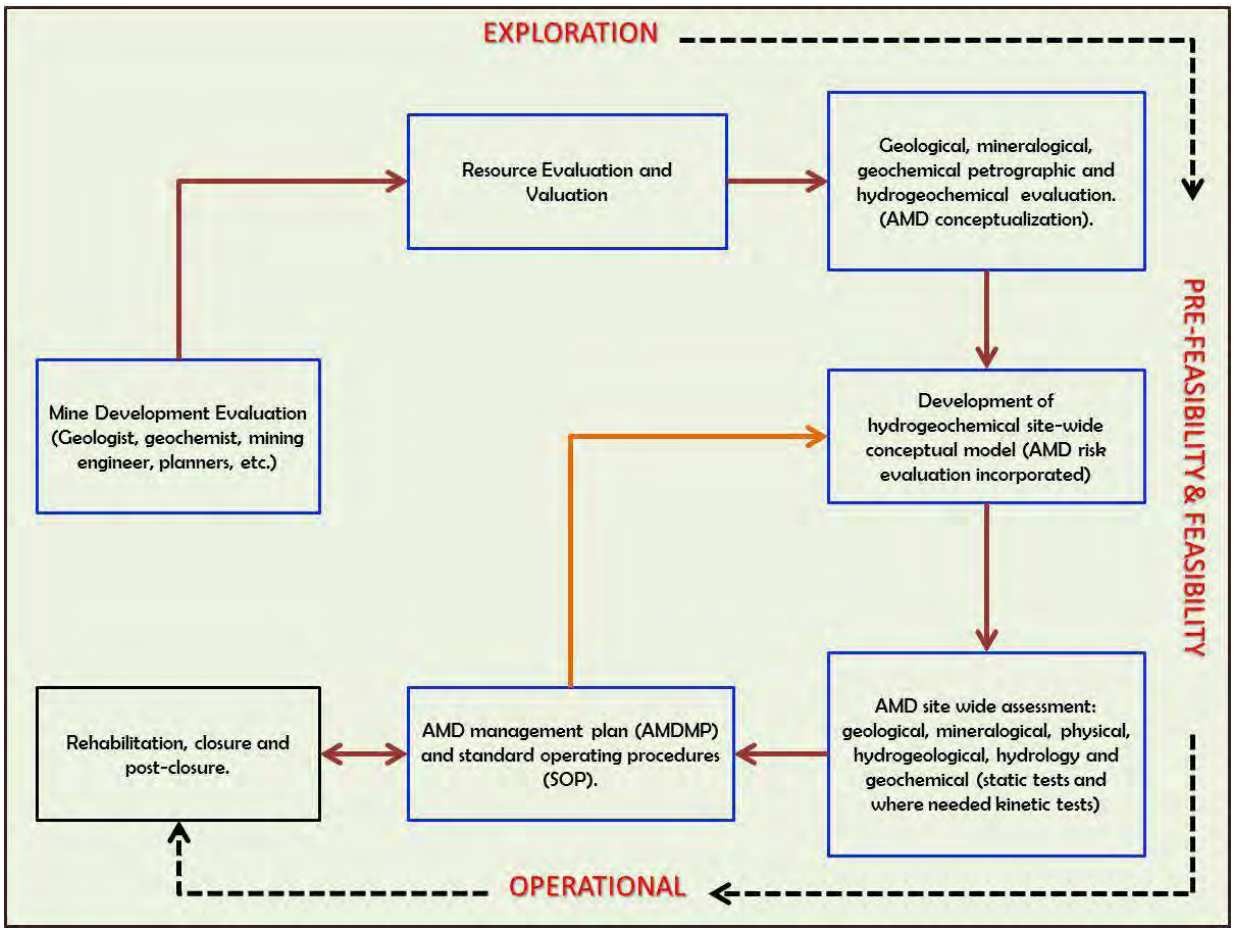

Figure 3 Flow Diagram to be adopted at the Exploration Stage

However, this approach needs to be incorporated at the exploration stage and continued through to the pre-feasibility, feasibility and operation phases. A good opportunity to further AMD studies is also presented by the grade control drilling program during feasibility studies and subsequent mining. This drilling program is developed to better understand grade distribution and variability of recoverable resources. Thus the development of a site wide hydrogeochemical conceptual model during the early stages of the exploration program should be used as a forum to:

- Analyse the potential for AMD formation.
- Assess the environmental sensitivity of the site and potential risks than this may pose.
- Assess the potential short- to long-term social, economic and environmental consequences.
- Define sample quality and number.
- Define methodologies to be used for AMD investigations and assessments.

ABSTRACT

The application of drilling surveys to assess economic viability, ground stability and hydrogeological conditions are typically completed prior to commencement of mining. It is generally accepted that in many instances insufficient geological samples are collected from these drilling programs specifically for geochemical analysis to effectively characterise the acid and metalliferous drainage (AMD) potential of the deposit. To minimise risk associated with incomplete characterisation of AMD potential, a continuing AMD sampling and analysis program can be developed and implemented to ensure adequate sample collection occurs.

The focus of this paper is to outline a case study of the development of such a sampling program for a large mining company that incorporates all of their Western Australian iron ore operations. The program utilises multi-discipline drilling programs at all stages of mine development to minimise AMD risk.

The continuing sampling and analysis program is initiated at the long term drilling schedule planning stage by selecting relevant upcoming programs. Potential drilling programs include exploration, geotechnical, hydrogeological and grade-control drilling. Engagement with project teams responsible for the individual drilling programs to express interest in drill core is initiated early with upfront cross-discipline drilling planning meetings. Once approval has been given to select splits of drill core, a sampling plan is developed and provided to the responsible project teams along with a detailed and easy to follow sample collection and dispatch procedure.

The implementation of the program over the previous ten months has successfully seen the selection and collection of geological samples from more than 35 drilling programs across 25 deposits spanning six mining operations within Western Australia. In addition to increasing the size of their regional environmental geochemical database, this has resulted in significant cost-savings by incorporating AMD sampling into existing drilling programs. Designing the program to have minimal impact on existing procedures and the positive adoption of site personnel to reducing AMD risk has contributed strongly to the success of the program.

Keywords: AMD sampling and analysis, large scale sampling, multi-discipline drilling

INTRODUCTION

Geological samples, in some form or another, are collected from the first to last drill hole for any given mining project. Drilling programs to assess economic viability, ground stability and hydrogeological conditions are typically completed prior to commencement of mining and all present opportunities for the collection of geological material. However, sufficient environmental geochemical samples to adequately characterise a site for its potential to generate acid and metalliferous drainage (AMD) are not commonly collected. This deficiency in waste rock geochemical knowledge can be due to a number of reasons:

- Exploration programs do not generally actively target waste units which are typically the key materials of interest for AMD predictions, rather they focus on ore bodies.
- Minimum sampling requirements for AMD assessments set by regulatory bodies are often vague and/or poorly interpreted by those developing sampling programs.
- AMD sampling programs are often considered to be complete and are ceased once approval to mine has been granted.
- The true monetary value of AMD risk is often poorly understood and/or insufficiently weighted against exploration/production targets.

AMD sampling programs can also have the propensity to be set at a level that is too intensive in the early stages of mine development. Intensive analysis of geological materials for AMD assessments prior to developing a sound geological understanding of the deposit can lead to disproportionate analysis of waste units. This can in many cases result in unnecessary expenditure by mining companies on environmental geochemical data not providing the value of its capital outlay.

These potential causes for insufficient sample collection or conversely early phase over-intensive analysis for AMD assessments, can be addressed by implementing an iterative sampling program throughout the life of the mining operation (Kentwell et al. 2012). Leveraging off the multiple drilling programs routinely completed as part of resource assessment can mean costly standalone drilling programs specifically for AMD assessments may be avoided.

Successfully taking advantage of drilling programs designed for purposes other than AMD sampling requires close interaction with the multiple stakeholders specific to each drilling program. Carefully designed and easy to follow procedures are critical to ensure consistency and sample integrity is achieved in sample selection and collection stages.

As part of geochemical risk management activities, an ongoing AMD sampling and analysis program was developed for the Western Australian iron operations of a large iron-ore mining company by the authors in collaboration with the mining company. The program developed utilises multi-discipline drilling programs at all stages of mine development to minimise AMD risk. This paper presents the various stages that comprise the developed ongoing sampling program including the incorporation of a data management and tracking procedure to ensure sample and data integrity is maintained.

METHODOLOGY

The mining company's ongoing sampling and analysis program comprises multiple stages with input required from various groups within the company. To ensure that sample and data integrity could be maintained over such a large program, a data tracking and management procedure was incorporated into the ongoing sampling and analysis program. The stages of the developed program are presented in Figure 1 and are:

- Identification and initiating involvement with key drilling programs and program stake holders.
- Development of a consistent sample selection procedure.
- Development of consistent sample collection procedure.
- Data tracking and management.
- AMD Data interpretation.

Adoption by Key Stakeholders

The first step to designing an ongoing sampling and analysis program that is to be successfully adopted by multiple operations and disciplines is understanding the drivers of each of the key stakeholders. That is, when taking advantage of planned drilling programs for opportunistic AMD sampling, the program must be designed to work around the key stakeholder's objectives.

For individual AMD sampling plans created within the ongoing sampling and analysis program, requesting site personnel or those responsible for the planning of the drilling programs to significantly alter an established process was deliberately avoided. The objective being to minimise the burden (perceived or actual) of the AMD sampling, particularly for site staff.

Some key factors that the effective adoption and implementation of the program (by multiple stakeholders) depended on, included:

- Frequent and open communications with site personnel and drilling program coordinators.
- Understanding the various sampling/logging/dispatch procedures employed across the site(s), e.g. geotechnical versus hydrogeological versus exploration versus grade control.
- Understanding the limitations of each drilling technique employed and therefore the limitations for AMD sampling.
- Designing the sampling and analysis plans to be cohesive with planned drilling programs.
- Avoiding requests for unnecessary collection of samples.

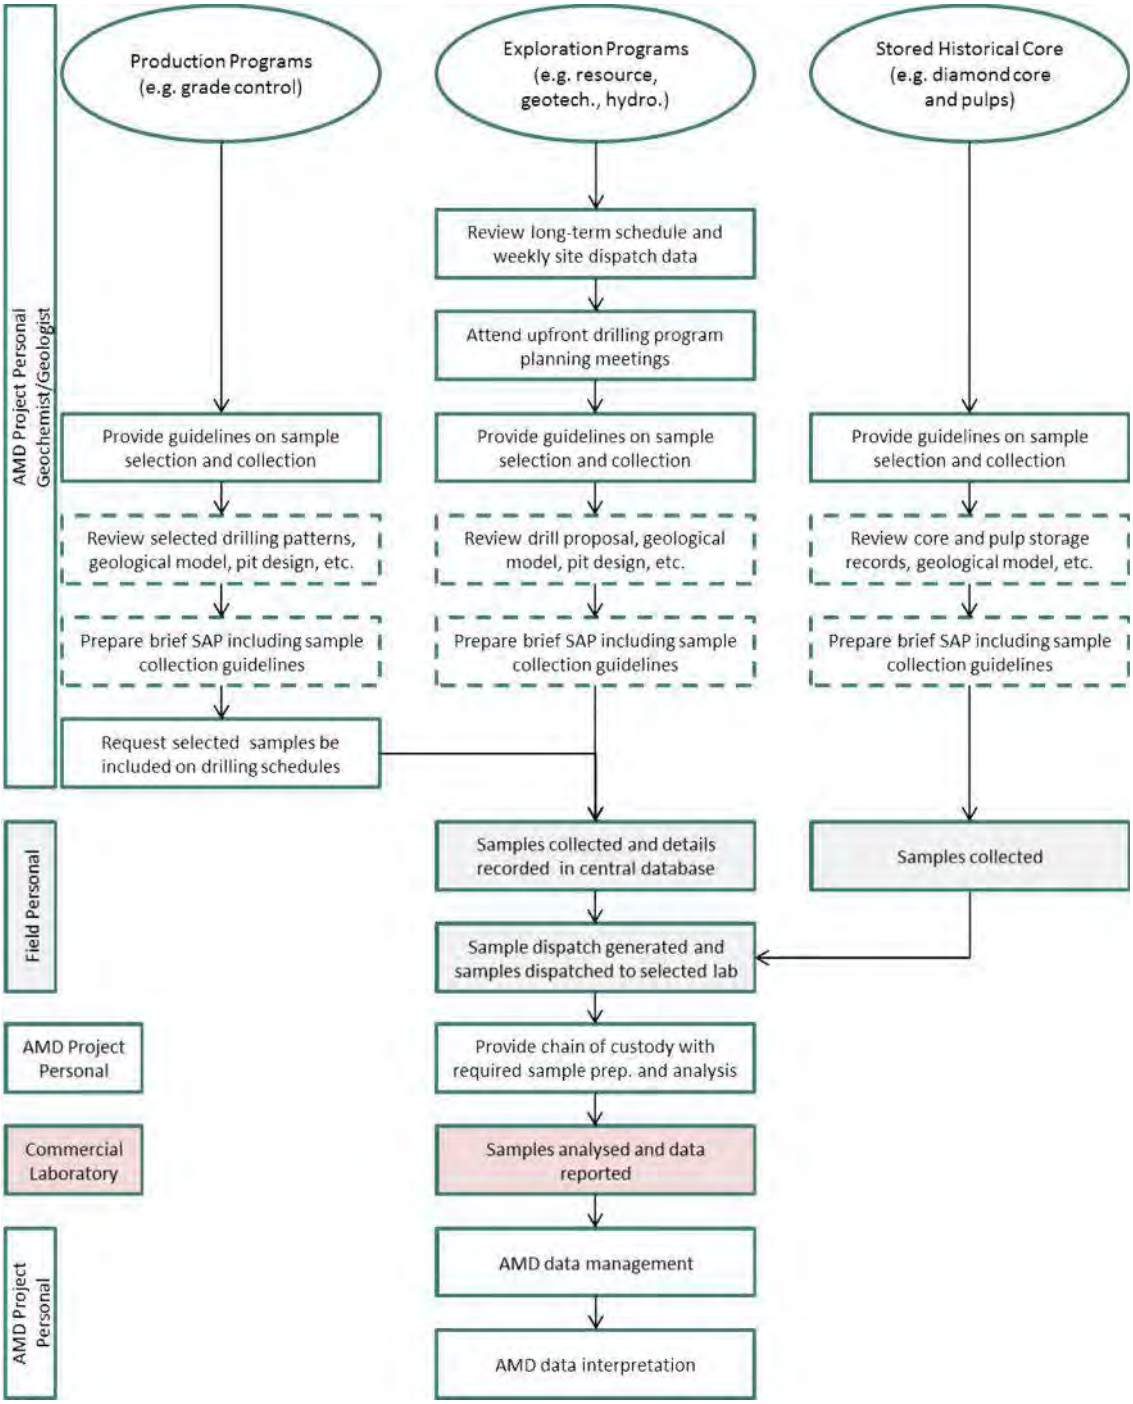

Figure 1 Ongoing sampling and analysis program flowchart

Identification and Initiating Involvement with Key Drilling Programs

The ongoing sampling and analysis program is initiated at the long term drilling schedule planning stage by selecting relevant upcoming programs. Potential drilling programs include exploration, geotechnical, hydrogeological and grade-control drilling. Engagement with project teams responsible for the individual drilling programs to express interest in drill core was initiated early with upfront cross-discipline drilling planning meetings.

For large mining companies with several standalone mining operations, careful consideration must be given to which drilling program is selected to avoid unnecessary expenditure. Unnecessary expenditure are not limited to direct laboratory costs but also the time taken by employees to select and collect samples.

Some key questions asked when deciding whether to pursue a planned drilling program included:

- Does the planned drilling program target a deposit of significant interest to the company?
- Will the drilling program intersect key lithological units with respect to AMD generation?
- Will the drilling program intersect lithological units for which little data is currently available?
- Is there sufficient knowledge of the orebody and potential pit shell to avoid unnecessary sampling, i.e. is it worthwhile waiting for an infill drilling program planned at a later date?
- Is the drilling method conducive to the collection of meaningful AMD samples?

Development of a Consistent Sample Selection Procedure

Once approval had been granted by project teams responsible for the individual drilling programs to select splits of drill core, a sampling plan was developed. A sample selection procedure was developed to promote consistency across the various operations. The procedure included the selection of samples from upcoming drilling programs and the selection of stored core/pulps.

The sample selection procedure was designed to be used for each phase of sampling with each preceding phase informing the current planned phase and is therefore iterative in nature. Several informed decisions are required throughout the procedure which are primarily based on the sampling program objectives, the size of the drilling program, the type of drilling method and existing geochemical information.

The sample selection procedure was comprised of the steps presented in Figure 2.

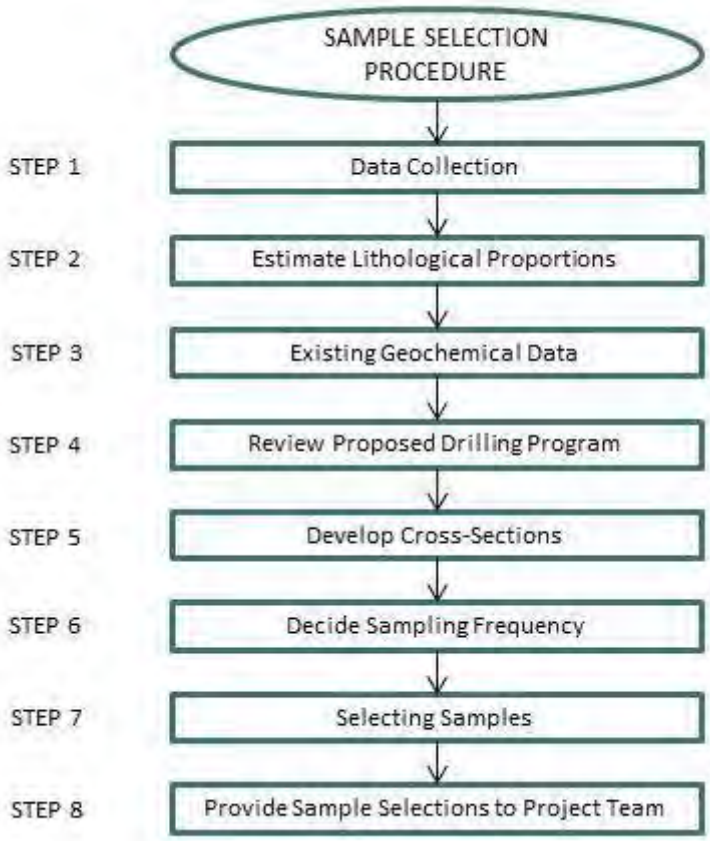

Figure 2 Sample selection procedure flowchart

Initially, the most up to date drilling proposal and geological resource model from the central database was collected (Step 1). Then, using geological modelling software, the percentages of each waste lithology to be mined within the proposed pit shell was estimated as well as lithologies remaining in the pit wall (Step 2).

To ensure informed sample selections incorporated all applicable data collected prior, relevant geochemical data for the deposit including the current assay database was reviewed (Step 3). If sulfur data was available within the assay database, the sulfur distribution within the geological model was assessed to identify any regions of high sulfur concentrations. The average sulfur concentrations per lithology was also estimated.

Following the review of all relevant data, the proposed drilling program was studied within the resource model to assess what lithologies may be intersected (Step 4). The potentially intersected lithologies were cross-checked with:

- Any lithologies previously identified as important with respect to AMD processes such as sulfide/carbonate bearing units or enrichment in elements of concern.
- Results of the existing geochemical data review (Step 3).

To assist site personal with sample selection and to also aid the later stages of data interpretation, geological modelling software was used to create cross sections (Step 5). Cross-sections included, at a minimum, proposed drill holes, historical drill holes (if appropriate), geological information (lithological domains, ore zone(s), weathered zones), proposed pit shell(s) and pre-mining water tables.

For drilling programs covering the entire deposit, cross-sections were spaced at relatively equal distances spanning the deposit in order to achieve a good spatial representation. For smaller targeted drilling programs (geotechnical, etc), all drill holes were presented on the cross-sections.

Several factors need to be considered when deciding the sampling frequency for Step 6. For large, deposit encompassing drilling programs, sufficient numbers of samples should be taken to accurately characterise the variability and central tendency (e.g. average, median, and 10th and 90th percentiles) of the different waste materials, project components and geological units (DoITR, 2007 and Price, 2009). For smaller targeted drilling programs (e.g. geotechnical) the sample frequency was largely reduced and was not necessarily focussed on spatial representativeness.

Figure 3 presents some of the factors to be considered when deciding on the sampling frequency for an individual drilling program.

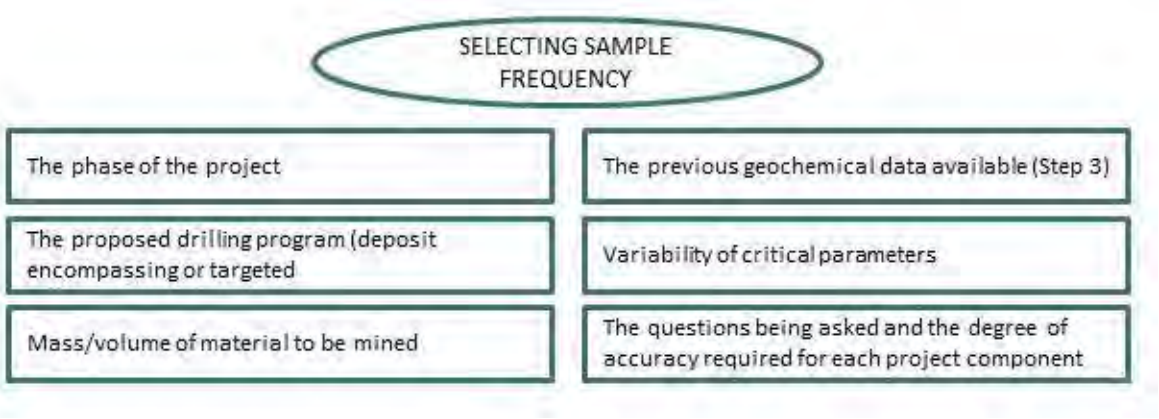

Figure 3: Selecting sample frequency

Providing good spatial, geological and geochemical representation in the sample population is important as AMD may be produced by only a portion of the geological materials (Price, 2009). For large deposit encompassing programs, the aim was to select sample proportions equivalent to the waste material to be mined as determined in Step 2.

Sampling locations (Step 7) were largely based on:

- The required accuracy and precision of the sampling program.
- Knowledge of the deposit.
- Areas of notable physical, mineralogical, geochemical and degrees of weathering differences.
- Findings from Step 3 and Step 4.

The proportions of specific lithologies may increase if lithologies to be intersected have been identified in previous geochemical assessments as units of interest. In addition, lithologies may have been targeted for extra sampling if specific drainage prediction questions were being investigated.

Once all samples were selected, selections were tabulated and their corresponding details were provided in a format easily followed by field personal (Step 8).

Development of a Consistent Sample Collection Procedure

To maintain sample and data integrity, particularly within a large company with multiple disciplines responsible for sample collection and dispatch, a consistent and easy to follow sample collection procedure is essential and as such was developed.

Sample recording, bagging, labelling and dispatch instructions were clearly provided in the sample collection procedure. The recording and entering of sample details into the central database represents the commencement of the phase that follows the ongoing sampling and analysis program (data tracking and management procedure).

Clear sample collection instructions for each drilling technique were needed to ensure sample integrity was maintained. Three separate sub-procedures were therefore developed for the three main drilling techniques employed at the various operations:

- Diamond Core – exploration, geotechnical, metallurgical and hydrogeological.
- Reverse Circulation – exploration, geotechnical, metallurgical and hydrogeological.
- Blast hole – grade control.

Diamond Core (Exploration, Geotechnical, Metallurgical and Hydrogeological)

Sampling of diamond core for AMD testing was undertaken in various ways because of the multiple programs employing this drilling method. Quarter core splits were generally collected and were largely obtained following a coarse crushing stage. Greater proportions than quarter were generally only permitted when core was not to be assayed.

Timing was critical for the requesting of diamond core intervals because generally all core was processed; if the request was delayed samples may have not been available. Therefore, when core arrived at the processing facilities, borehole logs had to be reviewed within the geological model as a priority prior to submitting a sample request form.

Reverse Circulation (Exploration, Geotechnical, Metallurgical and Hydrogeological)

Drilling programs employing reverse circulation drilling collected requested samples as a split sample directly from the cone or rotary cone splitter. For exploration drillholes, one composite sample was collected per rod (3 m interval).

Unlike diamond core selections which were selected after reviewing borehole logs, sample selections from reverse circulation drilling were made prior to drilling. Therefore, targeted lithologies were often missed as field staff collected requested intervals irrespective of the material intersected. This was counteracted by over-selection during the sample selection phase as the cost to collect and dispose of additional unwanted samples was considered to outweigh falling short on collection of key lithologies.

Blast hole (Grade Control)

Although the quality of samples collected from blastholes for environmental geochemistry purposes were considered lower than samples collected from diamond and reverse circulation drilling, there is still benefit in utilising this source for AMD characterisation. .

Taking the limitations into consideration, only one sample was collected for any given blasthole and specifically from the middle 3 m interval. This was to minimise contamination from the upper bench blasting pattern and bias introduced from collecting material from the lower portion of the drillhole.

Data Tracking and Management

The data tracking and management procedure begins when sample collection details are recorded and entered into the central database (Figure 4). Samples are then dispatched under a standardised dispatch system.

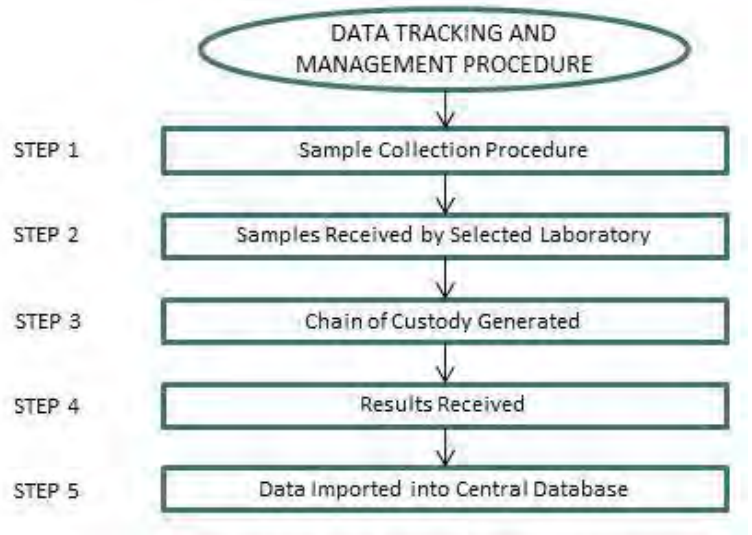

Figure 4: Data tracking and management procedure flowchart

Once samples arrived at the laboratory, received samples were assessed and analysis requests (chain of custodies) were prepared. This also provided an opportunity to review assay data if available for specific intervals to reduce unnecessary analysis. It also provided an additional control step to identify primary samples sent to the environmental laboratory that should have been directed to the metallurgical laboratory.

To streamline the importation of laboratory data into the central database, a database compatible format was developed. This file was provided to internal database specialists.

Data Interpretation

Once all data is located within the central database, it needs to be readily available for inclusion in AMD assessments for specific operations. To streamline the collation of required data for AMD assessments, an "AMD Export" file (readable as a csv) was developed that included all critical

available information for AMD assessments. The export includes a range of parameters for each data point, such as:

- Project and orebody.
- Borehole name, drilling method, borehole coordinates and coordinates grid name.
- Unique internal sample number and unique laboratory sample number.
- Sample depth.
- Lithology, waste/ore, degree of weathering, above or below water table.
- Laboratory results (environmental and assay where available).

RESULTS AND CONCLUSIONS

The implementation of the program over its first ten months successfully saw the selection and collection of geological samples from more than 35 drilling programs across 25 deposits spanning six mining operations within Western Australia. In addition to increasing the size of the regional environmental geochemical database, this has resulted in significant cost-savings by incorporating AMD sampling into existing drilling programs.

Designing the program to have minimal impact on existing procedures and the positive inclusion and "buy in" of site personnel to reducing AMD risk has contributed strongly to the success of the program. As a result of the careful consideration for implementation, it was noted that as the program developed teams in other disciplines were willing to allow redesigning of planned drilling programs for AMD specific drillholes. This was considered a positive sign of internal acceptance and approval of the program.

Some key learnings from the implementation of the program included:

- Understanding the limitations of the drilling methods and the already established sample collection procedures was required to ensure sensible sample requests were made.
- Understanding the limitations of the selection/collection procedures was paramount to (a) understanding the limitations of the data collected, and (b) appreciate that not all targeted units may be collected and to prepare inbuilt contingencies within the sampling plans.
- When selecting samples from geological block models, it is important to recognise the limitations in resolution/accuracy and select samples accordingly. That is, the successful collection of a targeted lithology is more likely if a wider interval range is provided to field personal (15-21m opposed to 15-18m).
- Different field staff may interpret requested sample intervals differently; one composite sample (3 m) collected within the requested 10 m interval opposed to the entire interval being collected (three samples). For this reason, the analysis request step was not included at the dispatch stage which allowed the prevention of unnecessary analysis.

Potential areas for further program development include:

- Incorporate other parameters where available into the sample selection procedure that may also be recorded within resource block models, (calcium, magnesium, selenium, etc).

- Where possible, request field staff to differentiate between sub-units when selecting and collecting samples. For example, sub-units can have significantly different acid forming potentials and reaction rates leading to different management options.

ACKNOWLEDGEMENTS

We would like to acknowledge the mining company and their staff for their assistance in developing and establishing the program. We would also like to acknowledge the advice provided by both the mining company and Golder Associates Pty Ltd staff.

Difficulties of Interpretation of NAG Test Results on Net Neutralizing Mine Wastes: Initial Observations of Elevated pH Conditions and Theory of CO_2 Disequilibrium

Jessica Charles, Andrew Barnes, Julien Declercq, Ruth Warrender, Christopher Brough, and Robert Bowell
SRK Consulting, United Kingdom

ABSTRACT

Hydrogen peroxide leach tests (NAG tests) are increasing in use by the mining industry for determining acid rock drainage characteristics of mine wastes. The test uses an excess of hydrogen peroxide (H_2O_2) to rapidly oxidise sulfide minerals in a sample, thus releasing acidity related to sulfide oxidation. The acidity released is neutralized by available (carbonate) neutralizing potential, theoretically resulting in a measure of Net Acid Generation (NAG) based on material reactivity. In addition, chemical analysis of the NAG leachates can be undertaken to provide an indication of solutes that may be mobilised during sulfide weathering.

NAG tests are complimentary tests to standard Acid Base Accounting (ABA), allowing clarification of ABA characteristics and better characterization of samples that show uncertain characteristics based on ABA testwork. However, experience has shown that the use of the NAG test method on samples with elevated carbonate content can result in excessively basic pH conditions which may be misleading and result in uncertainty in interpretation.

To understand the uncertainty mentioned above, tests were completed to measure and evaluate the pH change throughout the NAG test method. The results indicate that much of the pH change can be attributed to carbon dioxide (CO_2) disequilibrium during the heating stage of a NAG test. The study is supported by diagnostic mineralogical and geochemical investigation. In addition, the influence of CO_2 on NAG test pH conditions is demonstrated through numerical interpretation using the USGS thermodynamic equilibrium code PHREEQC.

Keywords: ARDML, NAG, PHREEQC, carbon dioxide, hydrogen peroxide

INTRODUCTION

Environmental concerns coupled with the strengthening of environmental legislation, has necessitated the development a range of testwork methods for the prediction of Acid Rock Drainage and Metal Leaching (ARDML) from mine wastes. One of the most accepted and widespread methods is the Acid Base Accounting (ABA) test, which is used to determine the balance between acid generation potential (AP) and acid neutralization potential (NP) of a material based on sulfide and carbonate content, respectively. Recently, the complimentary NAG) test method has seen increasing use within the industry. This test allows for the rapid determination of ARD characteristics of tailings and waste rock samples through the use of hydrogen peroxide (H_2O_2). The typical NAG test procedure is based upon H_2O_2 oxidation testing that has been developed over the past 40 years by: Smith *et al*. (1974), Sobek *et al*. (1978), O'Shay & Hossner, (1984), Finkelman & Giffin (1986), O'Shay *et al*., (1990), Miller *et al*. (1997), and most recently by Stewart *et al*. (2003); Stewart (2005) and Stewart *et al*. (2006).

Solutions generated during the NAG test can additionally be analysed to provide an indication of metal and metalloid (e.g. zinc, copper, lead, cadmium, arsenic) mobility during weathering and oxidation of the waste. Furthermore, there are possible advantages to using NAG tests and derivations of the NAG test (such as kinetic NAG) as a substitute for kinetic tests (Miller *et al*., 1997; Stewart *et al*., 2006; Sapsford *et al*., 2010) and for preliminary prediction of seepage water quality from mining waste facilities (Barnes et al., 2013; Barnes et al., 2015).

Although NAG tests allow for improved understanding of ARDML characteristics and classification of samples that show uncertain acid generating characteristics from ABA testing, it is not without its limitations. These limitations have been highlighted in studies undertaken on the NAG testing of coal spoils by Stewart, (2005) and Stewart *et al*., (2006). In addition, other authors have highlighted the sensitivity of the oxidising agent H_2O_2 to: base metal cations and dissolved carbonates (Lee *et al*., 2000 and references therein); and to elevated reaction temperatures (Yazici & Deveci, 2010).

Further to the above limitations with respect to the instability of H_2O_2, it has also been observed by the authors that the use of the NAG test method on samples with elevated transition metal carbonate content (such as ankerite) can produce excessively basic NAG pH conditions which may be misleading and result in uncertainty in interpretation. This paper intends to shed light on the mechanisms that induce the generation of excessively basic solution. It is hypothesised that the elevated pH conditions can be attributed to carbon dioxide (CO_2) disequilibrium during the heating stage of a NAG test.

METHODOLOGY

Ten waste rock samples were collected from a gold mine site in the UK. Local geology at the site consists of clastic marine sediments, minor volcanic units, sandstone and auriferous quartz-carbonate veins. The major gold-bearing formation comprises mixed semi-pelites, quartz semi-pelites, and psammites. The project area contains mesothermal gold mineralization, with gold disseminated in quartz-sulfide veins.

Acid base accounting testwork

ABA testing was undertaken in accordance with the method described in EN15875 (CEN, 2011). The method assesses the speciated carbon and sulfur content of the samples to determine the balance of acid generating sulfides (AP) and acid neutralizing carbonate minerals (NP). ABA testing does not make allowances for mineralogy and assumes all sulfide is present as pyrite and all carbonates are present as calcite. AP is calculated from the sulfide sulfur content of the samples whilst the NP is based on a modified Sobek procedure in which acid addition is determined from the Total Inorganic Carbon (TIC) content of the sample. The determination of a samples AP and NP in kg $CaCO_3$ equivalents per tonne allows for the calculation of net neutralizing potential (NNP) and neutralization potential ratio (NPR) which describe the samples potential for acid generation:

$$Net\ Neutralizing\ Potential\ (NNP)(kg\ CaCO_3) = NP - AP$$

$$Neutralization\ Potential\ Ratio\ (NPR) = {}^{NP}/_{AP}$$

An assessment of paste pH was also undertaken to determine the immediate sample pH without oxidation of the sample.

Mineralogical analysis

A mineralogical investigation was undertaken on the samples to assist in interpretation of the NAG test results. This consisted of optical and scanning electron microscopic (SEM) analysis and spectroscopic analysis using SEM electron dispersive X-Ray (EDX) analysis of grab samples from the drill core sample intervals. The investigation focussed on quartz, carbonate, and sulfides within mineralized veins.

Net acid generation testwork

The static NAG test differs from the ABA test in that it provides a direct empirical estimate of the overall sample reactivity, including any acid generated by semi-soluble sulfate minerals (e.g. alunite), as well as other potentially acid-generating sulfur-bearing minerals. As such, the NAG test provides a better estimate of potential for field acid generation than the more widely-used ABA methods. ABA defines acid potential based solely on sulfide sulfur, or total sulfur content, and assumes pyrite to be the dominant sulfide mineral present.

NAG testing was carried out in accordance with the method described in the AMIRA guidelines (2002) as follows: 250 mL of 15% H_2O_2 was added to 2.5g of pulverised sample. The H_2O_2 was allowed to react with the sample overnight, and the following day the NAG solution was gently heated, using a hot plate to near boiling for a minimum of 2 hours; deionised water was added as required to maintain an approximately constant volume of solution. The NAG solution is heated to remove excess H_2O_2 and also facilitate the release of inherent neutralizing capacity (carbonate buffering). The solution was then allowed to cool to room temperature, and at this point the NAG pH was measured and recorded. The test also reports the NAG value, measured in equivalent kilograms of sulfuric acid (H_2SO_4) per tonne.

The above method was adapted for the test samples in order to track the pH change through the latter portion of the test. pH was measured at the following times to determine the evolution of solution pH:

- *Step 1*: Prior to solution heating following completion of NAG test procedure (20 °C)
- *Step 2*: Following 2 hour heating step (at approximately 100 °C) after the solution is allowed to cool to room temperature (20 °C) - and then made up with deionised water - typical NAG pH
- *Step 3*: After solution allowed to equilibrate with atmosphere for 24 hours
- *Step 4*: After solution allowed to equilibrate with atmosphere at room temperature for 1 week.

The leachate generated during the NAG test was analysed for major ions, dissolved metals and metalloids using inductively coupled plasma mass spectrometry (ICP-MS). The aggressive oxidising conditions of the H_2O_2 used in the NAG test, effectively oxidises all physically exposed or chemically available sulfide minerals. Analysis of the NAG solution provides an indication of the potential for high level metal(loid) release that would occur during exposure of the mine-waste material to oxygen.

Thermodynamic equilibrium modeling

Thermodynamic equilibrium calculations were carried out to validate and numerically recreate the observations of the NAG testwork and demonstrate the influence of CO_2 on NAG pH. Thermodynamic calculations were carried out using the geochemical modelling code PHREEQC, version 3.1.2.8538 (Parkhurst & Appelo, 1999) together with the MINTEQ v8 database. This database is largely consistent with the MINTEQ v4 provided with PHREEQC, including updated thermodynamic data for arsenic and manganese. The NAG solutions defined in TABLE 1 were run initially in PHREEQC without any carbonate equilibrium phases, then the same simulations were run with CO_2 at atmospheric pressure (CO_2 partial pressure of 0.0003 bar). Forty PHREEQC simulations (four per initial starting solution; TABLE 1) were carried out in order to replicate the NAG experiment as described below:

- *Simulation 1*: Initial solution – at room temperature (20 °C)
- *Simulation 2*: Boiling initial solution (100 °C) - degassing of CO_2 in solution to atmospheric equilibrium
- *Simulation 3*: Cooling of solution back to room temperature (20 °C) – system at disequilibrium with respect to CO_2 and carbonate minerals with CO_2 in solution much lower than equilibrium CO_2 concentration
- *Simulation 4*: System allowed to reach equilibrium with respect to CO_2 (20 °C)

The input solution chemistries outlined in TABLE 1 were experimentally derived from the NAG test. Bicarbonate alkalinity was not measured directly and was determined via major ion charge balance.

Table 1 PHREEQC initial input solutions derived from NAG leachate analysis

RESULTS

ABA testwork

ABA testwork results for the ten samples are summarised in TABLE 2. Based on the results all samples are classified as Non Acid Forming (NAF). Paste pH of the samples ranged from 8.12 to 8.96 with an average of 8.47. The total sulfur concentrations range from 0.01 wt% to 0.16 wt%. The samples are classified as NAF based on their NNP and NPR values which were calculated from the NP and AP values. Nine of the 10 samples have a greater NP than AP and are therefore classified as net neutralizing mine waste. An NNP result of <-20 and an NPR result of <1 is indicative of a potentially acid forming (PAF) sample, whereas an NNP of >20 and an NPR of >3 is representative of a NAF sample. All samples except for sample 10 report an NPR of >3.

Table 2 Sample summary

PAF – Potentially Acid Forming; NAF – Non-Acid Forming; TIC – Total Inorganic Carbon

Mineralogical assessment

Optical microscope and SEM investigation confirmed the main sulfide mineral present within the deposit as pyrite (FeS_2), which was present in two main textural associations. First, pyrite was frequently present in trace (<1%) proportions within the main quartz-mica-schist (QMS) fabric; usually fine-grained and aligned along the foliation direction. Second, coarse to medium-grained euhderal to subhedral pyrite within cross-cutting veins. This pyrite was closely associated with quartz and ankerite (the main carbonate mineral observed). In addition to pyrite there was subordinate chalcopyrite ($FeCuS_2$), aikinite ($CuPbBiS_3$), enargite (Cu_3AsS_4), lautite (CuAsS), and galena (PbS). Mg-poor ankerite was the primary carbonate present in the samples, with an approximate stoichiometry of $0.5Ca0.2Mg0.3(Fe,Mn)CO_3$.

NAG testwork

The NAG pHs recorded during the various stages of the NAG tests are reported in TABLE 3 and FIGURE 1. In general, a NAG pH less than 4.5 and a NAG value greater than 5 kg H_2SO_4 equivalents per tonne are indicative of a PAF material. All NAG pH values recorded in the various stages of the testwork are neutral to alkaline (7.0 to 10.67). The table shows that following the NAG test but prior to the pre-heating stage, the measured pH for all solutions is in the range of 7.0 to 7.5 with little deviation. Comparison of the pre-boiling NAG pH with measured paste pH shows that pre-boiling NAG pH is consistently in the region of 1 to 1.5 pH units lower than paste pH.

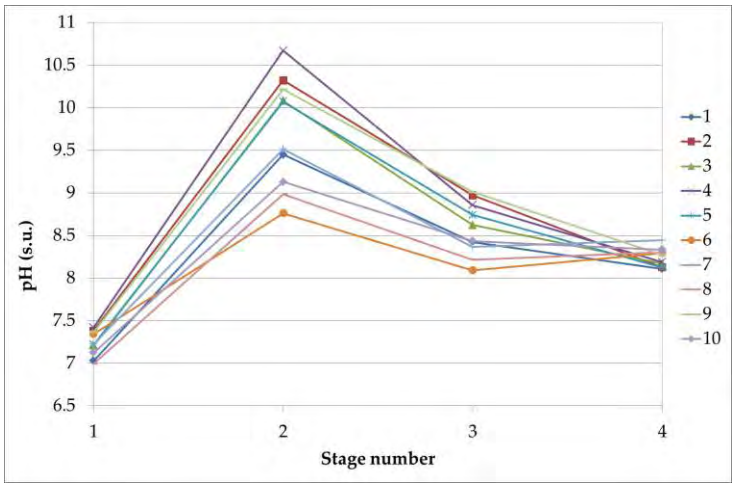

Figure 1 pH variability in NAG experiments

Following the initial pH measurement the NAG solution was heated as per the protocol for a period of approximately 2 hours. Following the heating step, the solution was allowed to cool back to room temperature and was then filled to 250mL with deionised water. Solution pH was then measured a second time (stage 2). The results show that the NAG pH of the solutions greatly increases following the boiling of the solution, suggesting that the solutions are out of equilibration with CO_2 when samples are allowed a standard cooling time. The average pH of the ten solutions increased from 7.23 at stage 1 to 9.72 at stage 2. The average pH dropped from 9.72 at stage 2 to 8.57 at stage 3 following 24 hours of further oxidation and equilibration. After a week, the pH of seven of the ten samples showed further decline, with the average pH decreasing from 8.57 at stage 3 to 8.24 at stage 4.

PHREEQC output results

The PHREEQC output results are in TABLE 3 and are compared with the results of the laboratory testwork in FIGURE 2. The results of thermodynamic equilibrium modelling using PHREEQC exhibit the same pH variability as seen in the laboratory based NAG testwork. The solutions were reacted at a temperature of 100°C; this resulted in the degassing of CO_2 to equilibrium with the atmosphere. The subsequent cooling of the solution back to room temperature results in the system being at disequilibrium with respect to atmospheric CO_2. Average pH increased from 7.23 in the input solution to 9.93 following the boiling and subsequent cooling of the solutions. Comparison between the laboratory data and the thermodynamic equilibrium simulation show good agreement with respect to average pH characteristics with average values in both the disequilibrium case and fully equilibrated cases showing agreement within 0.5 pH units.

DISCUSSION

The generally accepted NAG test method outlined in Stewart *et al*. (2006) instructs that the NAG solution is boiled to facilitate the breakdown of residual H_2O_2 and also the dissolution of carbonate neutralization potential (NP) buffering. The results of this work have shown that the boiling step in the NAG test methodology can lead to the over estimation of basic pH conditions when the NAG solutions are allowed the standard cooling time. It is postulated that this is the result of the solutions being out of equilibration with respect to CO_2 gas and carbonate minerals. Therefore, the use of such data may lead to a misleading prediction of solution composition, if NAG solution analysis for dissolved metals is to be undertaken.

In order to understand what is occurring in the NAG solution as a result of boiling, it is necessary to understand the carbonate buffer system in detail. Unlike a number of other naturally occurring buffer systems, such as borate, the carbonate buffer system has a gaseous component, and therefore the pH behaviour of the buffer is dependent on interaction between the solution phase and the gaseous phases (Stumm & Morgan, 1996). Furthermore, the nature of the NAG test, in which acidity rapidly dissolves carbonate minerals, means conditions are suitable for gas phase disequilibrium to occur in accordance with the following stoichiometry:

$$\textit{(Sulfide Oxidation by } H_2O_2 \textit{ – Chirita (2007))}\ FeS_2 + 7.5H_2O_2 \rightarrow Fe^{3+} + 2SO_4^{2-} + H^+ + 7H_2O$$

$$\textit{(Neutralization reaction)}\ 2H^+ + CaCO_{3(s)} \leftrightarrow 2HCO_3^+ + Ca^{2+}$$

$$\textit{(Gas Phase Equilibration)}\ HCO_3^+ \leftrightarrow CO_{2(g)} + OH^-$$

Owing to the sensitivity of gas solubility to solution temperature (in accordance with Henry's Law), any changes in solution temperature may have a marked effect on solution pH. Furthermore, the relatively shallow concentration gradients involved in $CO_{2(g)}$ equilibrium with a solution phase due largely to the relatively low atmospheric concentration, means the rates of CO_2 gas transfer between gaseous and solution phases (as described by Fick's law) is slow, requiring hours or days to attain.

The use of the typical NAG test method involving a heating step on NAF samples with elevated carbonate content can therefore produce excessively basic NAG pH as an artefact of test conditions. The basicity of the NAG solution pH reported in this study immediately following cooling after the boiling step may lead to the following potential issues:

- Increased mobility of certain elements, especially the oxyanions potentially including arsenic, selenium antimony, and chromium
- Decreased mobility of certain elements, especially metals whose minimum hydroxide solubility is above pH 9 such as zinc, nickel and cadmium.
- Potential misinterpretation of pH conditions from mine-waste rock drainage leading to incorrect classification of acid generation characteristics.

CONCLUSION

NAG testing has emerged as a useful tool in the assessment of ARDML at mine sites. However, the results of this study and previous work undertaken utilising NAG tests have identified that there is still much to understand about the nature of these tests, and the chemical mechanisms that control the stability and behaviour of the H_2O_2 solution. This study has focused on methodological variations in NAG test pH conditions, resulting from carbonate disequilibrium, resulting from the

particular prescribed methodology. The results suggest that the pH variations seen in the test may be attributed to CO_2 disequilibrium during the heating stage of the NAG test. Therefore NAG pH according to the standard test methodology (for certain net alkaline solutions) cannot be fully relied on as an indication of mine water pH, due largely to the gas phase disequilibrium created.

In order to address this, it is recommended that the pH of a NAG solution be recorded pre- and post-boiling in order to identify the discrepancy in pH disequilibrium. In addition, if the intention is to analyse the NAG solution to give an indication of the potential for mobilization of problematic elements, it is advised that the solution is collected prior to solution heating stage to avoid under- and/or over-reporting metal mobility.

Applicability of a New and More Efficient Approach to the ABCC Test

Carla Calderón Rosas, Natalia Farfán and Carolina Soto
Fundación Chile

ABSTRACT

Acid Rock drainage (ARD) from mining waste such as tailings, waste rock, leach piles, etc, is currently one of the most important environmental concerns of mining activities. In order to address this problem, different prediction tests exist that allow the characterization of mine wastes and the assessment if these have the potential to generate acid drainage in the future.

One of the existing prediction tests is the ABCC (Acid Buffering Characteristic Curve) test, which allows one to determine the percentage of the neutralization potential (NP) of a sample that effectively reacts to neutralize acid at different pH values (MEND Report 1.20.1 (2009); Warwick A. et al. 2006). This test involves a slow titration with hydrochloric acid (HCl), and the continuous recording of pH values. The shape of the resulting curve indicates the capacity of the sample to neutralize acids.

The procedure of the ABCC test consists of adding water to a sample in a proportion of 2% (w/v), and then titrate every 15 minutes with HCl (under continuous agitation), until the mixture reaches a pH value of 2.8.

This test yields a good estimation of the neutralization capacity of a sample; however, one of its main disadvantages is the long analysis time per sample. Therefore, the objective of this study is the search of an appropriate development time of the test, which would result in fewer analysis times per sample and thus a cost reduction.

The results show that reducing the time of acid addition resulted in curves with no significant statistical variations when compared to the ones obtained with the original protocol. In consequence, it can be established that it is possible to conduct the ABCC test in a significantly shorter time while still obtaining meaningful results.

Keywords: Test ABCC, NP, Acid drainage, static test, massive mine waste

INTRODUCTION

Acid Rock Drainage (ARD) is a phenomenon which is produced through the exposure of sulphide minerals (such as pyrite) to atmospheric oxygen and water. As a product of mining activities, this phenomenon can be accelerated due to the increased exposure of these minerals to the environment, as is the case with massive mine wastes, such as tailings, waste rock and leach piles, among others. Consequently, ARD is one of the most important environmental problems of mining activities today.

To address this problem, a series of procedures were developed that allow for the characterization of the materials which compose mining wastes, in order to assess whether or not these will potentially generate acid drainage in the future. Among the most common methods are static prediction tests, i.e., those which include only one measurement in time. These tests are conducted on a laboratory scale, and include the most well known and performed tests the ABA (Acid Base Accounting) test and the NAG (Net Acid Generation) test.

On the other hand, there are other static prediction tests that are not as common, but similarly produce important information that permits the characterization of these minerals. One of these tests is the ABCC test, which has the objective to determine which percentage of the NP of a sample effectively reacts to neutralize the pH at different pH levels (MEND Report 1.20.1 (2009); Warwick A. *et al.* 2006).

The ABCC test involves a slow titration of a mixture of 100 mL DI water and 2 g sample with HCl, until a pH of 2.8 is reached, which is monitored continuously. Approximately every 15 minutes small volumes of HCl are added, and the pH value is recorded once it is stable. The volume and concentration of the added acid varies according to the range of NP values of the sample. High acid volumes and concentrations are used on samples with high NP values, and vice versa. Finally, the added quantity of HCl is converted into kg CaCO3/tonnes, the latter which is then plotted (x-axis) against measured pH (y-axis) (MEND Report 1.20.1 (2009); Warwick A. *et al.* 2006).

Although this test gives a good estimation of the neutralization capacity of a sample, it has the main disadvantage that the analysis per sample is time consuming. Therefore, the objective of this study is to find an appropriate execution time, which can secure reliable results while reducing associated costs.

METHODOLOGY

The study compromised the application of the original ABCC test as well as a modified protocol, in which the time interval of HCl addition was varied (15, 5 and 3 minutes) by using tailings samples which correspond to samples from the copper flotation process. Afterwards, results were compared to determine whether or not significant differences could be observed. This comparison used statistical tools for each of the analyses conducted. Additionally the NP was determined to characterize the sample and to estimate the capacity of neutralizing acid, which is necessary in

order to define the conditions of the ABCC test. The methodology of the conduction of the study is described below.

Preparation and ID of the sample

The preparation of the sample consisted of: (1) drying the sample (not exceeding 40°C), and (2) the mechanical preparation of the sample, to obtain a sample of a grain size of 75 μm (for the conduction of ABCC test and determination of NP).

"ABCC-X" corresponds to the sample ID, where "-X" changes according to the analysis or test (Table 1).

Table 1 ID of the sample according to the analysis or test.

ID of the sample	Analysis or Test
ABCC-NP	NP determination
ABCC-(15)	ABCC test every 15 minutes
ABCC-(5)	ABCC test every 5 minutes
ABCC-(3)	ABCC test every 3 minutes

Mineralogical characterization

The mineralogical characterization of the sample was conducted by X- Ray Diffraction using TOPAS software. As observed in Table 2, the XRD analysis showed a sample characterized by the presence of quartz and aluminosilicates, and no presence of neither pyrite nor sulphide ore was detected.

Tabla 2 XRD characterization of the tailing sample tested

Mineral	Chemical Formula	Percentage (%)
SiO_2	Quartz	23.3
$Si_{2.83}\ Al_{1.17}\ Na_{0.84}\ Ca_{0.16}\ O_8$	Oligoclase An16	22.0
$Si_{2.72}\ Al_{1.28}\ Na_{0.75}\ Ca_{0.25}\ O_8$	Oligoclase An25	10.7
$Si_{1.5}\ Al_{0.5}\ Na_{0.07}\ K_{0.93}\ O_8$	Sanidine Na0.07	13.7
$Si_{1.5}\ Al_{0.5}\ Na_{0.1}\ K_{0.9}\ O_8$	Sanidine Na0.1	11.9

$Al_2\ Si_2\ O_5\ (OH)_4$	Dickite (BAILEY)	1.8
$Na_3Mn_5Si_8O_{24}$	Ungarettiite	0.0
FeS_2	Pyrite	0.0

Determination of Neutralization Potential (NP)

The determination of the neutralization potential of the sample was conducted using the Bulk Acid Neutralization method according to Modified Acid Base Accounting (1989). The procedure starts with the "fizz rating" test, which consists of adding 3-4 drops of a 25% HCl solution to a sample mass of 0.5 g, placed in a glass flask or a piece of aluminum foil, in order to observe any "fizz" and its magnitude, which is classified as "none, slight, moderate, or strong fizz". Afterwards, approximately 2 g of the sample are placed into a 250 mL Erlenmeyer flask, to which HCl is added. The volume and normality (N) of the acid depend on the "fizz rating" (Table 3). In this study, 20 mL of 0.1N HCl were used.

Table 3 Volume and Normality of HCl for NP determination, based in the Fizz Rating (After MEND Project 1.16.1b (2008).

Fizz Rating	Volume (mL)	Normality
None	20	0,1
Slight	40	0,1
Moderate	40	0,5
Strong	80	0,5

The HCl-sample mixture was left to react for 24 hours, placing the Erlenmeyer flask on a shaking apparatus. Finally, the sample is titrated with 0.1N NaOH (corresponding to the normality of HCl used), until a pH of 8.3 was reached. With the data obtained from the titration, the NP was determined in units of kg $CaCO_3$per tons of material, through the following equation:

$$NP = \frac{50a\left[x-\left(\frac{b}{a}\right)y\right]}{c} \quad (1)$$

Where:

NP: neutralization potential in kg $CaCO_3$/tonnes; a= normality of HCl; c= sample weight in grams; x= volume of HCl added in mL; y= volume of NaOH added to reach pH 8.3 in mL; b= normality of NaOH

Test ABCC (Acid Buffering Characteristic Curve)

The ABCC test is an analysis that allows the determination of the percentage that effectively reacts with and neutralizes acid (at different pH values) as it is directly related to the determination of NP described above. For this study, the ABCC test was conducted according to the protocol, as well as with modifications conducted by Fundación Chile.

ABCC TEST (Original Protocol) (MEND Report 1.20.1 (2009); Warwick A. et al. 2006)

This test consists of weighing approximately 2 g of sample into a 250 mL Erlenmeyer flask, and adding 100 mL of DI water. Afterwards, the mixture is slowly titrated until a pH of 2.8 is reached, the latter which is continuously monitored. This is carried out by adding 0.1 mL of 0.1 M (molar) HCl every 15 minutes, recording the pH value during this time. The volume and concentration of HCl used in the ABCC test depend on the NP value of the sample (Table 4).

Table 4 Suggested incremental additions and concentration of HCl (After MEND Report 1.20.1 (2009).

NP of sample (kg CaCO3 /tonnes of material)	Concentration of HCl (Molar)	Increments of HCl (mL)
10	0,1	0,1
20	0,1	0,2
50	0,1	0,5
100	0,5	0,2
200	0,5	0,4
500	0,5	1,0
1000	0,5	2,0

Finally, the quantity of HCL added in this test is converted into values of kg $CaCO_3$/tonnes of material (Equation 2), which are plotted against the pH (Y axis) measured every 15 minutes, obtaining the buffering curve.

$$\text{kg CaCO3} = \frac{[(\text{volume HCl (mL)addedx molar concentrationx100})/2]}{\text{sample weight (g)}} \quad (2)$$

ABCC TEST (FCh Protocol)

The procedure of the ABCC test developed by Fundación Chile is similar to the one described above. The difference is that the time interval of acid addition to the sample was modified, with the objective to reduce the time to conduct the test. In this procedure, the same sample and water quantities were used, as well as the concentration and volume of added HCl, as in the original protocol, while adding HCl and recording the pH value every 3 or 5 minutes. As in the original ABCC protocol, results in kg CaCO3/tonnes of material (x-axis) were plotted against the measured pH values (y-axis) to obtain the buffering curve.

Effective neutralization percentage (%RN)

Because the ABCC test allows determining what percentage of the NP actually reacts with and neutralizes acid, this percentage was determined for each of the three curves in this study; afterwards, the obtained results were compared with each other.To determine the percentage of neutralization (%RN) that effectively reacts, it is considered that neutralization reactions only occur until a pH value of 4.0, and the total neutralization capacity of a sample is determined through the Bulk Acid Neutralization Method. In consequence, the amount of NP that reacts is determined from the ABCC curve, with the value of kg CaCO3/tons of material that corresponds to a pH of 4 (Equation 3):

$$\%RN = \frac{(kgCaCO3/tonnesapH\ 4)}{(kgCaCO3/tonsofbulkacidneutralization)} x100 \quad (3)$$

Statistic Analysis

Statistical analysis was applied in order to assess if obtained results are acceptable. To achieve this goal, each ABCC test was conducted in triplicate, and the NP determination in duplicate.

To compare the results obtained from curves ABCC-(5) and ABCC-(3) with the reference curve ABCC-(15), t-student tests were performed for each point (average) of the curves, to determine if significant statistical differences exist. The t-test consists of determining the t value of student calculated from analytical experience, and compare this value with the so-called critical value, which is obtained from the t-student table for a given percentage of reliability. If no significant differences exist between 2 groups, the calculated "t" has to be smaller than the "t" value from the table (ISP (2010)). For all of the statistical measures, a 95% confidence interval was used.

RESULTS AND DISCUSSION

Determination of Neutralization Potential (NP)

The results of the determination of the NP of the samples present an average NP of 3.257 ±0.085 kg $CaCO_3$/tonnes (Table 5). As this is a positive value, it can be concluded that the sample does not have a high neutralization capacity.

Table 5 Results from the determination of NP.

ID sample	Fizz Test	NP (kg $CaCO_3$/tonnes)	Average NP (kg $CaCO_3$/tonnes)
ABCC-NP (A)	None	3,316	**3,257 ± 0,085**
ABCC-NP (B)	None	3,197	

ABCCTest (Acid Buffering Characteristic Curve)

The results presented below correspond to the analysis of one sample of tailings material, through the ABCC test, conducted in two forms, the original protocol and the modified one (FCh). To obtain reliable results, the sample was analyzed in triplicate for each of the protocols, so that results presented correspond to average values. The first results correspond to the curves obtained from adding HCl at three different time intervals. This volume of HCl was chosen, as all of the tests conducted, especially the original protocol, reached a pH of 3 with this volume. The results of the original protocol were used as a reference of comparison for the results of the modified test.

Comparing the results from the modified tests to the results of the original protocol, it can be seen that no significant differences exist for each of the points of the curve, neither in pH nor kg CaCO3/tonnes values.

Moreover, it can be observed that pH values of the ABCC-(15) curve are slightly greater than for the other two curves, with exception of the first points of the curves (before acid addition). It can be seen that the kg CaCO3/ton values are practically the same in all three curves (see Figure 1).

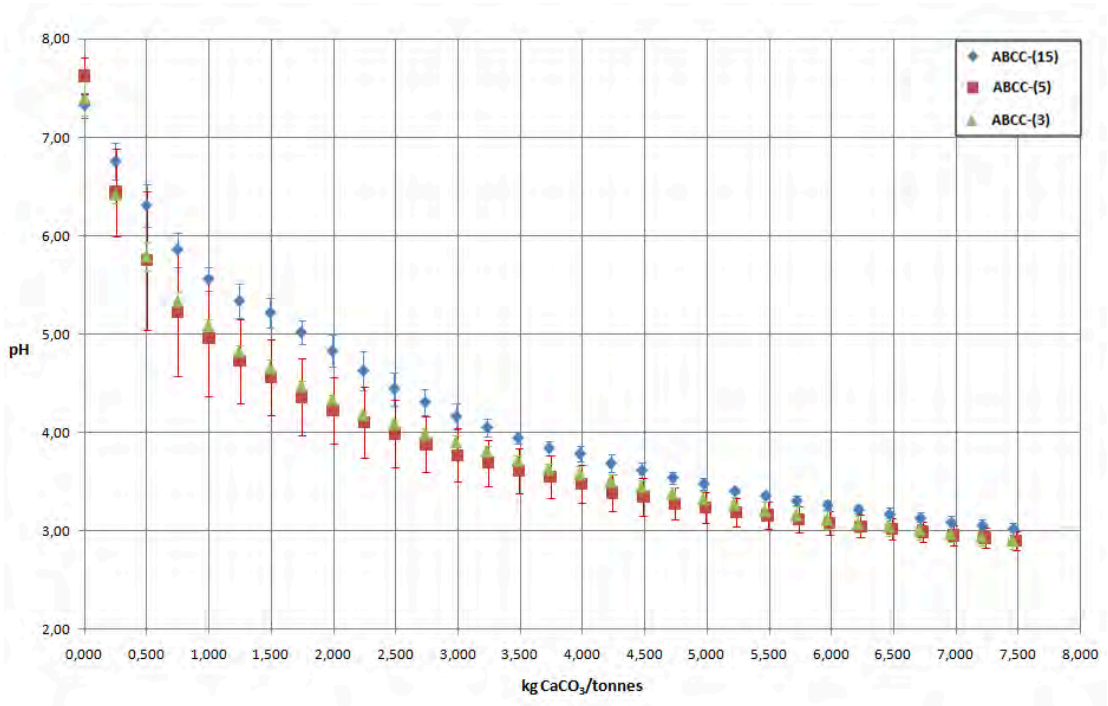

Figure 1 Acid Buffering Characteristics Curves of ABCC-(15) of reference, ABCC-(5) and ABCC-(3) protocols

It can be seen in Figure 1 that the three obtained curves show a similar behavior, and the major difference occurs in the first part of the curve. If the standard deviation is considered, the curves could be even more similar.

Another parameter to compare is the behavior of pH values concerning the amount of HCl added, as shown in Figures 2 and 3. It can be observed that pH values show greater differences among the different tests.

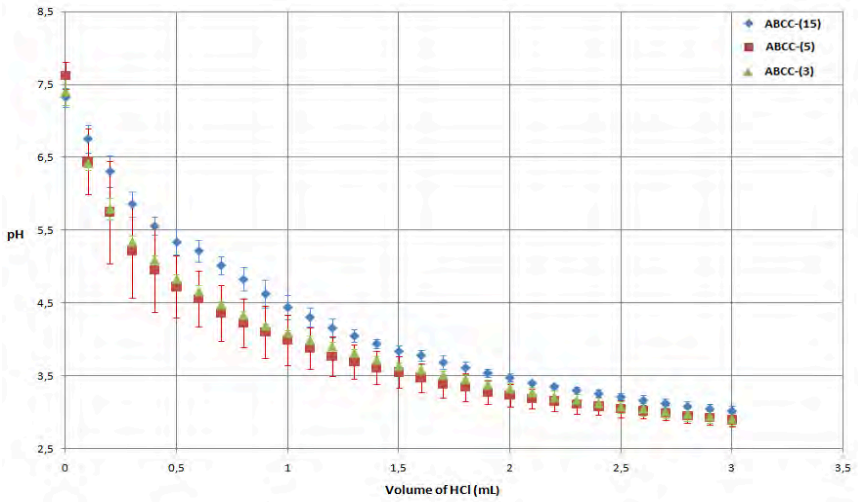

Figure 2 pH vs HCl added for reference ABCC-(15), ABCC-(5) and ABCC-(3) protocols

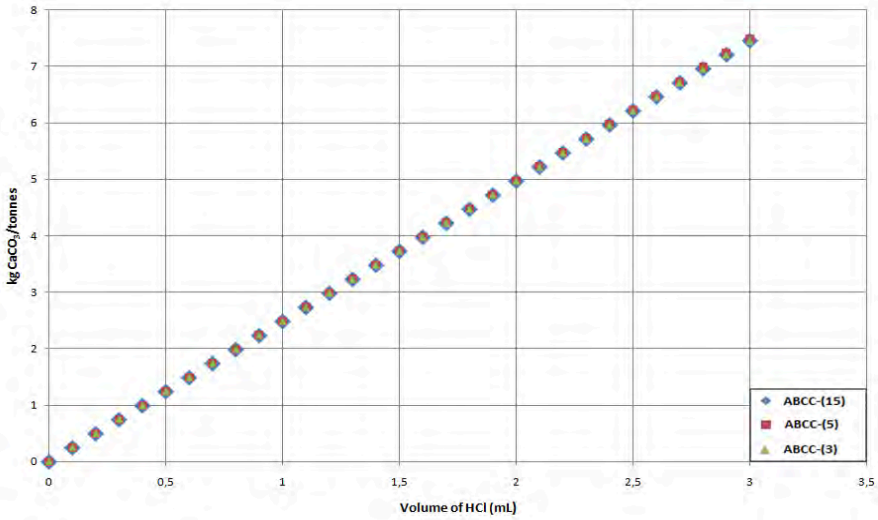

Figure 3 kg $CaCO_3$/tonnes vs HCl added for reference ABCC-(15), ABCC-(5) and ABCC-(3) protocols

All the values obtained and presented in each of the curves can be considered acceptable, as they show standard low deviation values and variation coefficients (%CV), the latter which are < 10% for all points, except 3 pH values in the ABCC-(5) curve (namely, 5.75±0.65; 5.22±0.65 and 4.96±0.59).

To analyze the differences between values of curves ABCC-(5) and ABCC-(3) related to the reference ABCC-(15), it can be concluded that these are quite low, as the first two curves show percent recovery (%R) between 80% and 110%, low systematic bias values, and complies with the rule that all tcal are smaller than tcrit for the t-student test. Thus, all values are acceptable and no significant differences exist between the reference curve and curves ABCC-(5) and ABCC-(3).

Effective percentage of neutralization (%EN)

This value was determined using the NP value obtained through the Bulk Acid Neutralization Method and of each of the ABCC curves. As in the reference curve (ABCC-(15)), a pH of 4 (4.05) was reached with a volume of 1.3 mL of HCl added, this value was used to determine the kg $CaCO_3$/tonnes values of the ABCC-(5) and ABCC-(3) curves for the determination of the %RN of both curves. The results are presented in Table 6 and 7.

Table 6 Neutralization Potential (NP) through the Bulk method and the capacity neutralization observed in ABCC curves at pH 4.

NP Bulk method (kg CaCO3/tonnes)	NP ABCC-(15) at pH 4(kg CaCO3/tonnes)	NP ABCC-(5) at pH 4(kg CaCO3/tonnes)	NP ABCC-(3) at pH 4(kg CaCO3/tonnes)
3,257	3,232	3,242	3,230

Table 7 Percentage of real neutralization (%RN) calculated of the 3 ABCC curves.

%RN ABCC-(15)	%RN ABCC-(5)	%RN ABCC-(3)
99,22	99,53	99,17

The results indicate that the three calculated %EN values from the ABCC curves are closely related. It can be observed that between curves ABCC-(15) and ABCC-(5), there is a difference of 0.0313 units in %EN; between ABCC-(15) and ABCC-(3), this difference is 0.049. It can be concluded that the difference between the three obtained %RN values is small, and is smaller between ABCC-(15) and ABCC-(3).

CONCLUSION

From the obtained results, it can be concluded that it is feasible to reduce the conduction time of the ABCC test in the manner proposed in this study, as the results indicate that no significant statistical differences exist in the data (curves) when comparing results from the original ABCC test and the test ABCC test modified by Fundación Chile. As shown in this study, the ABCC test with smaller time intervals for the addition of HCl, reliable data are obtained, which are very similar to those obtained by adding acid every 15 minutes.

Thus it was determined that the ABCC test can be conducted in a significantly shorter time, which permits developing studies and projects with reduced response times and costs, while working with reliable data.

Concerning the parameters assessed in the ABCC test, it can be concluded that the pH is the parameter that varies most, i.e. is the most sensitive, and could present an error, as it depends on the conditions under which the test is conducted, as it is an experimental parameter. Changes in kg

CaCO3/ton are minor, as this parameter is determined through a mathematical equation, which always should show a minor error.

It is important to note that all ABCC tests were conducted until a pH of 2.8 was reached as shown in protocols; however, only data until a pH of 3 were used as it was considered appropriate to work until this pH was reached. The results below a pH of 3 showed a very small variation by adding acid. The system is stable below a pH of 3, not producing any significant changes in pH values.

The protocols of the conducted ABCC tests in this study should use standard curves to compare results of a sample; as this was not possible in this study, the ABCC-(15) curve was used as a reference for all comparisons instead.

Finally, to mention that the ABCC tests conducted in this study were based on the description of two standard protocols: (1) MEND ("Prediction Manual for Drainage Chemistry from Sulphidic Geologic Materials (2009) and (2) Warwick A. et. al. (2006). Both protocols indicate that between each addition of acid solution 15 minutes must be waited and no additional information is provided about the reason of this determined time.

ACKNOWLEDGEMENTS

The authors would like to thank the geochemical team of the Environmental Risk Management Group, Department of Sustainability of Fundación Chile, for allowing the conduction of this study, which helps the constant development of tools and analyses for the characterization and prediction of acid rock drainage.

A Detailed ABA Study of the Coal-Bearing Formations in the Waterberg Coalfield, Limpopo Province, South Africa

Lorie Marie Deysel and Danie Vermeulen
Institute for Groundwater Studies, University of the Free State, South Africa

ABSTRACT

Coal constitutes 77% of the primary energy needs in the country, with the Waterberg Coalfield estimated to host about 40% of the remaining South African coal resources. The Karoo coals were deposited in a reduced environment that have the potential to produce sulphides within the sediments they are hosted. The sulphur content within the coal can range from 0.1 wt.% to as high as 10 wt.%. Mining generates a disturbance in the natural groundwater levels and affects the surrounding water chemistry when sulphate is produced as a result of pyrite oxidation.

Acid base accounting (ABA) was used to determine the balance between the acid producing potential (AP) and acid neutralizing potential (NP). From the analysis the Net Neutralising Potential (NNP) classified samples as either acid or non-acid producing. ARD does not only result in the generation of acid but is accompanied by decreased pH and increased values of specific conductance, dissolved metals and sulphate.

The ABA results showed that interburden and coal samples have higher risks of producing acid upon oxidation than overburden samples. Higher concentrations of neutralising minerals are present in overburden samples. ABA indicated that the material 60m below ground surface had a higher acid producing potential than the material above. The analysis from kinetic tests showed the long-term behaviour of different samples, with the electrical conductivity (EC) and pH changing over time. Samples with lower pH continued to produce more sulphate, while calcium continued to increase until it was depleted from the samples. Inductively coupled plasma analysis determined the release of the heavy metals which can be detrimental to the environment, such as As, Co, Ni and Pb.

The water demand will increase as mining continues in the area, with inter-catchment transfers identified to overcome local water scarcity issues. ARD poses a big threat to both groundwater and surface water resources.

Keywords: New coal mine, ABA, lithology classified

INTRODUCTION

The Waterberg coalfield (Figure 1) has been noted as the continental powerhouse of coal fuelled electricity production (Waterberg Municipality, 2013). The shortage of water is a problem as new mining communities are emerging. The impacts of acid mine drainage has been under investigation for years, in both operating and closed mines around the world.

Different methods are available for the prevention, management, treatment and prediction of ARD but no method can guarantee the remediation of ARD impact. No impacts have been noticed so far in the Grootegeluk mine, but according to the ABA done in the area (Vermeulen *et al.*, 2011) some of the lithology shows a very high acid potential.

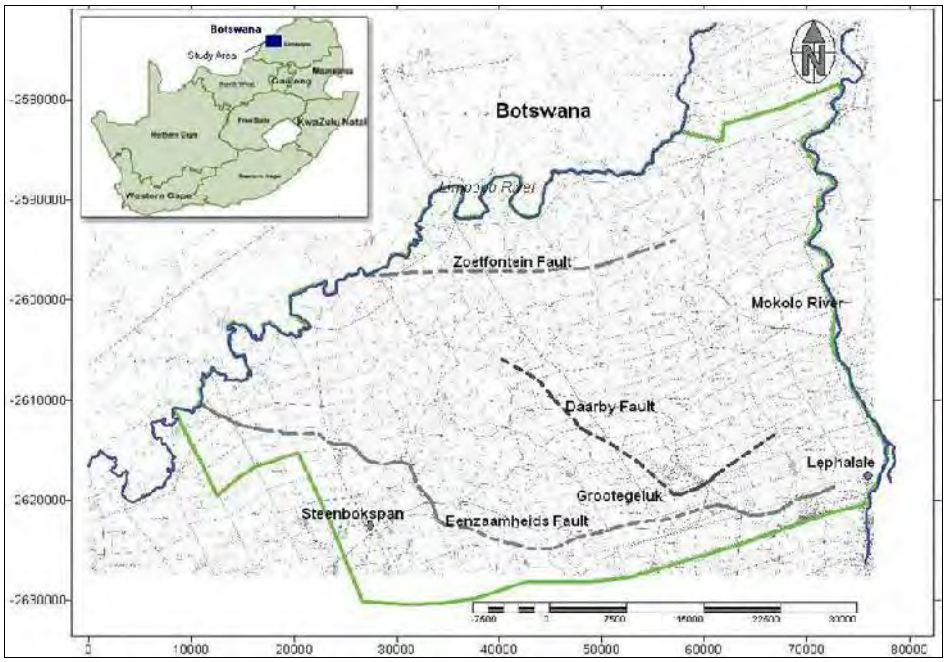

Figure 1 Location of study area. Insert: Map of South Africa indicating the position of the coalfield

Acid base accounting is used as a prediction tool to determine the acid potential of the lithological units. The 11 coal-bearing zones in the Waterberg coalfield are mined in benches and handled according to their intended use. There are two main coal-bearing formations in the Waterberg coalfield (Jeffrey, 2005); these coal zones extend from the Volksrust formation into the Vryheid formation. Vermeulen *et al.* (2011) described three main categories of coal thickness (identified by Bester, 2009), based on the weathered phase of the geology in the area. Figure 3 shows the three categories, green for full succession of coal, yellow for Middle Ecca and pink where area has been weathered in parts.

METHODOLOGY

Samples from different exploratian companies were collected from the study área in Figure 1. The investigation was conducted on various zones of borehole stratigraphy and on discards from the only active mine's beneficiation plant. The sampled material consisted of overburden, the mined interburden and discard after the coal material was liberated, as well as fly ash sampled form the Matimba Power Station.

Acid-Base Accounting was designed to evaluate the acid producing capability of coal mine wastes, and it is now used in a broader field to evaluate both the coal and the metal mine wastes (Lapakko *et al.*, 1999). The detection limits and outlines of static ABA criteria is shown in Table 1. The criteria is used during the analyses of the overburden and interburden. The balance between the acid producing potential (AP) and the neutralising potential (NP) is measured. The acid potential is calculated from the determination of the sulphur content and also represents the sulphur contained in the acid generating sulphide minerals within the sample. NP is determined by subjecting the mine waste samples to some form of acid digestion and represents the amount of acid-neutralising carbonate minerals present in the sample. Net Neutralising Potential (NNP) is the difference between NP and AP. NNP measurements classify rock or coal samples as potentially acid or non-acid producing. A greater NP than AP produces a positive NNP; on the contrary, if NP is less than AP, the resulting NNP will be negative.

Table 1 Detection limits and outlines of the Static ABA analyses

	Static ABA
Analyses / Used for	Used to determine the acid generating potential.
Data format	Expressed as calcium carbonate equivalents and compared to compute net acid-producing or neutralising potential.
Standards used	According to Usher et al. (2002), "material exhibiting a net acid production potential of 5 tons/ 1000 tons of overburden material or more as calcium carbonate equivalent, is classed as toxic or potentially toxic".
Sample preparation	Crushed by Retsch KG 5657 Haan BB100, milled by Giebtechnik Labor-Scheibenschwingmmuhle.

Oxidation products are analysed by using peroxide where only the reactive species (Usher, 2003) will oxidise. The reaction will produce acid and provides an indication of the heavy metal content. The final water quality is also provided as a result of the oxidation reaction.

Metal release

Metal and trace element content were analysed using the inductively coupled plasma optical emission spectroscopy (ICP-OES). This was used to analyse the release of the elements Ag, Al, As, Ba, Be, Ca, Cd, Cr, Co, Cu, Fe, K, Li, Mg, Mn, Mo, Na, Na, Ni, Sb, Se, Sn, Sr, Pb, V, Zn and SO_4. As the oxidation process takes place, metals are mobilized and some become soluble. In the case of the iron species it converts from Fe^{3+} to Fe^{2+} at a pH of 3.1 (Hodgson *et al.*, 1999). If the sample has not yet oxidized in the field the initial pH of a sample will have a higher concentration of sodium carbonate. Calcium/magnesium carbonate exists at a pH of 6 and decreases as the pH decreases during acidification.

Kinetic test

Table 2 lists the kinetic cells used in the study and the ABA results of the same samples. A total of 13 samples used in the analysis were taken from Grootegeluk, Sasol and Sekoko cored boreholes. The criteria that were used to select the samples are the ones that gave inconclusive ABA results, and samples which had extremely high or low NNP from the ABA analysis.

Table 2 Kinetic cell samples as selected from the ABA results

Kinetic cell	Initial pH	Final pH	AP (Open)	AP (Closed)	NNP (Open)	NNP (Closed)
S8	7.86	1.98	32.35	64.71	7.25	14.51

Comparison of Leco (%S) with H_2O_2 (%S)

The total sulphur content of the samples was determined by the Leco method. Total S will overestimate the acid potential if a significant amount of sulphate S, organic S or other non-pyritic forms occur in the sample. The same samples were selected and analysed by both the Leco and H_2O_2 method. The relationship of the different methods of analyses for %S is illustrated in Figure 2.

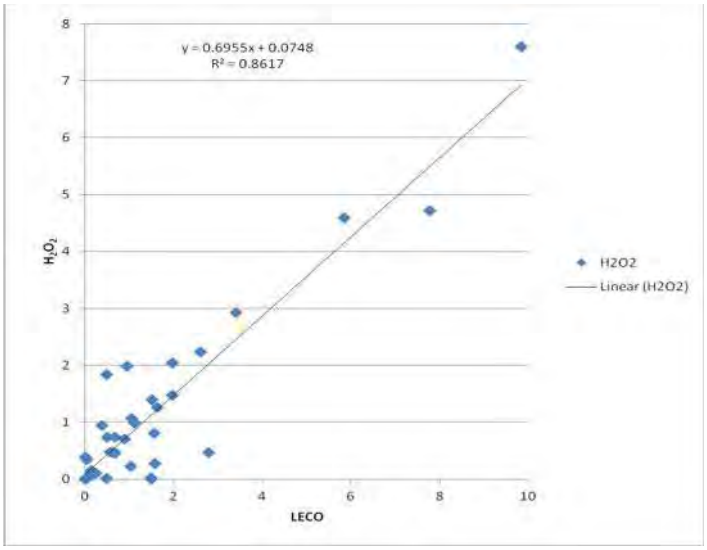

Figure 2 Comparison between the %S of the LECO method and the %S H_2O_2 method. The linear correlation between the two methods establishes that both methods %S can be used to determine the acid potentials of samples.

The Leco method has higher sulphur values than those obtained for the H_2O_2 method; however, the values for the H_2O_2 method compared well to the values of the Leco analyser. Due to this similarity, the H_2O_2 methods sulphur values can be used to determine the total sulphur present in the samples.

RESULTS AND DISCUSSION

Acid Base Accounting

The ABA and kinetic tests highlighted the lithological units that are prone to become acidic or poses a neutralising potential. The geological units with a NP above the coal units included calcrete and sandstone. These units typically consist of quartz, kaolinite, muscovite, calcite, dolomite, rutile and feldspar. The minerals identified within the mudstone and shale units included quartz, kaolinite, muscovite, pyrite, hematite, marcasite and calcite. A summary of the geological logs, the minerals within the units as well as their AP and NP, are illustrated in Figure 3.

Mineralogy

The samples with a NP mainly contained the minerals calcite and ankerite/dolomite. This is due to the carbonate content within the mineral chemistry. Pyrite is the dominant mineral in the acidifying samples. The mineral chemistry of pyrite contains iron and sulphide elements, which under favourable conditions, contribute to the production of acidic waters.

There is a difference in the mineral distribution of the three successions over the various lithologies. The different minerals found in the mudstones are shown in Table 3.

Table 3 The mineral distribution found in mudstones in the different successions.

Minerals	Full succession	Partly weathered	Middle Ecca
Quartz	■	■	■
Kaolinite	■	■	■
Siderite	■		
Calcite	■	■	
Muscovite	■	■	■
Rutile	■	■	■
Pyrite	■	■	
Marcasite	■		
Hematite	■		
Apatite		■	
Pyrrothite		■	
Feldspar			■

The mudstones have both neutralising and acid generating potential, which are associated with their mineral chemistry. The mineral chemistry for the sandstones from the three successions appears to be relatively similar with minor exceptions for hematite, ilmenite and feldspar (Table 4).

Table 4 The mineral distribution found in sandstones in the different successions.

Minerals	Full succession	Partly weathered	Middle Ecca
Quartz	■	■	■
Kaolinite	■	■	■
Siderite	■	■	■
Muscovite	■	■	■
Rutile	■	■	■
Pyrite	■	■	■
Hematite		■	
Ilmenite			■
Feldspar			■

On average, the samples with an acidifying potential and those with a base potential, contain similar concentrations of SiO_2. The major difference is found between the CaO and MgO of the samples, with a base potential to be 50% less in the samples which acidify.

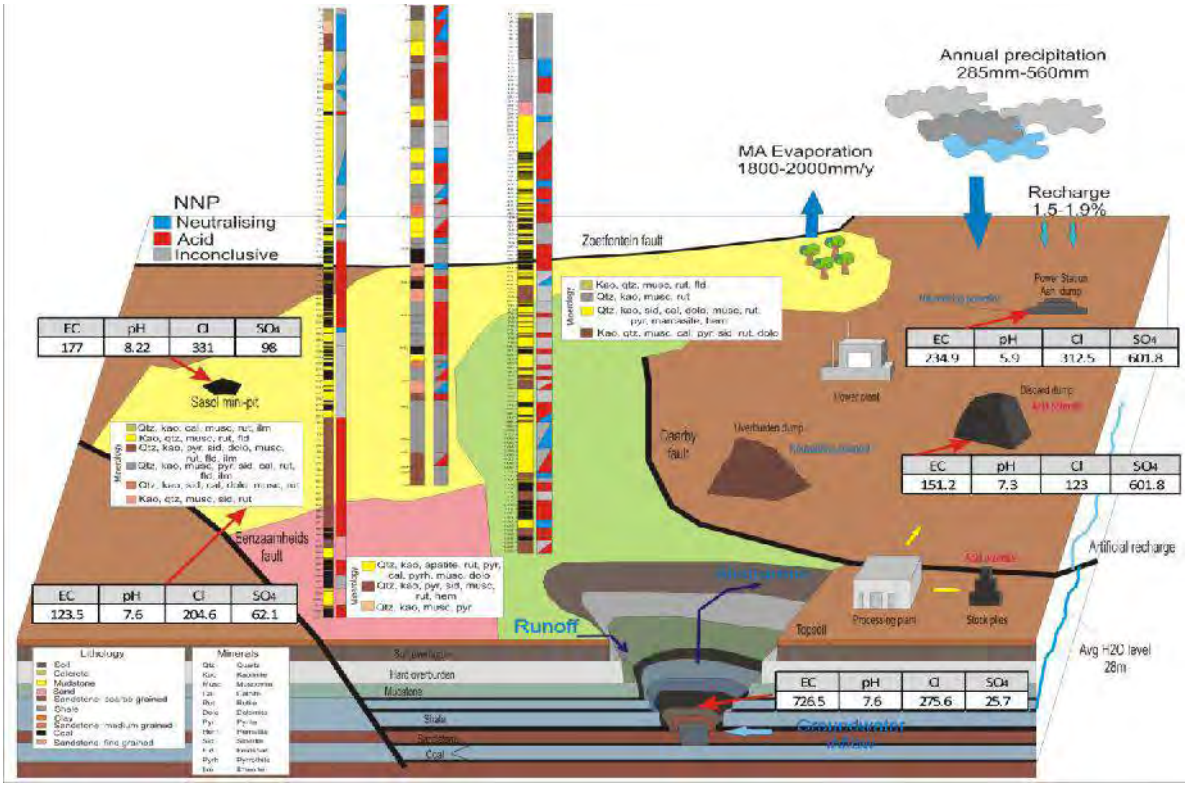

Figure 3 Summary of the acid and neutralising potential of the various contributing factors over the extent of the study area (Macdonald, 2014).

Metal release

Elements such as sodium, potassium and nickel (Figure 4) are present in quantities below their solubility limits. This is denoted by a decrease in concentration with a drop in the pH (Hodgson *et al.*, 1999). Calcium/ magnesium carbonate exist as a form of a buffer which will cause the pH to increase, and will again decrease when the buffering species are depleted.

Iron and sulphate (Figure 5) exhibit an associated rise indicating that pyrite is the most common sulphide mineral present. Calcium and magnesium concentrations increase until they are depleted from the rock and coal through reaction with the acid. Sodium ranges from low to intermediate levels, and the higher sodium levels often coincide with high pH-levels, suggesting the presence of sodium carbonate species.

Figure 4 shows that the sulphate values will increase as the pH decreases in the case of Sasol samples; Exxaro samples show very low concentrations of sulphate even when the pH drops. This might be because of the dominance of the carbonaceous material that is found in the Exxaro samples.

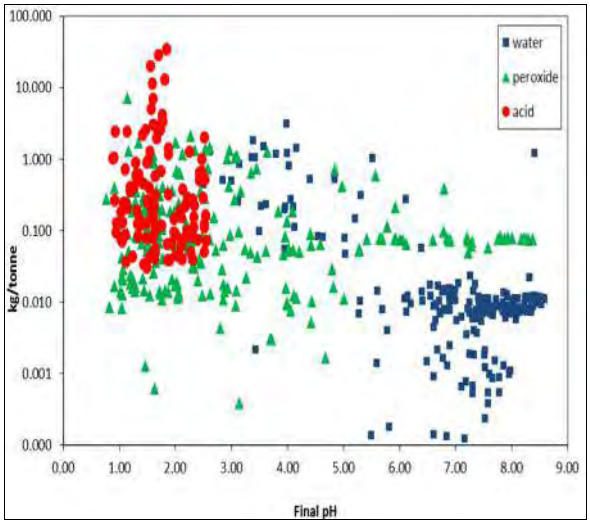

Figure 4 Nickel versus pH

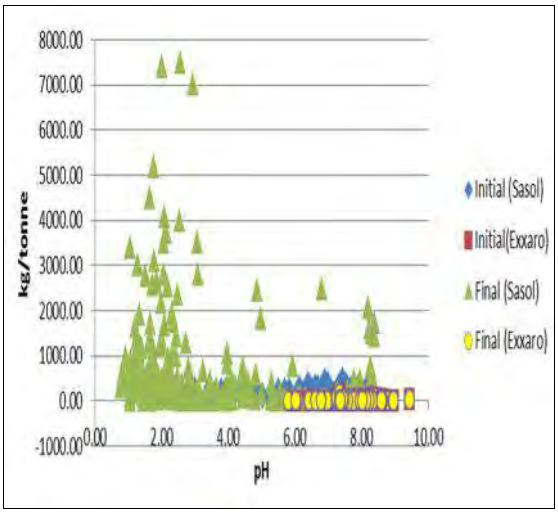

Figure 5 Sulphate versus pH

Kinetic test results

The thirteen samples are from different areas. Eight of the samples provided a closed NNP (-20 to 20 kg/tonne $CaCO_3$) which indicates inconclusive results and the other five had a higher closed NNP which classifies the samples as having the potential to turn acidic or basic. The Sasol samples (S6 to S38) were collected from the interburden and overburden (shale/mudstone) and interburden (sandstone). The Grootegeluk samples (G10 to G18) were taken from the partly weathered overburden which consists of carbonaceous mudstone and the Sekoko samples (SEK1 to SEK4) were taken from the Middle Ecca interburden. Figure 6 shows the pH of the 13 samples that were analysed. Throughout the leaching test the pH values of the samples remained high; an exception being S14 and S15 which showed a drop in pH over 20 weeks and which remained acidic.

Figure 7 shows the release of sulphate from the interburden samples; the analysis shows that the production rate for all the samples was lower at the beginning of the analysis. The highest recorded sulphate concentration at the end of week 20 is in S14 and S15, with an approximate production rate between 250 mg/kg/wk and 50 mg/kg/wk. The majority of the samples showed an increase in

the first three weeks, then decreased again thereafter due to the removal of already oxidised products. The increase in sulphate coincided with the decrease in pH. The samples which gave inconclusive closed NNP all produced rates that were below 150 mg/kg/wk in the first three weeks, and the production rate continued to decrease, which is indicative of the oxidised products that continued to be removed.

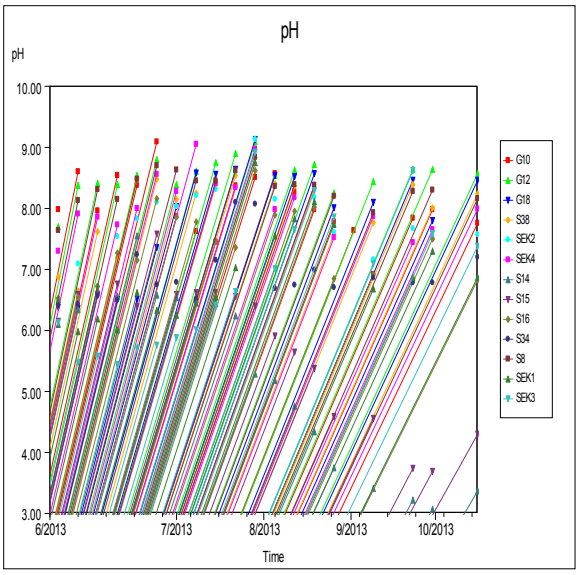

Figure 6 pH *values for Kinetic tests*

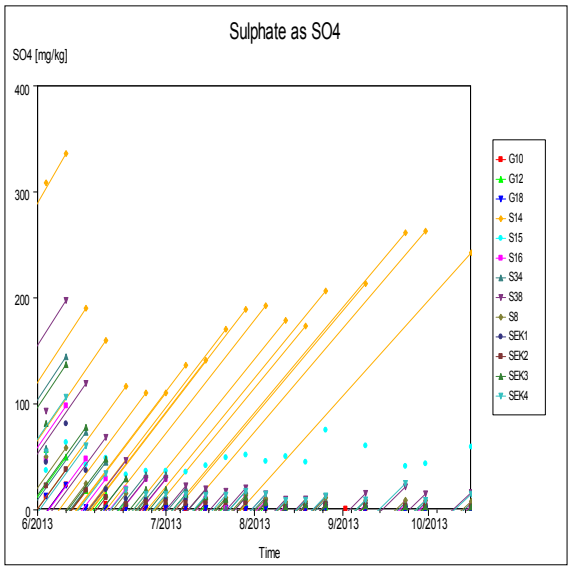

Figure 7 Sulphate *realease for interburden and overburden*

CONCLUSION

The ABA results showed that the coal seam has the highest AP, whilst overburden and shale have a NP. Leaching of heavy metals is evident when the pH decreases. This provides an idea of the post mining environment. Sample analyses was done on the interburden, overburden as well as the coal samples. The results indicated that over 35% to 50% of the samples in the different lithologies (interburden, overburden) have an excess AP. This classifies the samples as having a higher risk for acid generation. About 30% to 40% of the samples have a NP. The remainder of the samples have a medium risk for acid generation.

The ABA results determined that the interburden and discards used as backfill material has a potential to generate acid. This includes the composite samples with various densities from the processing plant. Overburden material has a NP. The ABA illustrated that the shale and mudstone samples have both acid and neutralising potentials and the majority of sandstone samples beneath 60 m have a distinct AP.

The composite material can be used as backfill material within the pit. It only becomes a risk upon exposure to oxygen and water. The Waterberg area has a relatively low annual rainfall, high evaporation and deep groundwater levels, thus the risk to produce acid from infiltrating water is limited. The risk of exposure to oxygen leads to the spontaneous combustion of discard material.

Kinetic test analysis were carried out on the overburden and interburden samples. The pH results showed variations throughout the analysis with all the samples having pH values above 5.5 for the first nine weeks of analysis. The majority of the samples exhibit a high pH throughout the course of

the analysis; a difference is only seen in two samples from the interburden which showed a drop below pH 4. According to ABA results the seven weathered interburden samples from the Middle Ecca have a higher risk of generating acid with the highest at pH of 2.97. An increase in sulphate production is directly related to an increase in EC. Six samples in the kinetic test results were classified as medium to lower risk of acid generation according to results with the lowest pH of 4.07. From the kinetic results, the samples also showed a final pH >7. After week 14 the sulphate production was below 50 mg/kg and the calcium production below 5 mg/kg, The EC values also remained low at constant values.

The pH variations of sandstone and mudstone within the overburden and interburden allowed the materials to be combined at an optimal ratio to ensure a neutral pH within the pit. The initial pH results before testing indicated no oxidation before ABA analysis were done. The interburden material with pH below 4 had correspondingly high sulphate loads (20000-350000 mg/kg). The overburden materials had a lower sulphate load between 5000-35000 mg/kg. The analyses indicated that the interburden material is more likely to generate acid.

The mining industry is always seeking new, cost-effective methods of improving operational efficiency within the mining infrastructure. There have been considerable improvements made to the various aspects of backfilling systems, including the availability and supply of fill materials, different types of backfill systems, backfill preparation procedures for transportation and placement, and the use of alternative cementing agents used in underground mining.

The preferred handling method for the waste generated at the coal mines is the *high and dry* method. Waste is placed layered in between non-reactive material (acidic potential and spontaneous combustion). At the bottom of the mined pit non-reactive interburden is placed in compartments and sealed on the sides and along the top of the backfilled heap. The individual heaps should not exceed 22° and not stacked higher than 17 m. The interburden must be the initial layer, stacked above the natural groundwater level. The stacking will not be affected as on-going mining operations will result in lowering the groundwater levels. The high and dry method places the acid prone material above the natural groundwater level, ensuring minimal to no contamination to groundwater bodies. The individual heaps are stacked to the specified heights and angles and then continue towards the mining advance. Overburden is used as sealing material, due to the shale and clay's low propensity of spontaneously combust or generate acid.

One suggestion to the handling would be to interlayer ash from Matimba Power Station close by. The ash is available, and the research showed it has a high neutralizing potential in ratios of 2:1 and 5:1, and it would help to reduce the volume of the final mine void. Ash reduces the iron and sulphate from acidic waters and continues to increase the pH by precipitating the problematic elements from the solution. It is however, a great challenge to transport ash in the study area due to the limited amount of water and the availability of ash material. The fine particles should be kept wet during transport. Cost of transport can be reduced when the same conveyor system that is already in place, is used to take ash back to the mine.

ABSTRACT

The weathering rate of primary silicate minerals in a waste rock storage facility determines dump drainage pH and associated behaviour of contaminants in the later stages of the acid rock drainage (ARD) profile due to their long-term acid neutralization capacity. This long-term non-carbonate neutralization rate (ANRnc) value can be used, for more economical ARD management, to estimate the cover thickness and saturation required to control the acid generation rate (AGR) within the waste storage facility, so that the two parameters (ANRnc and AGR) are matched, potentially providing an initial design target for emplacement and cover design. We previously established two methods to determine the ANRnc in a waste sample: i) silicate mineralogy using the available pH-dependent dissolution rate database from the literature; and ii) long-term column leach solution assays with the ANRnc calculated from cation release. The ANRnc values estimated using the two methods for a given waste show good agreement and reproducibility at pH < 4.

As part of the AMIRA International funded project "Alternative Treatment Options for Long-term ARD Control" (P933A), four case studies were carried out to estimate immediate AGR and ANRnc within weathered ARD waste rock storage facilities using mine site water monitoring data in combination with the waste mineralogical tests. These estimates may represent a useful tool to monitor, plan and ultimately help reduce the effects of ARD at mine sites; i.e. to determine what strategies may be necessary to attempt to reduce the AGR to equal the ANRnc.

This paper focuses on the results from our investigations of AGR and ANRnc within a number of mining waste dumps. Estimates of the evolution of dump profiles were determined with a view towards matching the values of the AGR and ANRnc within the wastes.

Keywords: long-term non-carbonate neutralization rate, acid generation rate, waste rock storage facility, site mineralogy, water quality monitoring

INTRODUCTION

The weathering rate of primary silicate minerals in a waste rock storage facility determines dump drainage pH and the associated behavior of contaminants in the later stages of the acid rock drainage (ARD) profile due to their long-term acid neutralization capacity. Given the abundance of these silicates in most mine wastes, the widespread occurrence of ARD shows that in many circumstances, silicates in the absence of carbonates do not provide neutralizing capacity at a sufficiently fast rate to neutralize acidity resulting from sulfide oxidation (Gerson et al., 2014a, Gerson et al., 2014b). The acid generation rate (AGR) from sulfide oxidation is therefore required to be reduced and the long-term non-carbonate neutralization rate (ANRnc) from dissolution of silicates needs to be measured so that the two parameters can be matched for long-term ARD management. These measurements can potentially provide an initial design target for emplacement and estimation of the cover thickness and saturation required to control the AGR within the waste storage facility. This paper will explain these estimates, their current limitations and their application to real ARD wastes.

We previously established two methods to determine the ANRnc in a waste sample: i) from silicate mineralogy using the available pH-dependent dissolution rate database from the literature (Palandri and Khraka, 2004); and ii) from long-term column leach solution assays with the ANRnc calculated from cation release. The ANRnc values estimated using the two methods for a given waste have shown good agreement and reproducibility at pH values < 4 (Miller et al., 2010). However, it has been noticed that at greater pH, ANRnc values calculated from mineralogy generally exceeded those calculated from leach column testing (Gerson et al., 2014a, Gerson et al., 2014b) possibly due to removal of some cations by precipitation in the leach columns. In a similar approach, Morin and Hutt (2011) compared ANRnc values derived from mineralogy with those obtained from short-term humidity cell tests. They found that the rates calculated from mineralogy were similar to, or substantially less than, the measured values. Most recently, we carried out four case studies to estimate immediate AGR and ANRnc within four weathered ARD waste rock storage facilities.

Site A

Site A is a zinc and lead mine located in Alaska. The site is sufficiently cold to support permafrost. Mean annual rainfall at the mine site is 467 mm with a mean measured ground temperature of -2 °C. The waste dump contains approximately 36 million tonnes (Mt) of potentially acid forming (PAF) waste rock. Acid rock drainage (ARD) from the stockpile is towards a tailings impoundment and is treated to meet specific water quality standards prior to discharge.

Site B

The Bingham Canyon porphyry Cu deposit is located in the Oquirrh Mountains immediately west of Salt Lake City, Utah. Large scale open pit Cu mining began at the Kennecott Utah Copper Bingham Canyon (KUCBC) mine in 1906 and mining is currently planned to continue for more than a decade. Waste rock placement on the eastern margin of the Oquirrh Mountains (Eastside dumps) began in 1953 and is still on-going (Borden 2003; Borden et al., 2006). The total mass of waste rock classified as PAF materials within the Eastside dumps was estimated to be approximately 2.2 billion tonnes up to 2004. Copper concentrations within the placed waste rock have averaged less than

0.1% (Borden, 2003). From 1941, Cu was recovered from the waste rock dumps by active heap leach operations, in addition to beneficiation and smelting operations (Borden et al., 2006), until all leach water applications were terminated in September 2000. Since infiltration into the dumps occurred only from natural rainfall after leaching was terminated, drain down of acidic water (at a flow rate of 45 L/s in 2004) has been collected, treated and used in the process water circuit (Borden et al., 2006).

Site C

The Savage River iron ore mine is located in north-west Tasmania, Australia. To date, mining operations have generated in excess of 50 million m^3 of ore and 300 million m^3 of waste rock since about 1975. Current mining plans allow for the potential of a further 100 million m^3 of waste rock over the next 15 years (Gerson et al., 2014a). However, ARD, emanating from legacy (sulfide-containing) waste-rock dumps at the mine site, which flows into both Main Creek and the Savage River, is impacting the river and its tributaries. The historic B-dump was identified as a significant source of ARD at the site and D-type PAF waste is responsible for the major part of the AMD issues in B-dump. From early 1970 to 1996, about 13 Mt of D-type PAF waste rock was placed into B-dump, from which approximately 40% of the total Cu load emanated, and which flows down the river through Main Creek (Li et al., 2011, Li et al., 2012). To reduce impact to the river, combined water shedding and alkaline (A-type chlorite-calcite schist) covers were constructed over the dump in 2006 for long-term ARD control. It has been reported that the average rainfall infiltration was reduced to 9% by the water shedding cover (Hutchison et al., 2009). The alkaline side cover allows rainwater infiltrating the cover to take up alkalinity from the A-type material, and this alkalinity can then react with, and neutralize, existing acid drainage (Hutchison et al., 2009). It was found that alkalinity from the side cover has been migrating down into the D-type PAF waste below, forming passivating layers on pyrite grains, but it may be some time before the remaining PAF waste in the dump is fully passivated (Li et al., 2011).

Site D

The Mount Whaleback mine is an iron ore mine located in the Pilbara region of Western Australia, six kilometers west of Newman. The mine is majority-owned (85%) and operated by BHP Billiton, and is one of seven iron ore mines the company operates in the Pilbara. Approximately 10 wt% of the total remaining waste rock at the BHPBIO Mount Whaleback Mine has been identified as PAF materials that contain sulfide minerals > 1 wt%; e.g. altered black shale from the Mount McRae shale contains 4 wt% pyrite, 50 wt% chlorite, 27 wt% muscovite, 2 wt% dolomite, 1 wt% hematite and 16 wt% quartz (Webb et al., 2006). The earliest acidic drainage found at the Mt Whaleback site was from seepage at the toe of the W39 Terrace Dump in 1995 (Huys, 2010). There are about 40 Mt of waste rock placed in the dump covering a surface area of 0.51 km^2. Based on the average annual rainfall of 314 mm in the Mt Whaleback area (Newman Aero weather station), the average seepage rate was estimated to be 5.08 L/s (assuming full rainfall infiltration). To manage this ARD, an ARD Dam (clay compacted floor) that is below and adjacent to the dump (capacity = 850 ML; surface area = 0.32 km^2) was constructed in 1995 to collect the seepage and some surface run-off waters from the mine site.

The aim of this study was to scale up our AGR and ANRnc estimation methodology to these four real waste rock storage facilities using existing mine site water monitoring data in combination with the waste mineralogical tests. This paper describes the results from our investigations of AGR and

ANRnc within the four ARD waste rock storage facilities, as well as combining the AGR and ANRnc to produce estimates of the evolution of the dump profiles towards matching these values within the wastes.

METHODOLOGY

Waste rock sample preparation

Site A and Site B waste rock samples were provided by their respective companies. Site C-dump waste rock sample (D-type, potentially acid forming) was collected through an excavation of the eastern alkaline side cover of the dump in 2010 (Li et al., 2011). A Site D waste rock sample of Mt McRae black shale was collected from WB 0505-403 at the mine site and column leached for 2.5 years. The leached residue solid is expected to have similar mineral composition to that in the W39 Terrace Dump. All the rock samples (particle size < 4 mm) were initially dried in an oven at 50 °C overnight with argon purging, ground, and dry sieved through a 75 μm screen. For X-ray diffraction (XRD) analyses, all the samples were micronized to -2 μm to reduce particle orientation effects on XRD data collection and corundum (α-Al_2O_3, 15 wt%) was added to each sample as an internal standard to quantify the amorphous content in the sample. Corundum (0.3 g) was added to 1.7 g of pulverised material (-75 μm) and then micronized with 10 mL of ethanol using a McCrone Micronizing Mill for 10 minutes. Each suspension obtained was dried in an oven at 50 °C and stored in a sealed tube prior to XRD analysis.

Silicate mineralogy

The simplest method of estimating ANRnc is to calculate the parameter from the known silicate mineralogy of the waste, determined at the time that the pH and AGR are measured using the available pH-dependent dissolution rate database from the literature. The mineralogy of waste samples was determined by XRD and mineral dissolution rate data used in the study is from Palandri and Kharaka (Palandri and Kharaka, 2004) and Lowson and coworkers (Lowson et al., 2007, Lowson et al., 2005) for chlorite. The methodology of the ANRnc calculation steps is described in detail in Miller et al. (2010).

XRD analyses of solid samples were conducted at the Bragg Crystallography Facility, School of Chemistry and Physics, the University of Adelaide. The data collection was performed on a Bruker D4 Endeavor diffractometer with Co Kα radiation (1.7902 Å) at 30 kV and 20 mA. Diffraction patterns were collected with $\theta/2\theta$ geometry from 5 to 80 °2θ at 0.02 °2θ increments with a rotating sample stage to ameliorate preferred orientation effects. Phase identification was carried out using the DiffracPlus EVA software (Bruker) with the ICDD-PDF2 database (International Center for Diffraction Data, 2000). Bruker-AXS TOPAS V4.2 software was then used to quantify each phase. Crystal structure information for all the minerals was obtained from the Bruker Structure Database.

Estimations from water quality monitoring data

An alternative method of estimating ANRnc can be formulated using solution assay data from long-term standard kinetic column leach tests of -4 mm crushed waste rocks and tailings (Smart et al., 2002) with the ANRnc calculated from cation release (Na, K, Ca, Mg and Al) (Miller et al., 2010). The ANRnc (mg H_2SO_4/kg/week) formulation was first developed by (Paktunc, 1999) and extended by (Miller et al., 2010) as expressed as Equation 1.

$$ANR_{nc}(mgH_2SO_4Kg^{-1}week^{-1}) = \frac{R_f \times 49}{m \times 1000} \times \left[\left(\frac{Na}{M_{w(Na)}} + \frac{K}{M_{w(K)}}\right) + \left(\frac{Mg}{M_{w(Mg)}} + \frac{Ca}{M_{w(Ca)}}\right) \times 2 + \left(\frac{Al}{M_{w(Al)}} \times 3\right)\right] \quad (1)$$

where, R_f is the measured drainage flow rate (L/week), m is the mass of a waste rock sample in the column (t), Na, K, Mg, Ca and Al are dissolved metal concentrations in the drainage (mg/L), M_w is the molecular weight and the factor 49 converts mmol H^+ ions to mg H_2SO_4.

In this study, Equation 1 was used to calculate immediate ANRnc within a waste rock storage facility using water quality monitoring data from each mine site.

RESULTS AND DISCUSSION

Site A

The waste rock collected in 2008 in the stockpile contains 13.9 wt% pyrite with 3.6 wt% sphalerite as sulphide minerals, 5.5 wt% barite and 0.1 wt% gunningite (sulfate minerals), 60.3 wt% quartz, 10.7 wt% biotite with 2.5 wt% albite, 2.2 wt% muscovite and 1.2 wt% sanidine, and is classified as PAF by the acid-base account (ABA) and net acid generation (NAG) testing. However, our recent XRD analyses on waste rock collected in 2010 in the stockpile but at a different area revealed a different mineral composition of 3.3 wt% pyrite, 3.0 wt% sphalerite, 2.5 wt% galena, 70.3 wt% barite and 20.9 wt% quartz within the waste rock. This suggests that the mineral composition of the waste rock varies significantly across the whole stockpile. Since the recent waste rock sample does not contain any silicates other than quartz the silicate mineralogy of the sample collected in 2008 was used for estimation of mineralogical ANRnc and the ANRnc value of 141 mg H_2SO_4/kg/week was obtained for the waste as shown in Table 1 the predominant contribution coming from biotite at the dump pH 2.7.

Water monitoring data for the samples collected from Site A in 2002 were averaged and are listed along with other measured parameters in Table 2 for the ANRnc and AGR (based on dissolved sulfate concentration) estimations. The average pH of these samples was low at 2.5. Solution assay data for a typical sample with pH 2.7 (collected in 2008 at the stockpile) was also used for the estimations (Table 2). Table 2 shows relatively high Mg and Al concentrations in the seep waters and the concentrations increased with weathering (six years), consistent with the dissolution of biotite identified in the waste rock mineralogy (Table 1). A relatively high Ca concentration and low K concentration are most likely due to dissolution of gypsum and formation of jarosite in the stockpile although these two secondary mineral phases were not identified by XRD, probably due to their relatively low content and ultrafine jarosite deposition.

The ANRnc value from leached cations was 0.8 mg H_2SO_4/kg/week. The AGR of 2.2 mg H_2SO_4/kg/week estimated from sulfate concentrations was about three times greater than the ANRnc in the stockpile in 2008 (Table 3). It is worth noting that the AGR within the stockpile decreased by a factor of five from 10.7 mg H_2SO_4/kg/week in 2002 to 2.2 mg H_2SO_4/kg/week in 2008 and the AGR/ANRnc ratio for the stockpile decreased from 14 to 3 during the six years of weathering (Table 3). These differences represent the evolution of the Site A waste rock oxidation with time; they suggest the stockpile is over the peak and on the downward path in its AGR/ANRnc ratio vs time profile. In 2008, it was clearly further down the path than in 2002.

Table 1 Calculated ANRnc (mg H_2SO_4/kg/week) from silicate mineralogy of different waste rock materials.

*kinetic dissolution rate data from Palandri and Khraka (2004).
#Clinochlore dissolution rate data from Lowson et al.. (2005; 2007).

The 2008 ANRnc (2.2 mg H_2SO_4/kg/week) estimated from seep assays is about two orders of magnitude slower than that (141 mg H_2SO_4/kg/week) calculated from the mineralogy of the waste rock collected at the same time. The mineralogy estimate assumes a 38-75 μm size fraction with average surface area of 1 m^2/g whereas the standard column leach used sieved -4 mm material. It was reported that waste rock in a storage facility commonly contains 10 - 30 wt% of -4 mm materials (Kempton, 2012) . Given the particle surface area differences, the difference between ANRnc values estimated using the waste stockpile seep assays and mineralogy/laboratory column leach assays are not surprising. This suggests that a scale factor of the order of 0.01 should be applied to the mineralogical estimate here and in the other case studies below. A closer estimate of the effective surface area in the -4 mm samples is currently being defined.

Table 2 Selected cation concentrations from water monitoring data of waste storage facility at different mine sites for AGR and ANRnc estimation.

Parameters	Site A		Site B	Site C	Site D

Table 3 Calculated ANRnc (mg H_2SO_4/kg/week) using water monitoring data from different waste storage facilities at the mine sites.

	pH	ANRnc	AGR	AGR/ANRnc	ANRc mineralogy
Site A (2002)	2.5	0.8	10.7	14.2	-
Site A (2008)	2.7	0.8	2.2	2.8	141
Site B (2004)	2.9	71.7	75.8	1.1	434
Site C (2009)	3.4	2.7	2.8	1.0	264
Site D (2008-2009)	4.2	0.5	0.6	1.0	72

Site B

The Site B waste rock contains 5 wt% pyrite (sulfide), 3 wt% alunite, 2 wt% jarosite and 1 wt% gypsum (sulfate minerals), 52 wt% quartz, 15 wt% clinochlore, 13 wt% orthoclase, 2.2 wt% muscovite and 10 wt% muscovite (silicate minerals) and are classified as PAF materials. Based on the silicate mineralogy, an ANRnc value of 434 mg H_2SO_4/kg/week, predominantly contributed from clinochlore, at the effluent pH of 2.9, was calculated (Table 1).

The typical water quality data reported by Borden et al. (Borden et al., 2006) for the seeps from the dump toe in 2004 show the seep waters were highly acidic (pH 2.9) with high Mg, Al and sulfate concentrations (Table 2). In addition to Al, Fe (250 mg/L), Mn (350 mg/L), Cu (140-600 mg/L) and Zn (170 mg/L) were also significant metals in the water (Borden et al., 2006) that contributed to a high titratable acidity (30 g $CaCO_3$/L). The high Mg and Al concentration is consistent with the predominant dissolution of clinochlore at pH 2.9 (Table 1). The ANRnc (72 mg H_2SO_4/kg/week) and AGR (76 mg H_2SO_4/kg/week) within the dumps were calculated. It was found that the ratio of AGR/ANRnc was close to 1 (Table 3). However, in this case the AGR may be underestimated due to formation of gypsum, jarosite and alunite, as identified by XRD. It is well known that the use of effluent sulfate concentration can lead to an underestimation of the AGR arising from pyrite

oxidation as formation of S containing secondary sulfate minerals may occur. In practice, this can be corrected using oxygen consumption measurements (e.g. using a sulfide oxidation cell). Table 3 shows that the ANRnc (72 mg H_2SO_4/kg/week) estimated from seep assays is about one order of magnitude slower than that (434 mg H_2SO_4/kg/week) calculated from the rock mineralogy.

Site C

The use of waste dump drainage assays and mineralogy methods to estimate ANR and AGR in the wastes may provide a possible measure for B-dump cover performance in ARD control at the Savage River Mine site. The D type PAF waste rock collected from the eastern side cover of the dump in 2010 was quantified to contain 2 wt% pyrite, 12 wt% clinochlore, 14 wt% albite, 22 wt% muscovite, 41 wt% quartz and 9 wt% amorphous. The mineralogical ANRnc was calculated to be 264 mg H_2SO_4/kg/week at pH 3.4 and the clinochlore chlorite in the rock contributed most of the ANRnc (Table 1).

B-dump water monitoring data extracted from Koehnken (2010) were used to calculate ANR and AGR (Table 2). Since the B-dump seep between the two Main Creek water monitoring points (Main Creek at Pilot Plant and Main Creek at Dolomite Dam) was predominantly from the side cover area under which there are 30 wt% of total D-type PAF rocks in the B-dump, the D-type waste rock mass of about 3.9 Mt was used for the rates calculation (Table 2). The relatively high Ca and Mg concentrations associated with a low Al concentration in the pH 3.4 seep water suggest some alkalinity from the side cover by the partial dissolution of calcite and dolomite, in addition to the dissolution of clinochlore in the D-type PAF waste rock. The sulfate concentration was low (Table 2), consistent with the partial passivation of pyrite surfaces observed in the cover - D type waste interface which has resulted in a reduced sulfide oxidation rate within the dump (Li et al., 2012, Li et al., 2011). The ANR (2.7 mg H_2SO_4/kg/week) and AGR (2.8 mg H_2SO_4/kg/week) with in the dump were calculated and the ratio of AGR/ANR was close to unity as expected (Table 3). Again, the ANR is about two orders of magnitude slower than the mineralogical ANRnc of 264 mg H_2SO_4/kg/week at pH 3.4.

Site D

Our recent XRD analysis has identified the mineralogy of the BHPBIO weathered waste rock as containing 25 wt% clinochlore, 45 wt% muscovite, 26 wt% quartz and 4 wt% amorphous. The mineralogical ANRnc was calculated as being 72 mg H_2SO_4/kg/week at pH 4.2 and the clinochlore in the rock contributed all of ANRnc with a very minor contribution from muscovite (Table 1).

Water monitoring data for five water samples was extracted from a water quality dataset collected at the ARD Dam from March 2008 to August 2009 and averaged for the ANRnc and AGR calculation (Table 2). A dilution factor of 1.6 was used for the calculation according to the Dam surface area and the annual rainfall. Table 1 shows that the average water pH was relatively high at 4.2 with a very low titratable acidity. Since carbonate alkalinity in the water was less than 1 mg $CaCO_3$/L (not shown), high Mg with corresponding Al and Si concentrations in the solution is consistent with dissolution of clinochlore ($Mg_{3.6}Fe_{1.4}Al_2Si_3O_{10}(OH)_8$) being the major neutralization mechanism within the dump. The high Ca concentration may have resulted from dissolution of other reactive silicate minerals in amorphous form, e.g. anorthite as a secondary product from gypsum during weathering in the dump. Values of ANRnc (0.6 mg H_2SO_4/kg/week) and AGR (0.6 mg H_2SO_4/kg/week) were estimated from the water monitoring data with an AGR/ANRnc ratio of 1.0 (Tables 2 and 3). The ratio of AGR/ANRnc of unity indicates that the AGR was fairly close to the

ANRnc provided by silicate minerals within the W39 Terrace Dump in 2008-2009 and that any further reduction in the acid generation rate will result in less acidic drainage from the dump with a subsequently increased water pH in the ARD Dam. Similar to other dumps, the ANRnc is about two orders of magnitude slower than the mineralogical ANRnc of 72 mg H_2SO_4/kg/week at pH 4.2.

Combination of AGR and ANRnc as a function of pH

We previously investigated the influence of the ratio of AGR to ANRnc on the pH of leachate from a number of long-term column leach tests and results are shown in Figure 1. When the AGR/ANRnc ratio approaches 1 the effluent pH starts to increase, but can still be as low as 3 when the AGR and ANRnc are matched (Miller et al., 2010). We have now extended this to include AGR/ANRnc and pH data from this study, which is also shown in Figure 1. The figure shows that the calculated AGR/ANRnc data estimated from each of the ARD waste storage facilities fall within the values measured for long-term column leach tests, suggesting that the estimates made for the facilities are quite reasonable.

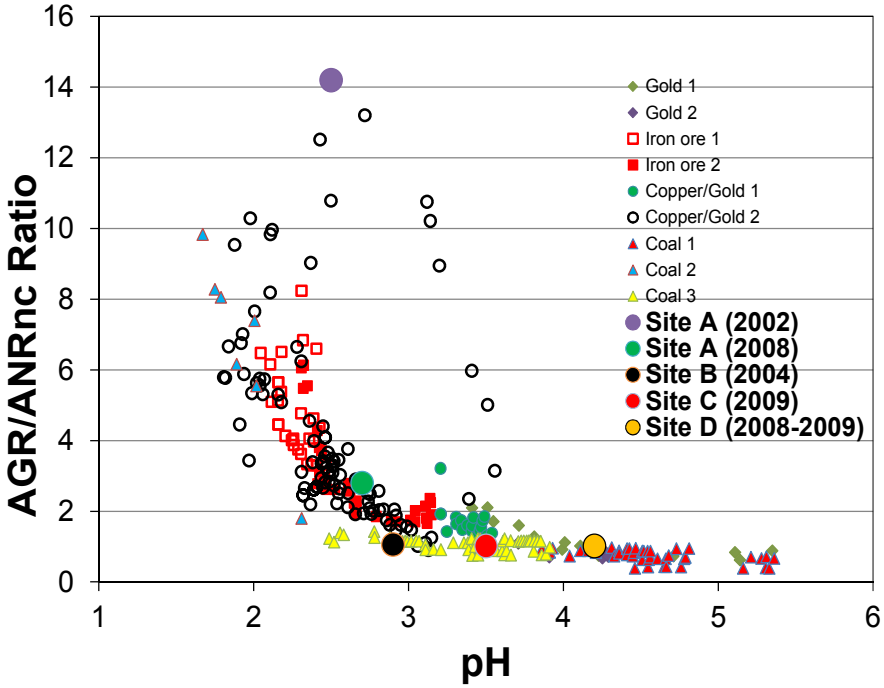

Figure 1 A comparison of ratios of AGR/ANRnc vs pH for different ARD waste rock storage facilities and columns

The evolution of ARD within the Site A stockpile can be seen in the data shown in Figure 1. In 2002, the AGR/ANRnc ratio estimated from water assays was around 14, but this had dropped to approximately 3 by 2008, indicating that AGR may well be matched by ANRnc in the future. The AGR/ANRnc was about unity for the other three dumps and these too appear to approaching the matching rate. However, for the Site B dumps, the low pH (2.9) and high acidity conditions suggest that these first-level estimates involve possible overestimation of the ANRnc and underestimation of the AGR. There is still 5 wt% active pyrite along with alunite (3 wt%) and jarosite (2 wt%) in the dumps requiring long-term management.

CONCLUSION

An initial estimation of the immediate AGR and ANRnc within a weathered ARD waste rock storage facility can be achieved using mine site water monitoring data in combination with waste mineralogical tests. Given the possible effects of climate, preferential flow paths and variation of waste rock mineralogy by weathering etc. on the pore water chemistry in a storage facility, the ANRnc estimated by the water monitoring data may sometimes involve large uncertainties. As an alternative, the dump ANRnc can also be simply determined from the mineralogy, at time scales significantly shorter than traditional kinetic methods but this requires refinement of the effective surface area in the estimate. Uncertainties in AGR estimates from sulfate release alone can be reduced by comparison with oxygen consumption measurements. These estimates may then represent a useful tool to monitor, plan and ultimately help reduce the effects of ARD at mine sites; i.e. to determine what strategies may be necessary to attempt to reduce the AGR to match the ANRnc in the long term evolution of the dump.

Acid Mine Drainage Risk Assessment Utilizing Drill-Hole Data and Geological Modelling Tools

Claire Linklater, Alison Hendry and John Chapman
SRK Consulting, Australia

ABSTRACT

For an Australian iron ore operation in the Pilbara region of Western Australia, an acid and metalliferous drainage (AMD) study has considered available drill-hole data (chemical assays and geological logging information) combined with mine planning information to conduct a high level assessment of the potential for AMD from mined waste storage facilities and within the pit void.

Geological modelling tools (Vulcan, Leapfrog) were used to generate 3D visualisations of the distribution of sulfur (a key parameter indicative of AMD risk) within the mined volume. The final sulfur model was aligned with the existing block model to aid future mine planning. Small volumes representing sulfur-bearing 'hot-spots' were identified and pit void maps were generated to determine the location of these hot spots on exposed pit walls. Similarly, volumetric quantities of sulfur-bearing material that would report to waste rock dumps and ore stockpiles were estimated.

Outcomes from the assessment were used to focus ongoing geochemical characterisation activities, and can be used as a basis for scoping calculations to predict the possible quality of drainage waters from mined waste storage facilities and pit walls. This paper describes the overall assessment approach and summarises outcomes from the AMD risk assessment.

Keywords: acid mine drainage, sulfur distribution, geological modelling

INTRODUCTION

There are numerous iron ore mines within the Pilbara, Western Australia. In many, mineralized ore is located within the Dales Gorge Member of the Brockman Iron Formation which is part of the Early Proterozoic Hamersley Group. The Brockman Iron Formation is stratigraphically underlain by the Mount McRae Shale, which is known to contain sulfidic mineralization. Due to the possible exposure of sulfidic materials during mining it is necessary to assess the potential for acidic and/or metalliferous drainage (AMD) at the site from mined materials placed above ground and also exposed on walls within the pit void (Figure 1).

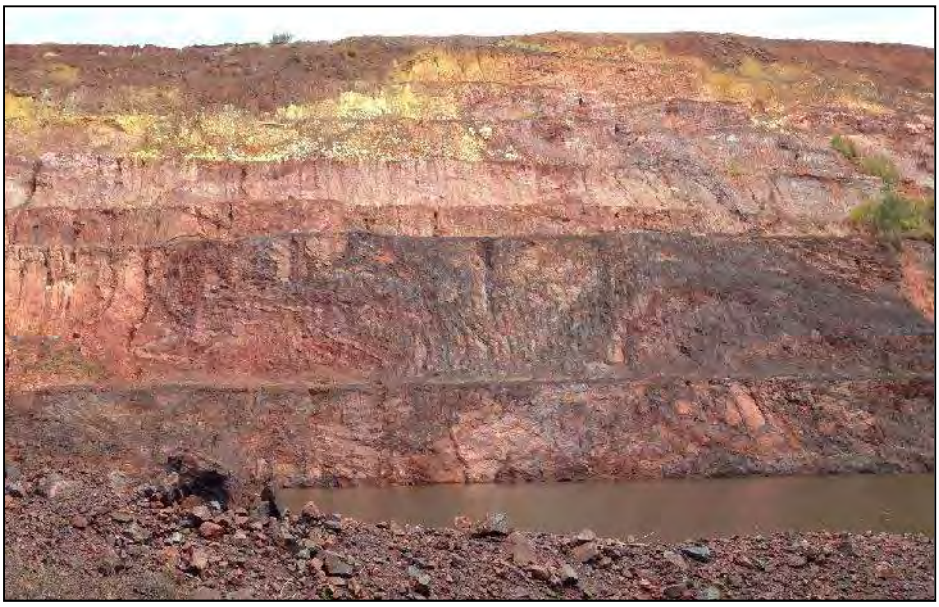

Figure 1 Photograph of exposed Mount McRae Shale (dark colored rock) on pit walls

This paper describes how sulfur data (a key parameter indicative of AMD risk) have been used to develop an approach to assess the risk of AMD. Geological modelling tools were utilized to build an understanding of the spatial distribution of sulfur within the mined void, helping to inform assessment of risk. Outcomes have been used to focus ongoing geochemical characterization activities, as a basis for scoping calculations to predict the possible quality of drainage waters, and as a foundation for closure planning.

APPROACH

The propensity for mined materials to generate acid is a balance between the abundance of acid forming minerals (i.e. sulfides) and acid neutralizing minerals (e.g. carbonates). In the current work, the geochemical characteristics of mined lithologies were assessed principally on the basis of geochemical data within the drill-hole database. These data comprised XRF results for the following parameters: Al_2O_3, CaO, Fe, K_2O, MgO, MnO, P, S, SiO_2, TiO_2.

Sulfur (S), was used to infer maximum acid potential (AP) based on the assumption that all sulfur present is in the form of reactive sulfide. This is a conservative approach, as some proportion of the sulfur may be present as sulfate in the form of gypsum or other non-acid forming minerals. CaO and MgO were assessed as possible surrogates for carbonate-based neutralization potential (NP)

but were found to over-estimate NP when compared to available acid-base accounting data – probably due the presence of Ca- and Mg-bearing silicates in the materials.

Because CaO and MgO were found to be unreliable surrogates for NP, the most conservative approach was to assume no NP and to classify materials on the basis of a sulfur cut-off threshold. Additionally, materials are flagged as 'pyritic' in the drill-hole database if they had been logged as un-oxidized Mount McRae Shale (i.e. Mount McRae Shale sourced from below the oxidation zone). This approach provided two broad categories of classification namely pyritic waste and non-pyritic waste; the non-pyritic waste is assumed non-acid forming (NAF) whereas the pyritic waste is categorized as potentially acid forming (PAF) only if the sulfur content is above 0.2%. Material with sulfur content below the sulfur threshold was considered to represent a low risk of acid generation.

To develop an understanding of the waste distribution and material classification, a statistical analysis was carried out to establish the occurrence of sulfur within each lithological unit using all data within the mining void. To account for materials that would be removed from site (i.e. ore), data were differentiated as ore or waste. Figure 2 illustrates sulfur statistics for waste, with the pyritic waste classification shown separately. The figure shows that the median values of sulfur content for the waste classification were low and fell below the 0.2% sulfur cutoff. The corresponding range (as indicated by the whiskers) of the assays also fell below the cutoff for the majority of the lithological units. The range of assays for some of the lithologies however exceeded the sulfur cutoff. In the absence of significant NP this may indicate a risk of acid generation.

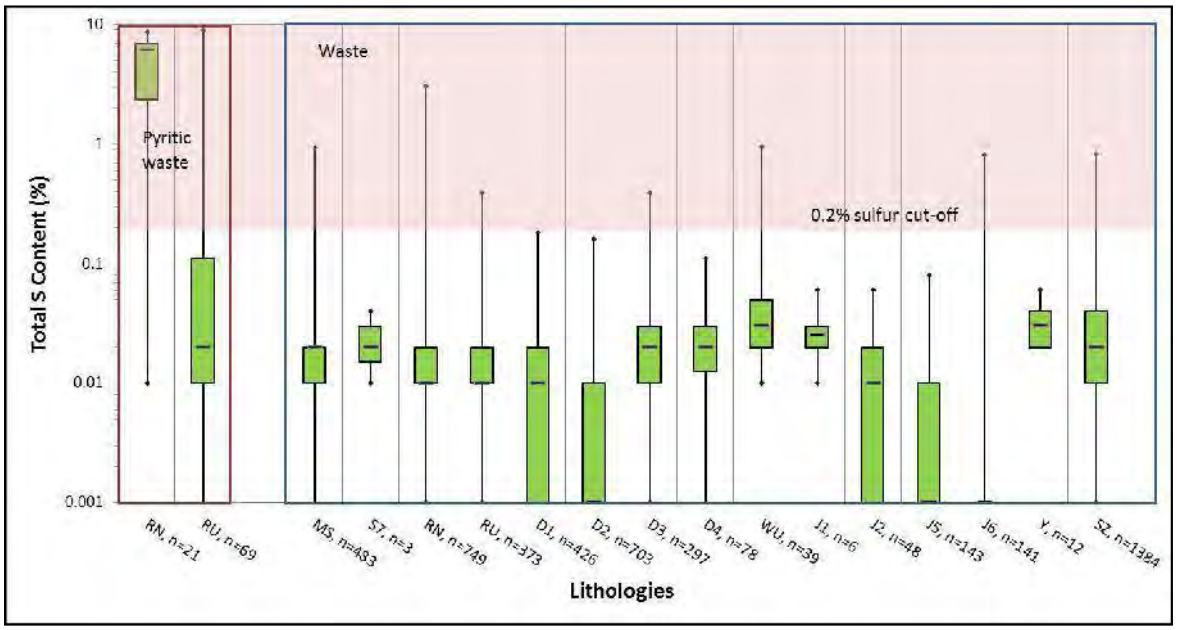

Figure 2 Box and whisker plots showing sulfur statistics in waste materials, by lithology

Note: The box and whisker plots show the minimum and maximum sulfur values (short horizontal dashes), median sulfur values (bold black dashes), and data falling within the 25th and 75th percentiles (green boxes). The number of samples, n, from each lithological unit is shown along the x-axis.

RU, RN – Mt McRae Shale (Upper and Nodular Zone, respectively); MS – Mt Sylvia, undifferentiated; S7 - Mt Sylvia (Bruno's Band); SZ – Surface Scree

Brockman Iron Formation: D1-4 – Units within the Dales Gorge Member; WU – Upper Whaleback Shale; J1-6 – Units within the Joffre Member; Y – Yandicoogina Shale.

Consistent with its classification, material categorized as pyritic waste contained a higher median sulfur grade, most notably for the Mount McRae Shale from within the Nodular Zone (RN); the majority of data for pyritic RN was above the 0.2% sulfur cut-off threshold. The Upper Zone of the Mount McRae Shale (RU) whilst classified as pyritic waste, showed a median sulfur content below the cutoff, but exhibited a large range in sulfur content.

On the assumption of a 0.2 % sulfur cutoff, the statistical analysis shows that the waste classification system would capture PAF materials within the pyritic waste category; however this is not necessarily the case for the waste category as illustrated by the range of assays exceeding the cutoff value for the remaining lithologies.

Therefore, the above analysis showed that to assess the overall potential risks of AMD, the range of sulfur values contained within each lithology is likely to influence the outcomes. Furthermore in the absence of NP data, a further level of conservatism in the form of a lower sulfur cut-off of 0.1 % was included in the subsequent evaluation.

Leapfrog® 3D modelling software[1] was used to process the drill-hole database to visualize the occurrence of the high sulfur zones within the mining void and that exposed on the final pit shell areas of reactive zones. To enable this, in addition to sulfur, the information imported into Leapfrog for 3D modelling purposes included:

- Geological wireframes;
- Pre-mining and proposed final (as mined pit shells) topographies; and,
- Pre-mining water table contours.

The resulting models were used to generate estimates of:

- Volumes of sulfur-bearing material that would report to waste rock dumps and ore stockpiles; and,
- Estimates of the pit wall exposure as a function of lithology and sulfur content.

Using these outcomes it was possible to build an understanding of the spatial distribution of sulfur-bearing materials.

The drill-hole assay data coordinates were then aligned with the block "mid-points" of the current mining models using Vulcan™ (3D modelling and mine planning) software[2], and blocks were classified according to the client's waste classification definitions, including a PAF waste category if > 0.2 % sulfur, to inform future mine planning and closure options at the site.

[1] Leapfrog® Mining 3D modelling software was used for this study, which utilises a "toolbox" approach to 3D geological modelling, allowing processing, viewing and interpretation of drill-hole data. Leapfrog® is 3D geological modelling software which is designed to be used in the mining, exploration, environmental and geothermal energy industries. Leapfrog® is the registered trademark of ARANZ Geo Limited.

[2] Vulcan™ is 3D modelling and mine planning software, allowing users to validate and transform raw mining data into dynamic 3D models, mine designs and operating plans. Vulcan™ is trademark registered to Maptek™.

RESULTS

Geochemical Characteristics of Mined Lithologies

Based on the sulfur statistics (see Figure 2), the majority of the lithologies to be mined would be considered to pose a low risk of acid generation. However, the sulfur ranges for many lithologies extend to maxima that lie above the sulfur cut-off thresholds, indicating that there may be quantities of material from several of the lithological units that could pose a risk of AMD.

Potential for Acid and Metalliferous Drainage - Pit Walls

Figure 3 is a Leapfrog image of the final pit shell showing the lithological composition of the exposed pit walls. One approach to assess the potential for AMD from the pit walls is to examine the sulfur statistics for the lithologies in question. Based on the statistical evaluation, the proportion of data with sulfur values above the cut-off threshold can be quantified and used a guide to the proportion of PAF material present. However, this approach takes no account of potential spatial variability in the distribution of sulfur within the lithological units.

Figure 4 shows another Leapfrog image of the final pit shell, this time showing the distribution of sulfur on the pit wall based on the sulfur model developed from the available drill-hole data.

The degree of correlation between lithological exposure and sulfur content is not entirely clear cut, which may reflect the fact that the density of data available to support the geological model is greater than that available to support the sulfur model. However, comparison of Figures 3 and 4 shows that higher sulfur values are often coincident with exposure of the Mount McRae Shale and the immediately overlying Colonial Chert Unit (D1). Most of these exposures are located at or near the base of the pit. Sulfur 'hot-spots' are shown to also extend up to the pit crest, many of which are coincident with exposure of surface scree.

Using the Leapfrog model, it was possible to quantify the composition of the exposed pit wall according to sulfur content, by elevation (Table 1). Note that having taken account of spatial variability the total percentage of PAF exposed on the pit wall is greater than was estimated on the basis of bulk sulfur statistics. Pit wall rock with total sulfur content greater than 0.1% is now 6%, rather than 3%, and wall rock with sulfur content greater than 0.2% is 5% rather than 0.3%.

Having developed a model of the spatial distribution of sulfur on the pit wall, a more robust risk assessment for the potential for AMD can be achieved. For example, the location of higher sulfur materials relative to post-closure water levels can be accounted for in the long term risk assessment; only materials remaining above the long term water table would be expected to continue to represent a potential source of AMD post-closure.

Totals	1,458,000	1,368,000	21,000	39,000	30,000
Percentage of Total Surface Area		**94%**	**1%**	**3%**	**2%**
Estimates based on evaluation of bulk sulfur statistics		**97%**	**3%**		
		99.7%		**0.3%**	

Note: Highlighting has been used to indicate material with total sulfur content above sulfur cut-off thresholds (i.e. PAF). Note that an elevation range from 382 (pit base) to 640 mRL has been considered in the analysis. The images presented in Figure 3 and 4 have been clipped at approximately 505 mRL (the level of the lowest point along the pit crest)

In the current assessment, the potential for AMD in pit wall runoff is considered low due to the relatively low proportion of higher sulfur material exposed. With respect to the small proportion of higher sulfur material identified:

- Material located on or near the pit floor is hosted by Mount McRae Shale and Colonial Chert. These lithologies are known to host sulfide mineralization, and could represent sources of AMD. Because these materials would be expected to be submerged following water table rebound, they would not represent long-term sources of AMD, post-closure. Short-term leaching of pre-existing soluble oxidation products is possible.

- Material located near the pit crest is hosted by surface scree. Though some sulfur in this lithology is expected to be non-sulfidic (e.g. gypsum), geochemical characterization studies have confirmed the presence of sulfidic sulfur in a small subset of samples. Data from ongoing detailed geochemical characterization activities suggest that sufficient neutralization potential is present to classify the materials generally as NAF. These materials may however represent a potential source of neutral mine drainage (NMD).

Potential for AMD - Waste Storage Areas

The lithological composition of waste to be mined is shown in Figure 5, based on Leapfrog modelling of the lithological volumes within the pit shell. Estimates of the overall proportion of PAF material present in the waste is shown in Table 2. The estimates combine the volume of each lithology with the bulk sulfur characteristics of the materials.

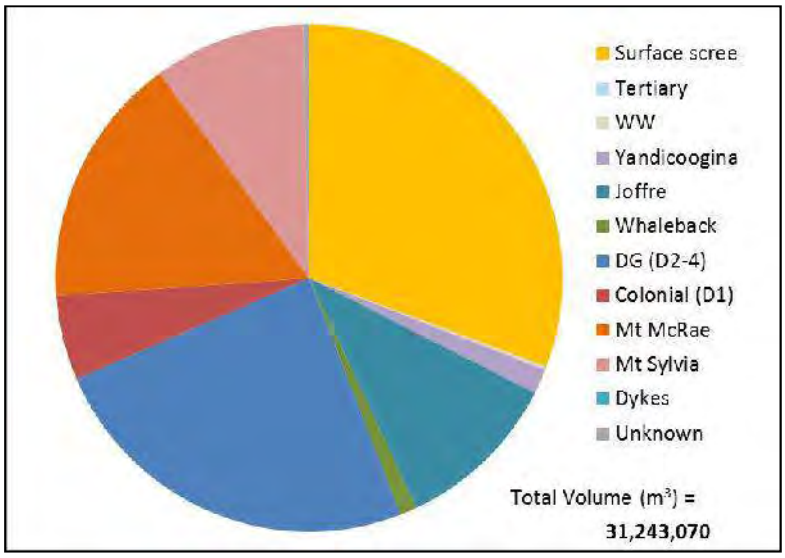

Figure 5 Pie-chart showing the lithological composition of waste to be mined from the pit

RU, RN – Mt McRae Shale (Upper and Nodular Zone, respectively); S – Mt Sylvia, undifferentiated; S7 - Mt Sylvia (Bruno's Band);

Potential for AMD – Stockpiled Ore

As was the case with waste, the volumetric proportion of PAF material in ore grade materials was estimated to be low. Combined with short residence times within stockpiles, the ore materials were considered to represent a low to negligible risk of AMD.

AMD RISK AND WATER QUALITY

As described in the previous section, the approach developed allowed the identification and quantification of potential AMD sources for waste storage areas, ore stockpiles, and exposed pit walls. Based a semi-qualitative assessment the AMD risks associated with the potential sources were considered low. However, a more robust assessment would include the estimation of water quality and solute loadings that would result from each of these sources, and then determining the potential impacts on the downstream environmental receptors. The approach presented herein provides fundamental inputs that are required to complete such an assessment, comprising properties, quantities and exposures for materials that have a potential to generate AMD. The assessment would however also require kinetic test data (to provide reaction rates and solute release rates) water flow rates (i.e. infiltration, runoff) and flowpath analysis to understand impacts on the receptors.

The outcomes risk assessment can also be used to infer possible closure management strategies at the site which may include backfilling of the pit void. If the pits were backfilled to above the long-term regional groundwater table, groundwater flow would be re-established and flow would likely pass through the backfill. Upon inundation, oxygen would be excluded from the backfill to very low levels and oxidation of any residual sulfides present would essentially cease. Readily soluble solutes contained in the backfill placed below the final water table (i.e. generated prior to inundation) would be released to the groundwater following inundation. The total potential for solute release would depend on the degree of oxidation (i.e. the duration of exposure) of sulfide minerals prior to inundation. Solute generation would be expected to continue in reactive materials (backfill and wall rocks) that remain above the water table.

Should the pits remain as open voids post closure (or be backfilled to below the long-term groundwater elevation), they could act as indefinite sinks for groundwater and would capture some seepage and runoff from waste storage areas that fall within the draw-downs that would occur around the voids. Under this scenario, although the pit lakes would be anticipated to salinize over time due to evapo-concentration, impacts on the key environmental receptors would be unlikely.

CONCLUSIONS

Sulfur has been used as an indicator of the potential for AP, and therefore AMD risk (a conservative approach since surrogates for NP in the geological database were found to be unreliable). Using geological modelling tools, drill-hole data were utilized to develop models of sulfur distribution within the mine volumes to provide estimates of quantities of materials, and wall rock exposure on the final void, that may pose a risk of AMD. This information is required to semi-quantitatively infer the potential risk of AMD. Taking into account spatial variability in the distribution was found to be an important foundation for the assessment of AMD risk. With respect to the pit walls, if spatial variability was not accounted for, the potential for AMD could be under-estimated.

ABSTRACT

Kinetic testing has been conducted on six samples of sulfidic Mount McRae Shale from the Pilbara, West Australia. The total sulfur content of the samples ranged from 0.2 to 8.9%. Whilst the sulfide mineralization was predominantly pyrite, the bulk mineralogy of the samples was dominated by silicates and iron oxides. Acid neutralizing capacity was low and sample classification ranged from Uncertain (UC) for the low sulfide samples, to potentially acid forming (PAF) for the higher sulfide samples.

Various small scale test methods have been developed within the industry to assess the rate of oxidation and solute release from mine waste materials. Whilst humidity cell tests (HCTs) were developed in North America as part of the MEND program, an alternate but similar free draining method was developed in Australia, referred to as the AMIRA free-draining method. These methods are conducted at a similar scale, but differ primarily in the frequency of irrigation, and the temperature at which testing is undertaken. The methods were compared to assess the implications on leach rates and water quality predictions.

Under acidic conditions, both test methods generated similar trends, and produced approximately equivalent results. One sample contained neutralizing capacity and the two methods yielded different pH profiles; the HCT remained circum neutral, whilst the AMIRA test developed acidic conditions. A possible cause of the discrepancy is comparatively high consumption of neutralization capacity in the saline AMIRA leachate environment. Further work is required to develop a more robust understanding of neutralization processes, and their effectiveness, as a function of leachate salinity.

The test results for acidic conditions would yield similar outcomes when used as the basis for water quality predictions at a larger scale, however, this was not the case for the sample containing reactive ANC.

Keywords: Sulfide oxidation, kinetic testing

INTRODUCTION

The stratigraphic sequence in the Pilbara, Western Australia, includes shale and lignite lithologies, both of which are known to host sulfide mineralization (Green and Borden, 2011). Extensive geochemical characterization programs have been conducted to build an understanding of the geochemical behavior of these materials.

Laboratory-scale testing methods are employed to give insights into sulfide oxidation rates, acid/neutralization potential of the material and solutes released. The results are the foundation for predictive modelling of future mine-affected water quality and are used to guide mine waste management decisions (Green and Borden, 2011; MEND, 2009; INAP, 2009).

In the current study, two kinetic test methods were evaluated in parallel: i) AMIRA free-draining columns and ii) humidity cell tests (HCTs). In addition, the work was performed to compare the results from the two methods in order to evaluate the test method constraints, functionality and reliability or accuracy.

METHODS AND MATERIALS

Two kinetic test methods were employed:

- **AMIRA Free-Draining Column Method** (AMIRA, 2002). The method involves placing 2 kg dry weight of crushed rock (< 10 mm) on a mesh in a free-draining container and subjecting it to periodic leaching with a known volume of de-ionized water (400 mL/kg). The sample is flushed once every four weeks. In the weeks between flush events, the sample is moistened by the addition of a small volume (100 mL/kg) of de-ionized water. Heat lamps are applied at regular intervals to ensure the sample dries out between solution applications and to ensure that the temperature remains in the range 30 to 35 °C.
- **Humidity Cell Test Method** (MEND, 2009). Humidity cell tests (HCT) involve loading approximately 1 kg dry weight of crushed rock (< 10 mm) into a humidity cell. In the initial week (Week 0) the sample is wetted and flushed. This is followed by a weekly cycle, involving continuously pumping dry air for three days, and humid air for a subsequent three days, through the sample. The sample is then flushed with 500 mL of de-ionized water on the seventh day. Tests are operated at ambient laboratory temperature, approximately 23 °C.

In both methods, after each leach cycle, the leachate draining from the sample is collected and analyzed.

Six rock samples sourced from Mount McRae Shale were selected to represent a range of sulfur contents and various classifications, as shown in Table 1. Four samples were subjected to both kinetic testing methods. Since insufficient sample mass was available for the remaining two samples to conduct both methods, one was tested as an AMIRA column and the other as a HCT.

In later stages of AMIRA testing for samples ETD297 and EUG180, insufficient leachate was generated to meet analytical requirements – possibly because physical properties of the samples were changing over time (e.g. reduction in porosity, permeability, leading to an increase in moisture retention). Consequently from approximately Week 40 onwards these samples were flushed at a higher rinse volume (500 mL/kg).

All testing and analyses were undertaken at the SGS Laboratories in Perth.

S – Sulfur; SO_4 – Sulfate; CRS=Chromium reducible sulfur; ANC – Acid Neutralizing Capacity; NAG – Net Acid Generation; MPA – Maximum Potential Acidity; AP – Acid potential; TIC=Total Inorganic Carbon; TOC=Total Organic Carbon; CarbNP – Carbonate Neutralizing Potential; NAPP – Net Acid Producing Potential; NPR – Net Potential Ratio; NAF – Non Acid Forming; UC – Uncertain; PAF – Potentially Acid Forming; LC – Low Capacity.

Notes:

[1] Calculated from XRD results.

[2] CarbNP was calculated from the total inorganic carbon content of the sample.

[3] NAPP and NPR calculated using the ANC and MPA.

[4] Anomalous (high) as it is inconsistent with other results for this sample, e.g. the pyrite content as determined by XRD, and the NAG test results.

RESULTS

Figure 1 and 2 show leachate pH and calculated sulfate release rates for each test, as a function of time. As applicable results from both AMIRA columns and humidity cell tests are shown on the same plot for ease of comparison.

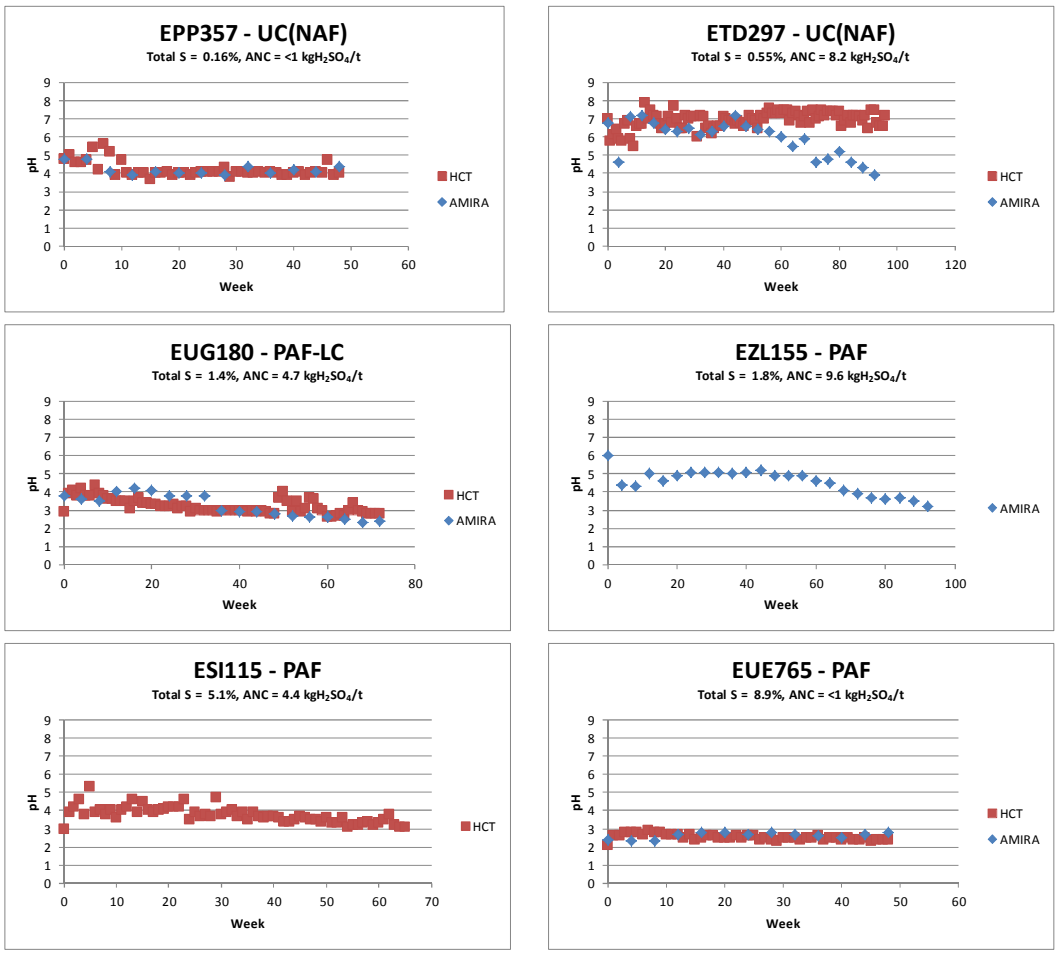

Figure 1 Leachate pH as a Function of Time
[The plots are arranged in order of sulfur content, reading from left to right]

Although a range of sample classifications was represented - UC(NAF), PAF-LC and PAF (see Table 1 footnote) - most of the tests progressed to acidic conditions (stable long-term average leachate pH values ranging from 2 to 4). The exception was the HCT test for sample ETD297 which remained circum neutral throughout (92 weeks). Though circum neutral at first, the AMIRA test for this sample progressed to acidic conditions at around Week 48 (not long after the increasing the rinsing volume from 400 mL/kg to 500 mL/kg).

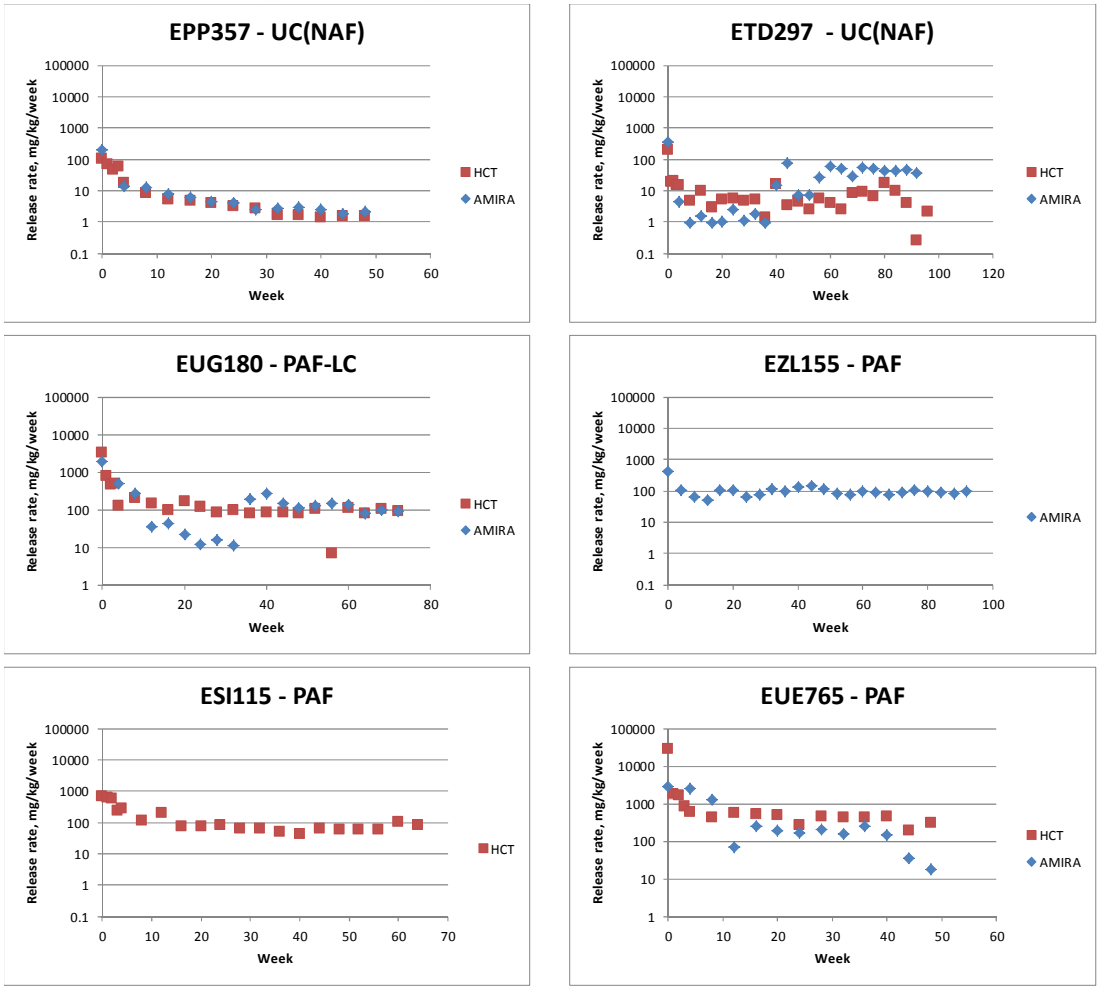

Figure 2 Calculated Sulfate Release Rate as a Function of Time.
[The plots are arranged in order of sulfur content, reading from left to right]

Sulfate release was highest in the early cycles of testing, and decreased in subsequent cycles, for the majority of tests, irrespective of test method. This reflects leaching of pre-existing readily soluble sulfate from the samples. The sulfate concentrations tended to stabilize at an approximately constant value in later stages for many of the tests, allowing calculation long-term average sulfate release rates. Exceptions were:

- AMIRA tests for samples ETD297 and EUG180 which showed a significant increase in release rate (by an order of magnitude or more) coincident with the increase in rinse volume
- AMIRA test containing sample EUE765 which showed a progressive decrease in release from Week 40 onwards.

Table 3 tabulates average release rates calculated for selected parameters.

Grey values are close to the approximate detection limits

Notes:

[1] Calculated from later column leachates, after most chemical parameters start showing stable trends (the week when stable conditions were attained is shown).

[2] Some calculated release rates are based on detection limit values and are therefore overestimates. The detection limit given in the table is approximate because, for the same analytical detection limit, the calculated release rate varies according to the volume of leachate collected and the mass of solid in the column.

[3] Average rates are based on data collected after the rinse volume had been increased.

[4] For this test, trends showed a sharp decline after 36 weeks, possibly due to armouring of reactive surface (see main text for discussion). The average release rates have been calculated using the data obtained between Week 16 (trends stabilised) and Week 36 (immediately prior to the declining trend).

DISCUSSION

Sulfide Oxidation, Acid Generation and Neutralization

Sulfate release rates from kinetic columns can be used to infer sulfide oxidation rates, assuming that no other geochemical processes increase or decrease sulfate concentrations in the leachates. PHREEQC modeling indicated that gypsum solubility may have controlled sulfate release in some of the early leaching cycles. At later stages, other sulfur-bearing minerals, e.g. hydroxysulfates such as jarosite, may have influenced leachate chemistry. However, the influence of these minerals on sulfate concentrations would have been limited by the low concentrations of other mineral constituents such as Al, K or Fe.

Figure 3 plots the average sulfate release rates against the sulfide sulfur content of the sample. The results from AMIRA columns and HCTs show the same general trend toward higher sulfate release rates as the sulfide sulfur content increases.

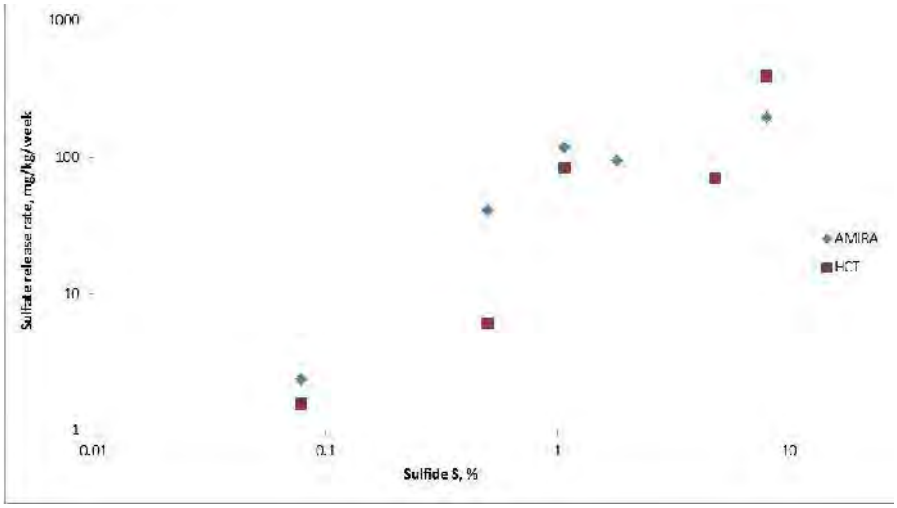

Figure 3 Sulfate Release Rate as a Function of Sulfide Content

Whilst sulfide content is interpreted as the primary variable controlling oxidation rates in the test materials, leachate pH clearly plays a role, explaining the higher sulfate release calculated in the AMIRA column (acidic) for sample ETD297 (about 0.5 % S) when compared to the equivalent HCT (circum neutral). The higher oxidation rate for the AMIRA test can be explained by:

- Catalysis by acidophilic bacteria is expected to be more effective under acidic conditions;
- An increased influence from ferric iron (Fe^{3+}) as an oxidant at acidic pH;
- Armoring of reactive surfaces is more likely under the circum neutral conditions of the HCT, and may have slowed reaction rates in this test.

Sample ETD297 was the only material that showed any evidence of effective neutralization during testing. In the early stages of both methods, circum neutral pH and $(Ca+Mg)/SO_4$ molar ratios in the leachates were interpreted as evidence of carbonate-based neutralization.

In the AMIRA test the leachate remained circum neutral until Week 40, when the pH started to decrease (Figure 1). The change in pH coincided with an increase in rinse volume. The increased rinse volume is

believed to have resulted in more effective flushing of accumulated products. The observed pH response suggests that either: (i) available neutralization capacity in the AMIRA method depleted at the same time as the operational conditions changed, or, (ii) the change in operating conditions somehow influenced the effectiveness of pH buffering in the material. The latter explanation is considered more likely, and could also explain why the results for the AMIRA test on sample EUG180 indicated a pH decrease coincident with a change in operating conditions (from pH 3 to pH 2; Figure 1).

Leachate pH is a complex balance of multiple influences, e.g. minerals that contribute acidity, and, minerals and aqueous complexes that can provide pH buffering. These complex equilibria are likely to be affected by changes in the leachate solute load (salinity). It appears that for the AMIRA test on sample ETD297 pH buffering was no longer effective following the increase in solute load. From that point onward in the test, increased oxidation rates (in response to the more acidic conditions) would have compounded the effect.

When compared to the AMIRA test leachates, solute concentrations in the HCT leachates were more dilute (due to more frequent rinsing with a higher volume of water). Perhaps for this reason, pH buffering remained effective for longer – explaining the continued neutralization observed in the HCT test for sample ETD297.

It is noteworthy that for all the samples the average Ca (and Mg) release is higher for the AMIRA tests than for the equivalent HCT tests, possibly indicating that the Ca/Mg mineral source is more reactive and/or soluble under the more saline condition of the AMIRA tests. In general terms, as most tests were acidic, this would indicate that pH neutralization is generally not effective (possibly indicative of a sideritic carbonate mineral source – siderite identified in ESI115, Table 1).

Elemental Release

Major elements, Al, Fe and Mn, and minor elements, As, Cd, Co, Cu, Ni, Sr, and Zn, release rates in general were in reasonable agreement between the two methods (Table 3 shows data for some of these elements); some deviations noted for sample ETD297 were related to the circum neutral pH observed for the leachates from the HCT method. Key controls on release were interpreted to be:

- Oxidizing sulfides – positive correlation with sulfate release suggested that some elements (e.g. Fe, Cu, As, Se) could be present in the matrix of the dissolving sulfide, whilst others (e.g. Al, Mg) could be sourced from minerals (e.g. carbonates, silicates) reacting in response to the acidic conditions produced by sulfide oxidation.
- Mn-bearing mineral – Cd, Co, Ni and Zn all showed strong correlation with Mn release. The identity of the mineral is unknown, possibilities are: manganese hydroxide, or Mn-bearing siderite or iron oxide. Release of Cd, Co, Ni and Zn (under acidic conditions) was also correlated to the bulk elemental content of the sample. As Mn itself did not correlate with bulk content it is inferred that only one of multiple Mn-bearing mineral sources in the material is reactive under the conditions of the tests.
- Mineral solubility – Fe and Al concentrations in some leachates were consistent with control by the solubility of iron and aluminium hydroxides and hydroxysulfates. Other possible solubility controls identified were amorphous silica (Si) and barite (Ba).

Comparison of Results from the Two Methods

Both methods were developed to measure sulfide oxidation and consequent solute release. The expectation is that all the soluble reaction products will be flushed entirely from the column during each irrigation event. The resulting leachate chemistries should therefore give a measure of the rate at which those reaction products are generated, provided the solutes are mobilized from the sample. Incomplete flushing of the oxidation products subject to solubility constraints would lead to underestimation of actual oxidation rates and solute release rates.

Table 3 Ratio of Calculated Average Long-Term Release Rates from HCTs: AMIRA Columns

Notes:

[1] Grey shading indicates ratios for parameters leaching close to or below analytical detection limits in both test methods. For an equivalent analytical detection limit, where the detection limit is adopted for the calculation, the calculated release rate for an HCT will be five times that for an AMIRA column (due to the weekly versus 4-weekly rinse frequency, and accounting for the different rinse volumes involved)

Elements not unduly affected by proximity to detection limits in general indicated the following:

- Reasonable agreement was observed between the two methods with HCT:AMIRA ratios often between 0.5 and 2 (i.e. rates were within a factor of two) for many elements.
- For sample ETD297, ratios were often less than 0.5, suggesting a significantly greater release rate from the AMIRA test. Note that the AMIRA test was acidic, whilst the HCT was circum neutral.
- Ca (and Mg, except for sample EUE765) release was consistently greater from the AMIRA columns, by a factor of between 3 and 10 (i.e. giving ratios between 0.1 and 0.3). This may be indicative of a temperature response. However, systematic temperature effects are not evident for other elements, and therefore an alternative explanation such as the influence of salinity is considered more likely.

- K and Si release rates from the two methods were in reasonable agreement for the lower sulfide content materials, but were greater in the HCT for higher sulfide materials. For the higher sulfide materials, the behavior may reflect a combination of incomplete rinsing of products from the AMIRA test, and/or the influence of solubility constraints.

CONCLUSIONS

Relative Merits of the Two Methods

The AMIRA and HCT methods showed the same broad trends, and equivalent release rates were observed. It should be noted however that most of the materials tested contained little or no effective neutralizing capacity, and leachates were mostly acidic.

The sample that contained available neutralization capacity, ETD297, yielded different pH profiles for the two methods; the HCT remained circum neutral over a testing period of 92 weeks, whilst the AMIRA test yielded acidic conditions after 40 weeks. The differing pH trends were interpreted as evidence that, for the higher solute and acidity concentrations expected during an AMIRA rinse event, (carbonate) neutralization is consumed or dissolved at a comparatively higher rate, and is more easily 'overwhelmed' (or armoured be secondary minerals), than is the case for more dilute leachates and higher frequency of flushing that occur for the HCT method. This interpretation may explain the differing pH profiles obtained for the ETD297 sample, and also the observation that Ca and Mg release is consistently greater for the AMIRA methods than for the HCT method. This difference in test outcomes has important implications with respect to utilization of the results for water quality predictions.

In terms of operational performance, the following is noted:

- Release profiles calculated from the AMIRA method tended to show a greater degree of variability than for the equivalent HCT method – interpreted as an increased sensitivity to the efficiency of leaching during individual rinse events.
- Leaching of pre-existing soluble salts (where present) was completed in a shorter time frame in the HCT – due to the more frequent rinsing regime.
- Limits of detection were encountered more often for the HCT method. For slow reacting samples, the AMIRA method facilitated collection of quantitative release rates for a wider range of elements when compared to the HCT methodology.

Implications for Data Utilization in Water Quality Prediction

Generally, trends in kinetic test datasets are used to examine relationships between sample properties (e.g. sulfur content) and oxidation rates, and to build confidence in conceptual models of processes controlling solute release. The current dataset showed that for acidic operating conditions, both test methods generated similar trends, and produced approximately equivalent datasets for use as a basis for estimating potential seepage quality from acid generating materials.

Leachate pH is a key influence on many geochemical processes, and an important aim of kinetic testing is to gain insight to the effectiveness and availability of neutralization capacity present, and facilitate estimation of times to the onset of acidic conditions. The different trends shown by sample ETD297 have important implications; the AMIRA method and the HCT gave different test outcomes, and led to differing conclusions with respect to the timescale, or even the likelihood, that acid conditions would develop in waters contacting this material type. The main cause of the discrepancy is interpreted to be a

comparatively high consumption of neutralization capacity in the more saline AMIRA leachate environment.

The climate in the Pilbara is arid, characterised by hot summers with periodic heavy rain and mild winters with occasional rain. In a full scale waste rock facility, time periods between 'rinse' events may be long, and the volumes of water involved low. Thus, contact waters would be expected to be saline. It is possible therefore that the outcomes from the AMIRA method could be more representative of neutralization behavior in a larger scale facility.

The current study included only one sample that allowed insight to the effectiveness of neutralization processes in the tests. Also, the internal variability for each of the test methods (i.e. effects of subsample variability, method variability, flushing efficiency etc.) has not been established for either method. Further work, on sample types known to contain effective neutralization capacity, would be necessary to develop a more robust understanding of neutralization processes, and their effectiveness, as a function of leachate salinity.

Lessons Learned in the Interpretation of Mine Waste Static Testing Results

Cheryl Ross and Rens Verburg
Golder Associates, USA

ABSTRACT

A mine waste geochemical characterization program is a fundamental component of the Environmental and Social Impact Assessment (ESIA) for a proposed mine. Typically, the primary objective of the geochemical characterization program is to characterize the acid rock drainage and metal leaching (ARD/ML) potential of mine materials (e.g., development rock, tailing and ore). Often, the laboratory testing program begins with static testing followed by kinetic testing, if deemed appropriate. Static testing is conducted to describe the bulk chemical characteristics of a material and evaluate the potential of a material to leach metals or generate acid. If static testing indicates an ARD/ML potential, kinetic testing is typically conducted to verify whether the various ARD/ML potentials identified will indeed be realized over time, to determine reaction rates, and to assess lag times to acid generation. Static and kinetic testing results often form the basis for the prediction of water qualities during operations and at closure.

This paper discusses the interpretation of results for industry standard static testing procedures. Laboratory testing examples are presented to demonstrate how static test results can be affected by the selection of a particular analytical method or the execution of the selected method. The examples presented include: (1) the potential for contamination from laboratory reagents to affect Net Acid Generation (NAG) test leachate concentrations; (2) the potential for filter selection to bias Synthetic Precipitation Leaching Procedure (SPLP) leachate pH values; and, (3) differences in sulfur and carbon determinations using different analytical methods.

This paper demonstrates the importance of a comprehensive understanding of the laboratory methods and the inclusion of data validation procedures in the development of a robust static testing data set for use in prediction of ARD/ML potential and water quality prediction.

Keywords: static, laboratory, NAG, SPLP, ABA, data validation

INTRODUCTION

A mine waste geochemical characterization program is a fundamental component of the Environmental and Social Impact Assessment (ESIA) for a proposed mine. Typically, the primary objective of the geochemical characterization program is to characterize the acid rock drainage and metal leaching (ARD/ML) potential of mine materials (e.g., development rock, tailing and ore). Often, the laboratory testing program begins with static testing followed by kinetic testing, if deemed appropriate. Static testing is conducted to describe the bulk chemical characteristics of a material and evaluate the potential of a material to leach metals or generate acid. If static testing indicates an ARD/ML potential, kinetic testing is typically conducted to verify whether the various ARD/ML potentials identified will indeed be realized over time, to determine reaction rates, and to assess lag times to acid generation. Static and kinetic testing results often form the basis for the prediction of water qualities resulting from the interaction between mine waste materials and the ambient environment during operations and at closure.

Leach testing is conducted to characterize the metal leaching potential of a mine material. The results of leach tests are sensitive to the methodology used (e.g., solid to solution ratio, nature of the lixiviant, grain size reduction). Therefore, although leach tests provide an estimation of which metals are most likely to leach from a particular material, leachate metal concentrations will exhibit variability related to the specific test methodology used and may not be representative of field-scale conditions. Two examples of how leach test method implementation can affect test results are presented in this paper.

Acid base accounting (ABA) is the industry standard method used to provide an initial assessment of ARD potential of a mine material. The acid generation potential (AP) of a material is derived from a sulfur determination. The most environmentally conservative approach to calculate AP is to make the assumption that all sulfur in a sample is potentially reactive and therefore capable of generating acid; however, this ignores the fact that not all sulfur will contribute acidity. Total sulfur is often determined using a combustion method (e.g., Leco furnace) but acid digestion methods may also be used. Results from these methods are compared in this paper to show differences in calculated AP. The neutralization potential (NP) of a material is often estimated based on carbon analysis. Differences in carbon analysis results by method are also presented.

STATIC TEST RESULTS AND POTENTIAL PITFALLS

Net Acid Generation Leachate

The Net Acid Generation (NAG) test is an acid-base accounting test developed initially in Australia but now widely applied internationally. The NAG procedure uses a strong oxidant (hydrogen peroxide) to rapidly oxidize sulfide minerals in a crushed rock sample (AMIRA 2002). The NP of the sample then can be directly challenged by the acidity generated by rapidly oxidizing sulfides. If the sample has sufficient available NP, the alkalinity of the whole rock will not be entirely depleted, and the system is expected to have the capacity to remain circum-neutral. If there is inadequate available NP, then the pH of the test solution will fall below 4.5 and there will be net acidity rather than net alkalinity. In this case, a sample shows potential for acid generation.

The steps in the single-addition analytical procedure from AMIRA (2002) are summarized below:

- **Step 1:** Place 2.5 grams of a pulverized rock sample to a conical beaker.
- **Step 2:** Add 250 millilitres (mL) of 15% hydrogen peroxide (H_2O_2)
- **Step 3:** Cover the beaker with a watchglass and place in a fume head. Allow the sample to react until boiling or effervescence ceases.
- **Step 4**: Once the reaction is complete, place the beaker on a hot plate and heat until effervescence stops or a minimum of 2 hours.
- **Step 5:** Allow the sample to cool to room temperature. Add deionized water to increase the volume to 250 mL.
- **Step 5:** Measure the pH of the solution.
- **Step 6:** Titrate with sodium hydroxide (NaOH) to a final pH of 7.0.

Increasingly, comprehensive chemical analysis of NAG test leachate is conducted following Step 5 (i.e. prior to back titration). These results may then be used in mine water quality predictions as an indication of worst case or terminal water quality.

For quality assurance/quality control (QA/QC) purposes, it is critical that a blank sample be analysed in association with any NAG leachate analysis. The reagent grade hydrogen peroxide typically used by laboratories contains a number of impurities, including metals. Phosphorus is also present due to the use of phosphoric acid as a stabilizer. Other chemicals used for stabilization may also impart impurities (e.g., colloidal stannates, organophosphonates and colloidal silicates). The pH of hydrogen peroxide is variable due to the presence of stabilizing agents. Acids and bases used in pH adjustment of the hydrogen peroxide are another possible source of impurities. The NAG test method stipulates a target hydrogen peroxide pH between 4.5 and 6.0.

As an example, the specifications for a 30% reagent grade hydrogen peroxide, American Chemical Society (ACS) certified, are shown in Table 1 (Fisher Scientific 2014). An example analysis of a NAG blank for a test conducted with reagent grade hydrogen peroxide is shown in Table 2.

Table 1 Example of 30% reagent grade hydrogen peroxide specifications

Parameter	Maximum Permissible Concentration (mg/L)
Iron (Fe)	0.5
Nitrate (NO_3)	2
Sulfate (SO_4)	5
Copper (Cu)	0.1
Nickel (Ni)	0.1
Ammonium (NH_4)	5.
Chloride (Cl)	3
Heavy Metals (as Pb)	1
Phosphate (PO_4)	2

Table 2 NAG Blank Analysis Results

Param.	Conc.	Param.	Conc.	Param.	Conc.	Param.	Conc.

		Cr	0.0536	Sb	0.006	Zr	<0.002

Param = parameter
Conc. = concentration in mg/L for all parameters with the exception of pH

The NAG blank results indicate the presence of a number of metals at concentrations above their respective analytical reporting limits. For some metals/metalloids (e.g., antimony), the reported concentrations are of the same order of magnitude as the water quality standards against which leach test results are often compared (e.g., United States Environmental Protection Agency [USEPA] drinking water maximum contaminant level [MCL] [USEPA 2009]). Phosphorus was measured at a concentration of almost 50 mg/L. The hydrogen peroxide therefore is a likely source of metals and phosphorus. The concentrations of phosphorus and chloride measured in the blank are higher than their respective maximum permissible concentration in the reagent grade hydrogen peroxide. The results for other parameters (e.g., alkalinity and tin) demonstrate the importance of a blank in the interpretation of NAG leachate results.

To reduce the potential for the hydrogen peroxide to be a source of contamination, it is recommended that ultra-pure hydrogen peroxide be used in NAG testing when leachate analysis is performed. This change will result in a significant increase in the cost of laboratory analysis. The cost of reagent ACS grade hydrogen peroxide currently is approximately 15 US$ per litre compared to 500 US$ per litre for ultra-pure hydrogen peroxide. Regardless of the type of hydrogen peroxide used, it is recommended that a blank analysis always be performed in association with NAG leachate analyses.

Synthetic Precipitation Leaching Procedure

The USEPA Synthetic Precipitation Leaching Procedure (SPLP) simulates the short-term interaction between meteoric water and a material (USEPA 1994). This test is frequently used in the mining industry to characterize the metal leaching potential of mine materials.

The SPLP test is conducted at a 20:1 solution to solid ratio. The lixiviant is prepared by the addition of a 60/40 weight percent mixture of sulfuric and nitric acids to reagent water to an end point pH of either 4.2 or 5.0, intended to be comparable to the pH of rainwater. The method calls for use of a pH 4.2 or 5.0 lixiviant for sites located east and west of the Mississippi River, respectively. Sample

preparation may include particle size reduction (<9.5 cm). Following 18 hours of reaction time, the leachate is filtered through a 0.6 to 0.8 μm glass fiber filter prior to chemical analysis.

Review of SPLP test results from multiple commercial laboratories has shown that an increase in leachate pH is sometimes observed following filtration. Example SPLP pH results for five waste rock samples tested using a pH 5.0 lixiviant are shown in Figure 1. These tests were conducted at a 4:1 solution to solid ratio instead of the standard 20:1 ratio. Leachate pH values were measured in the SPLP extraction vessel at the conclusion of testing (blue bars) and after filtration (green bars). The blank sample showed an increase in pH from 5.0, prior to filtration, to 6.2 after filtration. Significant increases (i.e. 10 to 20%) in pH were also observed for two of the five waste rock samples. The samples that demonstrated an increase in pH reported an initial value close to that of the lixiviant. As shown in Figure 2, these samples reported the lowest alkalinity and acidity concentrations and are therefore described as poorly buffered solutions. Poorly buffered solutions are the most susceptible to changes in pH following addition of an acid or base.

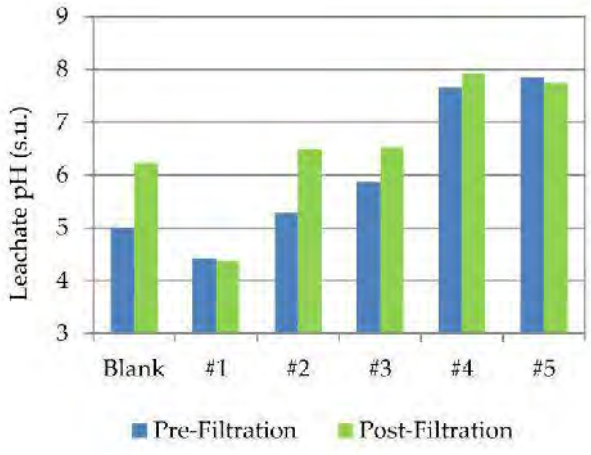

Figure 1 SPLP leachate pH results

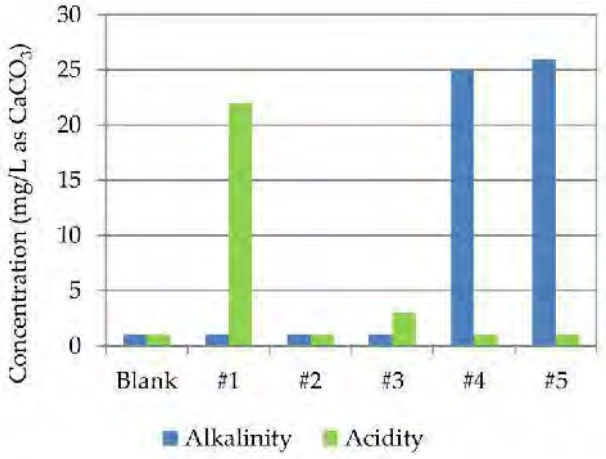

Figure 2 SPLP leachate alkalinity and acidity

Based on the results of additional laboratory testing, it was determined that improper filter preparation was the cause of the observed increase in pH. The potential for changes in the partial pressure of carbon dioxide in sample leachates was considered and discounted as the primary cause of the increase in pH.

The SPLP method stipulates that when evaluating the mobility of metals, filters shall be acid-washed and rinsed prior to use (USEPA 1994). Because the mobility of many metals is pH dependent, often decreasing as pH increases, a change in leachate pH has the potential to affect leachate metal concentrations. Therefore, use of a filter that does not impart a change in leachate pH is fundamental to the accurate determination of metal leaching.

Method specifications for SPLP filters include (USEPA 1994):

- Filters shall be made of borosilicate glass fiber, shall contain no binder materials, and shall have an effective pore size of 0.6 to 0.8 μm.
- Pre-filters must not be used.
- When evaluating the mobility of metals, filters shall be acid-washed prior to use by rinsing with 1 normal (N) nitric acid followed by three consecutive rinses with reagent water (a minimum of 1-liter per rinse is recommended).

To evaluate the potential for filters to affect leachate pH, it is recommended that a method blank be performed in association with all SPLP tests. Although not stipulated in the SPLP method, it is further recommended that leachate pH be measured before and after the filtration step.

Total Sulfur Analysis

Accurate determination of total sulfur is an essential component of many mine waste management programs. Two common methods for total sulfur determination are combustion (i.e. Leco furnace) and strong acid digestion. Total sulfur determinations using these methods for samples from a magmatic sulfide deposit are compared in Figures 3 and 4 (both figures present the same data on a linear and logarithmic scale, respectively). Each analytical method is described below:

- **Sulfur by Combustion (ASTM 2009) –** Sulfur content is determined by the combustion of a dry and pulverized sample in an oxygen atmosphere. Sulfur in the sample is converted to sulfur dioxide gas. The amount of sulfur dioxide gas evolved is measured by infrared adsorption.
- **Sulfur by Acid Digestion (Rudolph 1979)** - Characterization of the elemental (including sulfur) composition of a sample is a two-step process that includes an acid digestion to release elements into the solution phase followed by analysis of the elements in the resulting digestion. The 4-acid digest used in this study was a mixture of hydrochloric (HCl), hydrofluoric (HF), nitric (HNO_3) and perchloric ($HClO_4$) acids. The digestion was analysed by inductively coupled plasma (ICP).

In Figures 3 and 4, sample results with relative percent difference (RPD) values between the two results less than 35% are identified. An RPD less than 35% represents acceptable precision for solid phase duplicate analysis (USEPA 2010). These figures show that, at sulfur values greater than approximately 0.15 wt.%, the two analyses yield similar results. Below this concentration threshold, total sulfur values determined by the 4-acid digestion method were consistently higher than values reported by Leco furnace. As shown in Figure 3, at low sulfur values, the combustion method returns values that range from 0.005 to 0.1 wt.%; however, the 4-acid digestion method yields results for these same samples that are consistently higher (i.e. generally in the range of 0.1 to 0.2 wt.%). The reporting limits (RL) for total sulfur by combustion and 4-acid digestion are the same (0.005 wt.%) according to the method descriptions. At total sulfur values greater than 1 wt.%, although the two methods yielded similar results (i.e. RPD <35%), total sulfur by combustion consistently yielded higher values than the 4-acid digest method. This trend is likely attributable to loss of sulfur by volatilization with the 4-acid digest method. Based on the assumption that the Leco furnace results are more accurate, acid potential estimated from total sulfur determined by 4-acid digest would result in a biased high estimate of acid potential at low total sulfur concentrations and a biased low estimate of acid potential at high total sulfur concentrations. Use of mineralogical results is recommended to verify that sulfur determinations provide accurate estimates of AP.

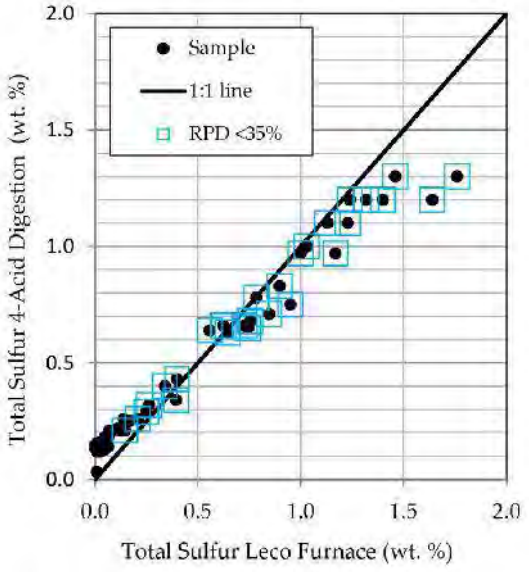

Figure 3 Total sulfur by Leco versus 4-acid digestion (linear scale)

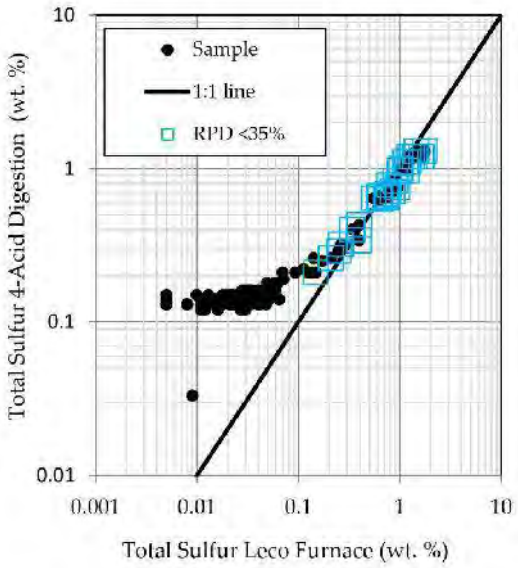

Figure 4 Total sulfur by Leco versus 4-acid digestion (logarithmic scale)

Carbon Analysis

The American Society for Testing Materials method (ASTM E1915-09) for total inorganic carbon (TIC) analysis provides two options: acid leach or pyrolysis (ASTM 2009). For both methods, total carbon (TC) is determined by the combustion of a dry and pulverized sample in an oxygen atmosphere. Carbon in the sample is converted to carbon dioxide gas. The amount of carbon dioxide gas evolved is measured by infrared adsorption. For the acid leach option, TIC analysis is conducted following the method described for TC; however, the sample is treated with hydrochloric acid (HCl) prior to analysis to remove the inorganic carbon fraction. TIC is then determined by difference (i.e. TC minus residual carbon following an acid leach). The pyrolysis method does not include a pre-treatment step. Instead, the sample is combusted at 550 °C to promote volatilization of organic carbon. The residual carbon (residue) is reported as TIC. Because siderite [$FeCO_3$] may decompose below 550 °C, the pyrolysis method may underestimate the TIC content of a sample when siderite is present (ASTM 2009).

TIC analysis results for 20 gold mine tailing samples are shown in Figure 5. For these samples, TIC values determined by HCl leach consistently yielded higher concentrations than TIC determined by pyrolysis. As shown in Figure 6, TIC by HCl leach was essentially equal to TC. TIC determined by pyrolysis indicated the presence of an organic carbon fraction (i.e. organic carbon equal to the difference between TC and TIC).

Mineralogical analysis by X-ray diffraction (XRD) indicated that the dominant carbonate mineral in all tailing samples was calcite [$CaCO_3$], with concentrations ranging from 1.2 to 5.8 wt.%. Siderite was identified in six samples at concentrations of <1 wt.%. TIC values determined by the acid leach and pyrolysis methods are compared to TIC calculated from mineralogy in Figure 7. Compared to the mineralogy results, TIC by acid leach generally overestimates TIC and TIC by pyrolysis often underestimates TIC. The presence of siderite does not appear to affect this trend.

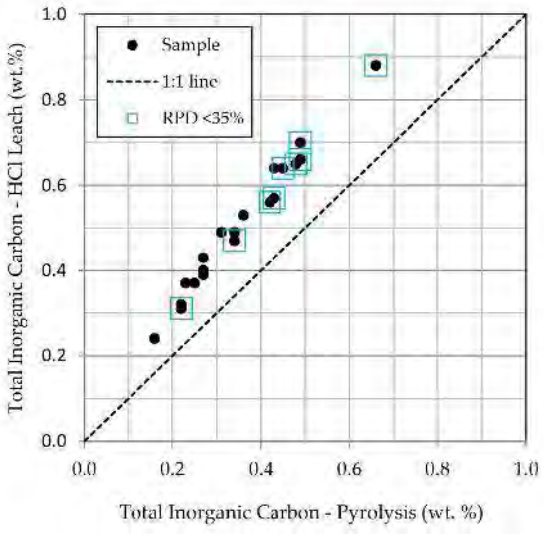

Figure 5 Total inorganic carbon by two methods

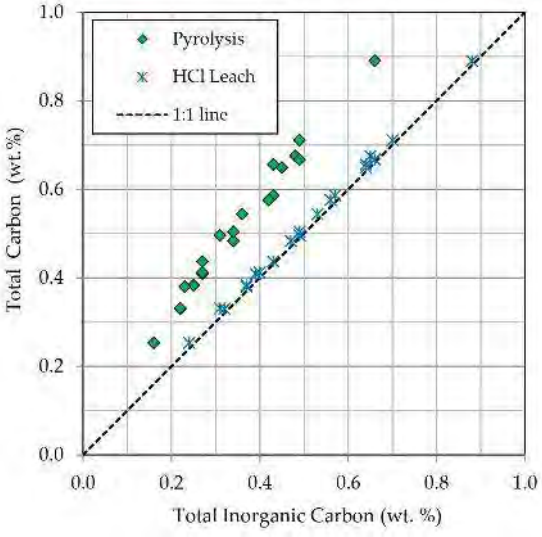

Figure 6 Total inorganic carbon versus total carbon

The average AP of the 20 tailing samples calculated from sulfide sulfur was 61 kg $CaCO_3$/t, whereas the average NP determined from calcite was 31 kg $CaCO_3$/t. The average difference in NP determined from TIC by the two methods was 13 kg $CaCO_3$/t, roughly one third of total NP. For a few samples, the difference in calculated NP is significant as the difference resulted in a change in the ARD classification of the sample as determined by neutralization potential ratio (NPR). Therefore, for these samples, even a small difference in estimated NP based on TIC is considered significant. Use of mineralogical results is recommended to verify that TIC determinations provide accurate estimates of NP.

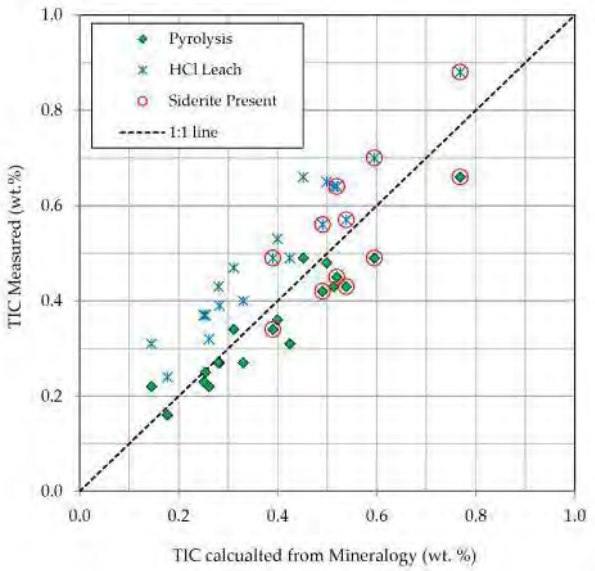

Figure 7 Comparison of total inorganic carbon by three methods

SUMMARY AND CONCLUSION

The examples presented in this paper demonstrate the importance of a comprehensive understanding of the laboratory methods and the inclusion of data validation procedures in the development of a robust static testing data set for use in water quality predictions. Development of QA/QC procedures is required to evaluate the accuracy and precision of the analytical results prior to use in predictions.

As demonstrated by the NAG and SPLP examples, inclusion of a method blank is recommended for QA purposes. Method blank results should be used to evaluate laboratory contamination and confirm the target lixiviant pH. Although not specified in the SPLP method, measurement of leachate pH before and after filtration is recommended. When NAG leachate analysis is conducted, use of ultra-pure hydrogen peroxide is recommended.

Acid base accounting is the industry standard method to provide a preliminary indication of a material's ARD potential. As demonstrated by the examples presented in this paper, the analytical method selected for sulfur and carbon determinations may affect the results, and therefore the estimates of AP and NP. For the total sulfur determination example presented in this paper, total sulfur determined by Leco furnace is considered more accurate than total sulfur determined by 4-acid digest. For both sulfur and carbon determinations, use of mineralogical analysis results is recommended to verify that total sulfur and TIC determinations provide accurate estimates of AP and NP, respectively.

ABSTRACT

Mine wastes produced from sulfide-bearing ores exploitation and processing are often characterized by acid mine drainage (AMD) generation, which leads to high dissolved metal concentrations in addition to acidity. When the acidic drainage is neutralized (generally through neutralization by carbonates), the phenomenon is called contaminated neutral drainage (CND). The quality of these drainages can be predicted by static tests, which can quickly assess the acid-generating potential (AP) and the neutralization potential (NP) by chemical and/or mineralogical calculations. With the Paktunc static test, the mineralogical composition of the sample is used to calculate both AP and NP. For AP calculation, equal oxidation rates are assumed for all sulfides. Since the sulfide minerals oxidize at different rates, the objective of the present paper is to compare the oxidation rates of various sulfides and sulfosalts often encountered in mine wastes in order to take them into account in AP prediction. Thus, seventeen pure sulfide minerals and sulfosalts (pyrite, pyrrhotite, bornite, chalcocite, chalcopyrite, covellite, galena, sphalerite, arsenopyrite, stibnite, gersdorffite and fahlore) were characterized physically, chemically and mineralogically, and submitted to kinetic tests (modified weathering cells) in order to compare their oxidation rates, acidity generation, and metal leaching potentials (As, Cu, Fe, Ni, Sb or Zn). The oxidation rates vary from 2 to 15 times between the sulfide minerals studied. Moreover, the metal concentrations in leachates from the sulfosalts are 30 to 40 times higher than those of the sulfide minerals.

This study fills a knowledge gap in the oxidation rates of common sulfides and sulfosalts, which enable a more precise prediction of AMD and CND generation, mainly through the integration of a kinetic parameter in the modified Paktunc AP calculation.

INTRODUCTION

Solid mine wastes resulting from extraction and ore treatment are often stored at the surface in waste rock piles and tailings impoundments. Mine wastes from sulfide-bearing ores contain different sulfide minerals which, upon exposure to atmospheric conditions, may generate acidic effluents in the absence of neutralizing minerals. The phenomenon, well-known as Acid Mine Drainage (AMD), is a complex process of chemical, physical and biological reactions. The prediction of water quality is of significant importance for the mining industry, due to increasingly restrictive regulations and higher social awareness.

AMD is very well documented in the literature (Brodie, Broughton & Robertson, 1991; Alpers & Nordstrom, 1999; Aubertin, Bussière & Bernier, 2002; Blowes et al., 2014). A reliable prediction of the quality of mine drainage at the earliest stage of the mining projects is beneficial. Different water quality prediction tools such as static and kinetic testing were developed in the past 30 years (Sobek et al., 1978; Adam et al., 1997; Lawrence & Scheske, 1997; Paktunc, 1999; Blowes et al., 2014). Prediction static procedures often examine the balance between the acid generating potential (AP) and neutralization potential (NP) of samples and are called acid–base accounting (ABA) tests (Ferguson & Morin, 1991). There are distinct classes of static tests: chemical methods and mineralogical methods. Chemical methods require testing in a chemistry lab, while mineralogical methods are mainly based on the mineralogical composition of the mine wastes. The AP and NP are calculated as the sum of the individual contributions of each acidifying and neutralizing mineral, based on their proportions in the sample and their relative reactivity (only for NP). The NP procedure has been largely investigated in the literature (e.g. Lapakko, 1994; Lawrence & Wang, 1997; Li, 1997; Paktunc, 1999). On the other hand, the AP is still often simply calculated on the basis of the bulk sulfide concentration in the sample, considering all sulfides are present as pyrite and based on the stoichiometry of pyrite oxidation (EQUATION 1). Thus, this simple AP calculation is biased because the possible different acid generation (on a molar basis) of other sulfides is not taken into account. To overcome this issue, (Paktunc, 1999) proposed an AP calculation based on the theoretical oxidation rates of the different sulfides (EQUATION 2).

$$AP = 31.25 \times \%Ssulfide \quad (kg\ CaCO_3/t) \quad (1)$$

$$AP = \sum_{s=1}^{m}\left(\frac{n_s \times 98 \times X_s \times 10}{w_s}\right) \quad (kg\ H_2SO_4/t) \quad (2)$$

- AP: acidification potential;
- ns: number of moles of H2SO4 formed by the oxidation of one mole of sulfide mineral s;
- 98: molecular weight of H2SO4 (g.mol–1);
- 10: conversion factor for recasting in kg.t–1;
- Xs: amount of sulfide mineral s in wt%;
- ws: molecular weight of sulfide mineral s (g.mol–1);
- m: number of sulfide minerals in the sample.

This equation improves the AP calculation but does not take into consideration the relative acidity production rates of the different sulfides; the latter was evaluated by several other authors (Nicholson, 1994; Rimstidt, Chermak & Gagen, 1994; Jambor & Blowes, 1998; Plumlee, Logsdon & Filipek, 1999). Moreover, based on the Paktunc equation, Bouzahzah, Benzaazoua & Bussière (2013) proposed another modified equation taking account the relative rates of acidity production of each sulfide by using a relative reactivity factor. This factor is determined by the average of the total

acidity produced by each sulfide calculated relatively to the acidity production of pyrite. However, only five common sulfides have been studied (arsenopyrite, chalcopyrite, galena, pyrite and sphalerite). Thus, based on their work, seventeen sulfide minerals were submitted to kinetic testing. The main objective of this study is to compare the acidity production rate of various sulfide minerals and sulfosalts often encountered in mine wastes, including pyrite (FeS_2), As and Ni-bearing pyrite, and pyrrhotite ($Fe_{(1-x)}S$, $0<x<0,17$) (hereinafter referred to as iron-sulfides); bornite (Cu_5FeS_4), chalcocite (Cu_2S), chalcopyrite ($CuFeS_2$), covellite (CuS), galena (PbS), sphalerite ((Zn,Fe)S), and sphalerite-Fe (hereinafter referred to as base-metals sulfides); arsenopyrite (FeAsS), fahlore (tetrahedrite-tennantite solid solution) $(Cu,Fe,Ag,Zn)_{12}(Sb,As)_4S_{13}$), gersdorffite (NiAsS), and stibnite (Sb_2S_3) (hereinafter referred to as As/Sb-bearing sulfides). To do this, a series of standard sample were prepared by mixing pure sulfide minerals with quartz (considered as inert). The reactivity of each compound within standard samples is evaluated by laboratory kinetic tests in modified weathering cells (small-scale humidity cell tests; see Cruz et al., 2001 and Benzaazoua et al., 2004 for details).

METHODOLOGY

Materials

A total of 17 sulfides and sulfosalts were selected based on their presences in typical polymetallic sulfides-rich deposits. These sulfides were acquired as pure mineral samples from a specialized minerals supplier. Five of these seventeen sulfides (arsenopyrite, chalcopyrite, galena, pyrite and sphalerite) were previously studied at the RIME (Bouzahzah, Benzaazoua & Bussière, 2013; Bouzahzah et al., 2008). The other samples were hand sorted to remove macroscopic impurities under a binocular lens before grinding to reach typical tailings grain size distribution (Bussière, 2007) according to their own grindability. Representative samples of the pure mineral powders were submitted to a full characterization and then used into the kinetic test.

Polished sections of the powders were examined and showed that some materials contain minor sulfide and/or gangue contaminants. Pure quartz was mixed with the pure sulfides and sulfosalts (95 wt% quartz and 5 wt% pure minerals) for kinetic testing.

Solid material characterization

The physical, chemical and mineralogical properties were determined for all studied materials (pure and mixtures). The grain size distributions were measured with a Microtrac S3500 laser grain size analyzer. The D_{10}, D_{50} and D_{90} values taken from the grain size distributions are presented below. The grain size distributions of the studied pure minerals are typical of tailings with D_{10} values ranging approximately from 1 to 20 µm and 80 to 95 % passing 130 µm. The total sulfur content S_t, including S from sulfide and sulfate minerals, was analyzed by an ELTRA induction furnace coupled with an infrared analyzer. The bulk chemical composition was analyzed by ICP-AES (Perkin Elmer Optima 3100-RL) following a multi-acid digestion ($HNO_3/Br_2/HF/HCl$). TABLE 1 summarizes the physical and chemical properties of the pure minerals.

Table 1 Physical and chemical properties of the pure studied minerals as solid samples

Mineral	D_{10} (µm)	D_{50} (µm)	D_{90} (µm)	St (%)	Fe (%)	Cu (%)	Zn (%)	Pb (%)	As (ppm)	Ni (ppm)	Sb (ppm)	Other traces (<2000ppm)

Polished sections were observed by optical microscopy to identify the gangue minerals or/and other minor sulfides. The composition of gersdorffite and fahlore was first evaluated using a JEOL J7600F Field Emission Scanning Electron Microscope (FE-SEM) coupled with an Oxford EDS (Energy Dispersive X-ray Spectrometry) spectrometer. Then, the more precise composition of these two samples and trace elements in pyrite 2 and 3, pyrrhotite 1 and 2, and in sphalerite-Fe (choosed along the assay of the sample and/or the oxidation behavior) was determined by analyzing 10 particles from each section using a Castaing Cameca SX100 Electron Probe MicroAnalyser (EPMA) coupled with a WDS (Wavelength-dispersive X-ray Spectometry) spectrometer for the microanalysis. All quantitative EPMA were done in wavelength-dispersive mode with an

accelerating voltage of 20 kV and a constant beam current of 20 nA. The counting time on each peak was 10 s with the exception of Mn (40 s), Ag (40 s) and trace elements (Cd, Co:40 s). The results are shown in TABLE 2. Gersdorffite is a solid solution (Fanlo et al., 2004; Ahmed, Arai & Ikenne, 2009) which contains more As and less S and Ni than the gersdorffite approved by the IMA, and which also contains Co. Fahlore is a solid solution between the tetrahedrite and tennantite poles.

Table 2 Microanalysis by EPMA of the pure studied minerals as solid samples

Modified kinetic testing

The samples were submitted to kinetic testing in modified weathering cells. These weathering cells (Cruz et al., 2001) are small-scale humidity cells which render similar results for the rates of reactions (Cruz et al., 2001). These tests could be considered as reproducible (Demers et al., 2011). Moreover, weathering cells can be used as an alternative to humidity cells when working on small sample quantities (< 100 g). This method is also known to be more aggressive than humidity cells (Villeneuve, 2004). The procedure consists of a 100 mm Büchner funnel with a 0.45 µm glass-fiber filter holding a 67 g sample. The sample is leached twice a week (3 days between flushes) with 50 mL deionized water. The cells were placed in a controlled-weather box to maintain the samples under optimal saturation conditions and avoid extreme drying (Bouzahzah, Benzaazoua & Bussière, 2013). Leachates from the weathering cells were analyzed for pH, conductivity, acidity, sulfur and elemental concentrations. The element concentrations in the leachates are analyzed by ICP-AES on an aliquot acidified to 2% HNO_3 for preservation. The weathering cells were run for 55 to 70 cycles (stopped upon reaching steady-state).

RESULTS AND DISCUSSION

pH

FIGURE 1 shows the comparison of the pH leachate of all studied minerals. The pyrrhotite 1 provided neutral pH at the beginning of the test which is related to the neutralization by calcite (6.8%). After its complete dissolution, the pH became acidic and then reached the pH value of the pyrrhotite 2. Almost all of the iron sulfide minerals showed more acidic pH at the beginning, certainly due to the dissolution of secondary products at the surface of the samples. The sphalerite

and sphalerite-Fe display very similar pH around 6. The covellite pH fluctuated between 5 and 6. The arsenopyrite generated the most acidic leachates of all samples. The gersdorffite produces acidic leachates at the test start and increases to more neutral pH along the test.

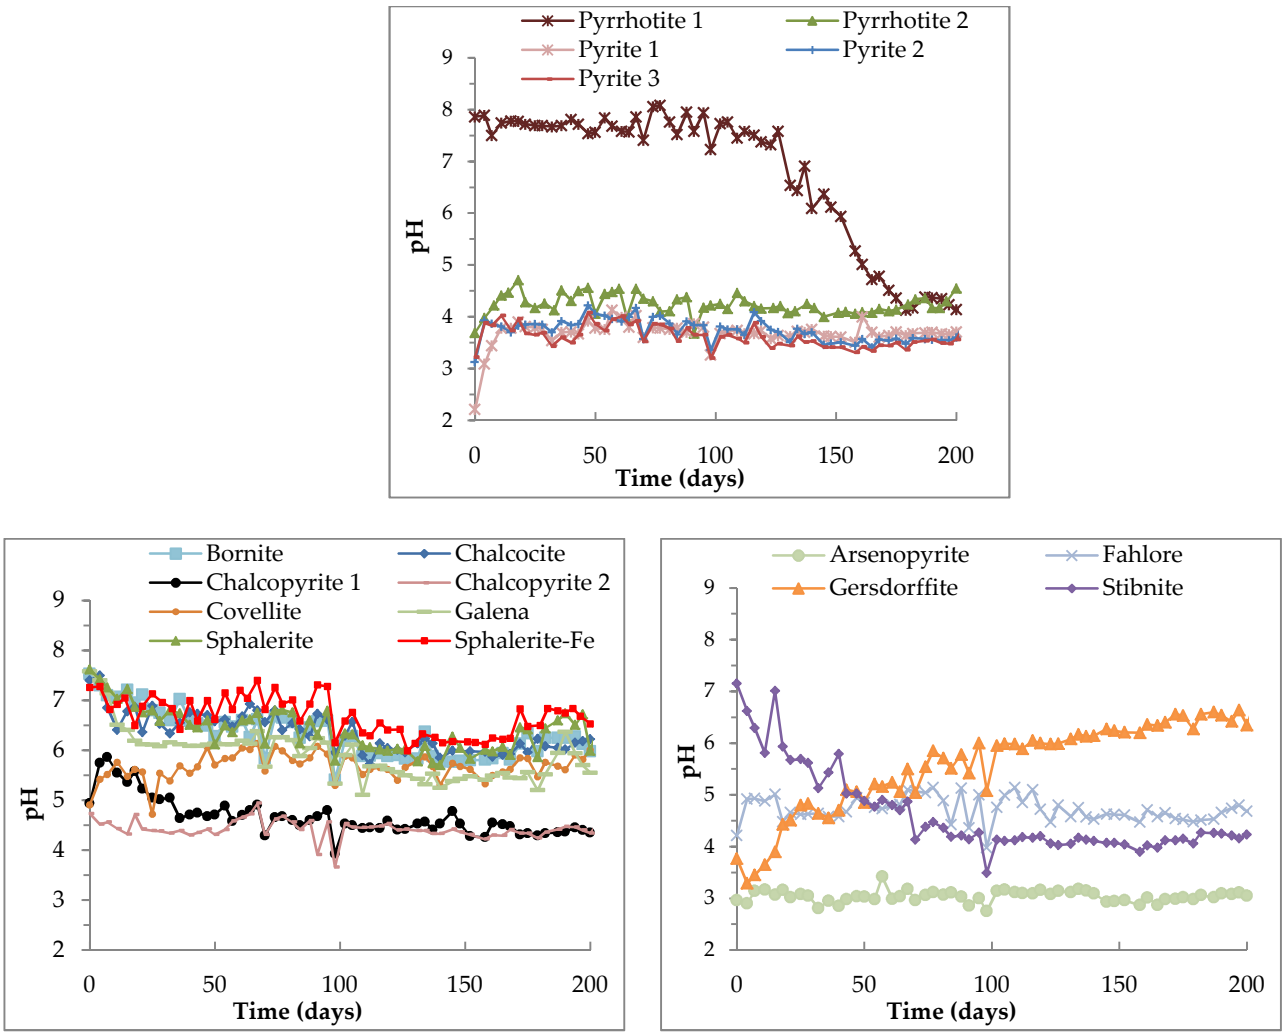

Figure 1 pH results of the leachates of the weathering cells for all minerals studied

Reactivity rates

As no other S-bearing oxidation products are suspected to form under the acidic and highly oxidative conditions of the kinetic tests, it is assumed that the entire S was present as sulfate in solution (pH > 2 and Eh > 0.4 V during all experiments) and ended up in the leachates. Therefore, this study uses the rate of sulfate production as the direct indicator of the acid generation rate and of the sulfide oxidation rate. The cumulative dissolved element loads are normalized regarding the initial sample mass for expressing the rates. The Specific Surface Area (SSA) of the studied minerals will be determined in a further study to take into account the influence of particle sizes in the oxidation rates.

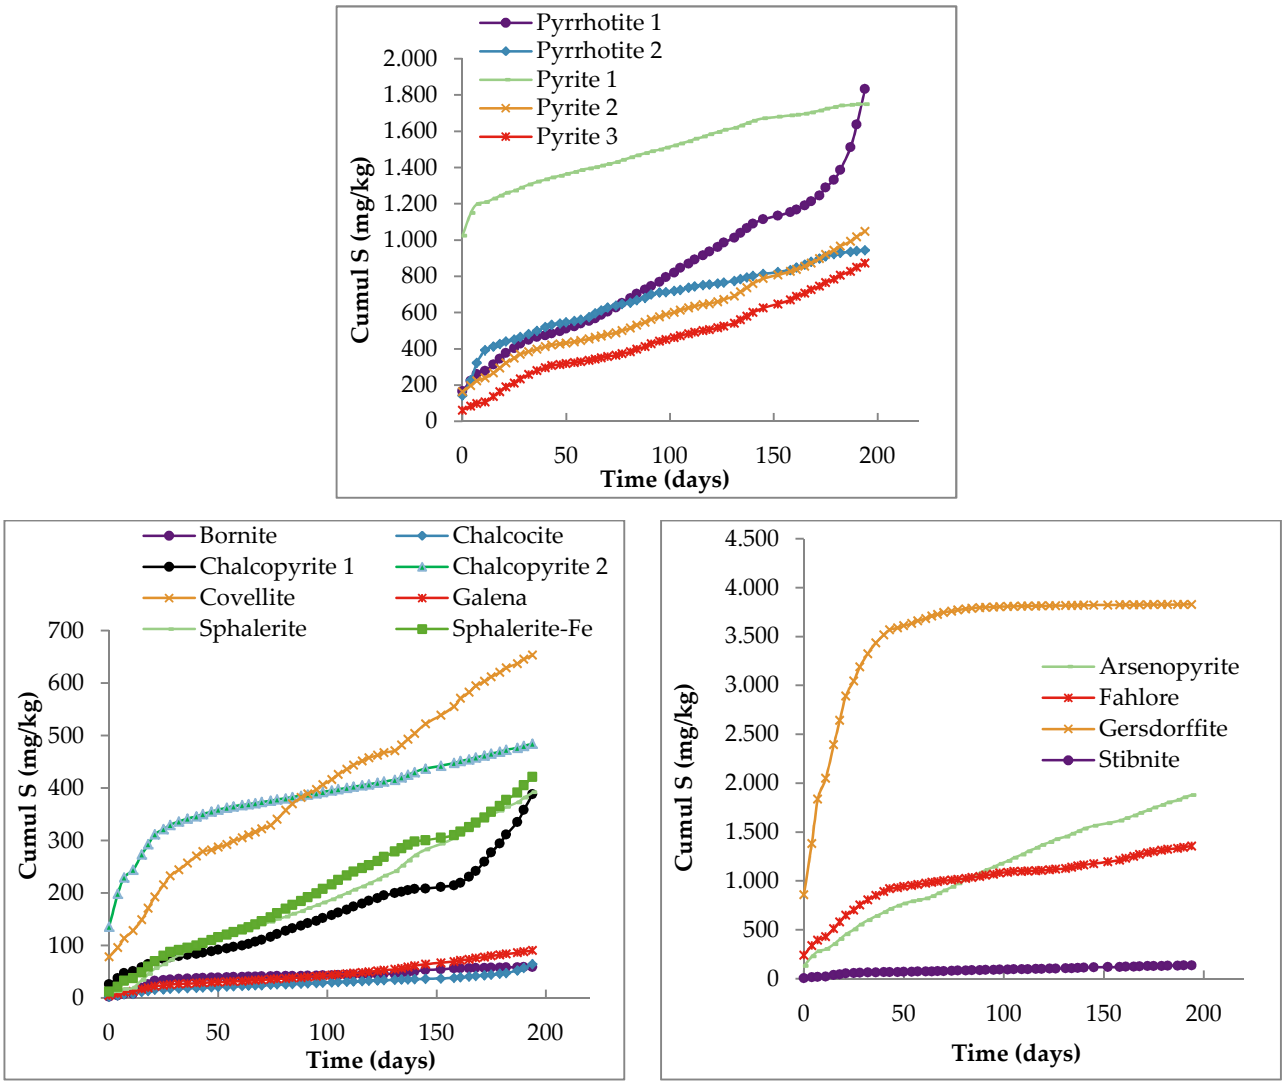

Figure 2 Cumulative normalized charges of S for the studied sulfides. Black arrows show points of inflexion for three specific minerals curves

FIGURE 2 shows the S release rate of the studied sulfides. The inflexion point of pyrrhotite 1 is due to the complete depletion of the carbonates content in the sample. The inflexion points of the sphalerites and chalcopyrites need further investigations and are not currently explained. We can note that the Mn content of the sphalerite-Fe may influence its rate of oxidation. This will be verified in a further study. TABLE 3 shows the oxidation rates of the studied sulfides, obtained by calculating the slope of the linear regression within the stabilized portion of these cumulative normalized loadings over time (mg of S/kg/day). These rates allowed the classification of iron-sulfides based on their reactivity as follows: pyrrhotite 1 > pyrite 2 > pyrite 3 > pyrrhotite 2 > pyrite 1. We have to mentionnthat the pyrrhotite 2 sample is not pure and contains 10 % of pentlandite. Moreover, this pyrrhotite contains trace Ni, certainly in its crystal network (about 1%, see TABLE 2), which may influence its reactivity (Dold, 2010). For this mineral, the Ni concentration in the leachates is higher (from 2 to 16 mg/L). The high concentration of Ni in pyrrhotite's leachates is

probably both due to the presence of pentlandite and trace Ni in the pyrrhotite grains. At the end of the test, the outline of almost all pyrrhotite grains is altered. For the base-metals sulfides, the classification is as follow: sphalerite-Fe > covellite > sphalerite > chalcopyrite 1 > chalcopyrite 2 > galena > chalcocite > bornite. Chalcopyrite 1 is more reactive than chalcopyrite 2 because it contains 26.5% of pyrrhotite. The sphalerite-Fe is more reactive than the sphalerite because of the presence of trace Mn (see TABLE 2) and its higher Fe-content. The As/Sb-bearing sulfides can be classified as: gersdorffite >>> arsenopyrite > fahlore > stibnite. We have to keep in mind that the gersdorffite is very reactive at the beginning of the test. Actually, the stabilized portion for gersdorffite either shows a depletion of the mineral of 70% (calculated by depletion of S) or could be due to a passivation of the reactive surfaces. Another duplicate test is currently ongoing.

Table 3 Experimental oxidation rates for the studied sulfides

Oxidation rates (mg of S/kg/d)					
Iron-sulfides		*Base-metals sulfides*		*As/Sb-bearing sulfides*	
Pyrrhotite 1	8.2	**Bornite**	0.23	**Arsenopyrite**	6.9
Pyrrhotite 2	2.6	**Chalcocite**	0.28	**Gersdorffite**	93.6
Pyrite 1	2.4	**Chalcopyrite 1**	2.0	**Fahlore**	3.2
Pyrite 2	4.8	**Chalcopyrite 2**	1.0	**Stibnite**	0.49
Pyrite 3	4.6	**Covellite**	2.7		
		Galena	0.53		
		Sphalerite	2.3		
		Sphalerite-Fe	3.2		

CONCLUSIONS AND FURTHER WORK

In order to complete the lack of knowledge about the oxidation rates of certain sulfide and sulfosalt minerals often encountered in mine wastes, the oxidation rates of seventeen of them were assessed by a modified weathering cell test. Based on the obtained results, these minerals can be classified in terms of oxidation based on their S release rates from the highest to the lowest: gersdorffite > pyrrhotite > arsenopyrite > pyrite > fahlore > covellite > sphalerite-Fe ≥ chalcopyrite > sphalerite > galena > stibnite > chalcocite > bornite. The results highlight the importance of trace element composition in the stability of individual sulfides (Dold, 2010). Pyrrhotite 2, which contains around 1.2% Ni, is less reactive than the pure pyrrhotite 1. Gersdorffite shows a different behavior which can be interpreted as a high initial oxidation rate and a high initial release of As. On the other hand, this study demonstrates that minerals could be very problematic for the environment, even if present at low concentrations in a sample. In fact, gersdorffite (As), arsenopyrite (As), stibnite (Sb) and fahlore (As, Sb) are very reactive minerals and release metal and metalloids. Further work will consist in the evaluation of their influence in real mine waste samples. Moreover, other metals or metalloids, like Cd, Co, Mo, Mn, Ni or Zn have been found in the leachates at concentrations over the existing regulation. More work will be done to improve the prediction of CND.

ABSTRACT

To assess potential impacts to groundwater from the disturbance of acid sulfate soils at a large construction project in coastal Victoria, Australia, an extensive program of fieldwork was undertaken to provide geological, meteorological and hydrogeological inputs into a site conceptual model to assess source, pathway and receptor linkages at the site. Soils were geochemically and geotechnically characterised from both background and disturbed areas, and free draining kinetic columns were constructed using local rainwater as the leachant.

The results of a ten month kinetic leach program were used to assess the potential long term risk posed to the receiving environment from insitu and stockpiled soils and assist in the development of groundwater management measures and improved water management at the constructed facility.

Keywords: Kinetic leach trial, acid sulfate soils

INTRODUCTION

The site is located in an area comprising gentle undulating terrace sand covered plains and alluvial floodplains and swamps (Rosengren and Boyd, 2008) of the early to mid Holocene, affected by both periods of drought (during 2007-2009) and flooding (during the winter of 2013). The groundwater level within the overburden groundwater aquifer at the site was reported to seasonally fluctuate by up to 1.5 m. Soils comprising acid sulfate soils (ASS) are present above and below the groundwater level, across the site, with soils with the highest potential to generate acidity present within the low lying swampy areas.

During the development of the site, ASS had been excavated and placed in stockpiles to represent artificial dunes, while in other areas, insitu ASS was dewatered due to construction activities. Concerns were raised about long term risks presented by ASS oxidation. In response, an extensive program of work was undertaken to evaluate the potential impact of ASS at the site on the surrounding environment.

To assess the risk associated with the release of acid from the disturbed soils a probabilistic statistical assessment of the sulfidic soils sampled at the site was conducted (Barker and Wallis, 2014). A GoldSim model was constructed to undertake a preliminary assessment of fate and transport of non-attenuated solute (i.e. acidic leachate) migrating off-site. In particular, the time it could take for a non-attenuated solute to migrate towards key environmental receptors was conservatively estimated. Two potential receptors; the Powlett River, situated approximately 1100 m east/northeast from the site and a tributary of the Powlett River, situated approximately 500 m from the site were identified.

The results demonstrated that there was a 50% probability that (a non-attenuated) leachate could reach the Powlett River in 12 years and the tributary in 4 years. There was a 5% probability that the leachate would reach the River in less than 2 years. Given the potential for impacts to the surrounding environment, an intensive investigation was undertaken to better understand the acid loads and timing of acidification.

Characterisation of the site conditions comprising assessment for the presence of ASS (using Suspension Peroxide Oxidation Combined Acidity & Sulfur (SPOCAS) analysis) combined with kinetic geochemical characterisation methods was undertaken. Groundwater quality at the site was monitored at a high frequency, through a network of groundwater wells within the overburden material, with a view to capturing local variations to groundwater quality from the construction activities that were ongoing (Dannatt and Wallis, 2014).

The kinetic methods employed were those typically used for mine-related acid drainage projects, this was one of the few construction projects known in Australia where kinetic techniques have been employed in any assessment. The free draining leach column method was modified from the standard methodology (with respect to leachate volumes and frequency of leach events) to reflect the site conditions encountered and the material properties (adapted from McElnea and Ahern (2000)).

The specific objectives of this geochemical leach assessment were to quantify the acid load released from each of the insitu and exsitu areas and provide an indication of the length of time that active management practices would be required.

METHODOLOGY

Sample Collection

Sample locations were selected based on the ASS test results obtained from previous soil investigations. The purpose was to obtain a range of different soil types with varying acidity regimes which would represent typical insitu and exsitu soil conditions. Approximately 4 kg of soil sample was collected from each location using a Geoprobe® drill rig with a push tube system. The soil samples were logged using the Unified Soil Classification System.

Sample Analysis

Samples were submitted to a National Analytical Testing Authority (NATA) accredited laboratory for static geochemical analytical work. A sub-sample of approximately 500 g was sent to Golder geotechnical laboratory for geomechanical testing. Soil samples were analysed for the parameters listed in Table 1.

Table 1 Soil and groundwater analysis methods and parameters

	Standard Parameters	Limit of Reporting
Soil		
Geomechanical	Atterberg Limits	1% and (0.5% for Linear Shrinkage)
pH/Electrical Conductivity	pH (1:5)	0.1 pH units
	EC (1:5)	1 µS/cm
Static Acid Base Account	SPOCAS Suite	pH unit, 2 mole H+/T, 0.02%S
Multi-Elements in Solids	Total Metals (Al, As, Ba, Be, Cd Cr, Co, Cu, Fe, Pb, Mn, Ni, V, Zn)	1-50 mg/kg
	Hg	0.1 mg/kg
	Sulfate	50 mg/kg
	Chloride (Cl-)	10 mg/kg
	Soluble Major Cations (Ca, Mg, Na, K)	10 mg/kg
Multi- Elements in water	Leachable Metals (Al, As, Ba, Be, Cd Cr, Co, Cu, Fe, Pb, Mn, Ni, V, Zn, Hg)	0.0001-0.01 mg/L
Soil Parameters	Cation Exchange Capacity (CEC), Organic Matter, Moisture Content,	0.1 meq/100 g, 0.5%, 1%
X-Ray Fluorescence (XRF)	Fused disc XRF	SiO2 – 0.05%, Cr2O3, MnO, P2O5 – 0.005%:
		Others: 0.01%

X-Ray Defraction (XRD)	XRD and Siroquant Analysis	Generally 0.1%
Leachate		
Acidity	Acidity	1 mg/L
Dissolved Major Anions and Cations	Cl, SO_4, Alkalinity and Ca, Mg, K and Na	1 mg/L
Dissolved Metals	As, Ba, Be, Cd, Co, Cr, Cu, Mn, Ni, Pb, V, Zn, Fe, Al and Hg	Al – 0.01 mg/L, Cd-0.0001 mg/L, Zn–0.005 mg/L, V/Fe–0.05 mg/L Others:0.001 mg/L

Kinetic Leach Column Testing

Two procedures for kinetic testing of solid mine waste materials; the Free Draining Leach Test, described in Appendix E of the AMIRA International ARD Test Handbook (2002) developed in Australia and the ASTM Designation: D 5744 – 96 (Reapproved 2001) accelerated weathering test method developed in the USA. Modifications to the above methods have been made based on available refereed literature describing ASS studies that have utilised column experiments. Further modifications, described below, were made during the running of the leach experiments.

Rainfall collected at the site was used as the leachant. The volume of rainwater used per leach event was initially based on the Bureau of Meteorology's monthly climate statistics for the Wonthaggi Weather Station obtained during the period 1981 to 2010. The aim was to leach the columns with the same amount of water as that which falls on the site in a 20 year period. Based on an average monthly rainfall of 79.2 mm (and taking into account total annual actual evapotranspiration), the volume of rainwater required to be leached through the columns over a 10 month period (to simulate a 20 year period), was 3.4 litres per week (total of 136 L).

Approximately 2.5 kg of 'as received' soil (i.e. no drying or grinding), was placed in each column (C01-C09) except for columns C05 and duplicate column C06 where approximately 1.8 kg of soil was used in the column. The sample weight was corrected to 'dry weight' using the soil moisture content test results.

Four columns comprised soil samples collected from the stockpiled soil (C01, C03, C04, C05) and two columns comprised soil samples collected from the insitu, expected dewatered zone, (C07 and C09). Three duplicate columns (C02 duplicate of C01, C06 duplicate of C05 and C08 duplicate of C07) were also included in the program.

A total of 20 leach events were undertaken for all columns except C05 and C06, where the experiments were terminated early due to the dispersive nature of the material (only 14 and 12 leach events were completed respectively). Samples of leachate are then collected and analysed (presented in Table 1).

During the first one to two leaching events, it was attempted to leach 3.4 Litres through the soil samples, however, due to low the permeability of the soil the method required modification; the frequency of leach events and the volume of leachant had to be reduced. The frequency of leaching

events was reduced from weekly to approximately every 2 weeks and the volume of leachant was reduced to approximately 1.7 litres per sampling event. In addition, following the first leach event, a vacuum pump was employed to assist in the collection of samples as insufficient sample was leaching by free drainage.

For four of the columns (C02, C03, C05 and C06), the volume of leachant had to be further reduced due to the highly dispersive nature of the fines. These challenges provide useful information regarding the soil behaviour and aided the development of the site conceptual hydrogeological model. The total volume of leachant added to each column over the leach events was between 20.1 and 37.4 Litres. This volume is equivalent to that which would be received at the site over a 3 to 5.5 year period.

RESULTS AND DISCUSSION

Pre leached Static

Soils sampled for this study comprised medium plasticity soft silty clay overlying low to medium dense silty sand . The organic matter content ranged from less than 0.5 %, in C09, to 2.1 %, in C07.

The pH (1:5 soil:water) of the exsitu samples range from 5.4 to 6.9 pH units. The pH of the insitu samples ranged from 4.9 to 5.5 pH units with samples from C07 returning the lowest pH values of 4.9 and 5.1 pH units. The EC values of the exsitu samples ranged from 325 to 718 µS/cm and are higher than the EC of the two insitu samples which are 147 µS/cm and 207 µS/cm. The titratable actual acidity (TAA) test results of the exsitu samples ranged from 6 to 13 moles H+/t and were generally lower than the TAA results for the insitu samples which range from 5 to 59 moles H+/t. Insitu soil samples from C07 exhibited the highest TAA test results compared to other samples.

The potential sulfidic acidity (S_{POS}) test results of the exsitu samples ranged from <10 to 47 moles H+/t although the majority of the samples had S_{POS} test results between 12 and 24 moles H+/t. Only one sample (from C04) returned a S_{POS} value of 47 moles H+/t. The SPOS test results of the exsitu samples are generally lower that the S_{POS} test results of the insitu samples which ranged from <10 to 178 moles H+/t. Test results from insitu soil samples from C09 were considerably higher than test results from other soil samples.

Nine of the 12 samples returned S_{POS} values above the laboratory limit of reporting. None of the exsitu or insitu samples contained any retained acidity. None of the exsitu or insitu samples contained acid neutralising capacity (ANC), as measured by acid reacted magnesium or acid reacted calcium. The 'net acidity' values of the exsitu samples ranged from <10 to 54 moles H+/t and were generally, lower than the 'net acidity' value of the insitu samples which ranged from 24 to 183 moles H+/t.

Post-Leach Testing

The concentration of metals within the leachate, over the course of the project is presented in Figure 1.The pH (1:5 soil:water) of all post-leach samples remained comparable to the pre-leach test results except for samples from C01, which returned a higher pH, and samples from C04, C05 and its duplicate C06, and C09 which returned a lower pH. The sample in C01 was the only sample that was leached of all its actual acidity and it is likely that the pH of the post-leach soil was influenced by the pH of rainfall more so that the samples in the other columns. Columns C04 and C09

generated the most amount of acidity via oxidation of sulfides whilst C05 and C06 could not be leached for the full extent of the monitoring program and may have retained some acidity.

Based on the S_{POS} test results of the leached soil, the entire measureable pyrite content of the soil placed within the columns had oxidised during the 10 month leaching program except at C01 and C09 where S_{POS} results of 18 moles H^+/t were recorded post the leach program. At C01, the post-leach S_{POS} result exceeded the pre-leach S_{POS} result (by 4 H^+ mole/tonne) which was likely due to the sample heterogeneity. As C09, the post-leach S_{POS} results was significantly less than the pre-leach S_{POS} result (i.e. reduced by 150 moles H^+/t) however, some potential acidity remained.

The TAA test results are above the laboratory limit of reporting for all samples except C01. This is inferred to indicate that all leached soils, apart from that at C01, contain some actual acidity which has the potential to be leached in the future; moderate levels of TAA (~30 moles H+/t) were recorded in columns C04, C07 and C08 whilst low levels (<15 moles H+/t) were recorded in the remaining columns.

Leachate Quality

In general, leachate from C04 (exsitu soil) and C09 (insitu soil) contained the highest concentrations of metals (Figure 1). At C09, the concentrations of metals in the leachate rose until leach event 4 to 5 after which the dissolved metal concentrations in the leachate began to decline. This trend is consistent with the trends in decreasing pH and increasing sulfate (Figure 2). A second increase in dissolved Al, As, Fe and Zn concentrations was observed in the leachate from C09, following leach event 10. This trend is consistent with a second rise in sulfate concentration and drop in pH post leach event 10 (Figure 2 (iii)).

The trend in dissolved metal concentrations (i.e. decrease following initial leach events) was similar for all metals except Cu where the concentration generally increased during the testing period. Based on this trend, the dissolved Cu test results suggest that Cu in the soil in column C09 is more strongly attenuated than other metals tested and the rate of Cu release increases when the pH drops to below approximately 2.6 pH units. Low levels of dissolved Al and Fe were detected in the leachate which was expected given the static test results for these metals.

Dissolved Al is likely present due to the dissolution of aluminosilicate clay minerals following the drop in pH whilst the dissolved Fe is likely present due to the dissociation of pyrite within the samples.

Leachate results were compared to groundwater quality at the site. Groundwater quality was found to be relatively stable when teh whole site was considered. Localised variability was recorded, but these impacts could be correlated to the construction activities in close proximity to the monitoring point, thus impact from the acidic run off were not identified . Nevertheless, as a precautionary measure, run off from the stockpiles at the site is collected in a network of drains and treated.

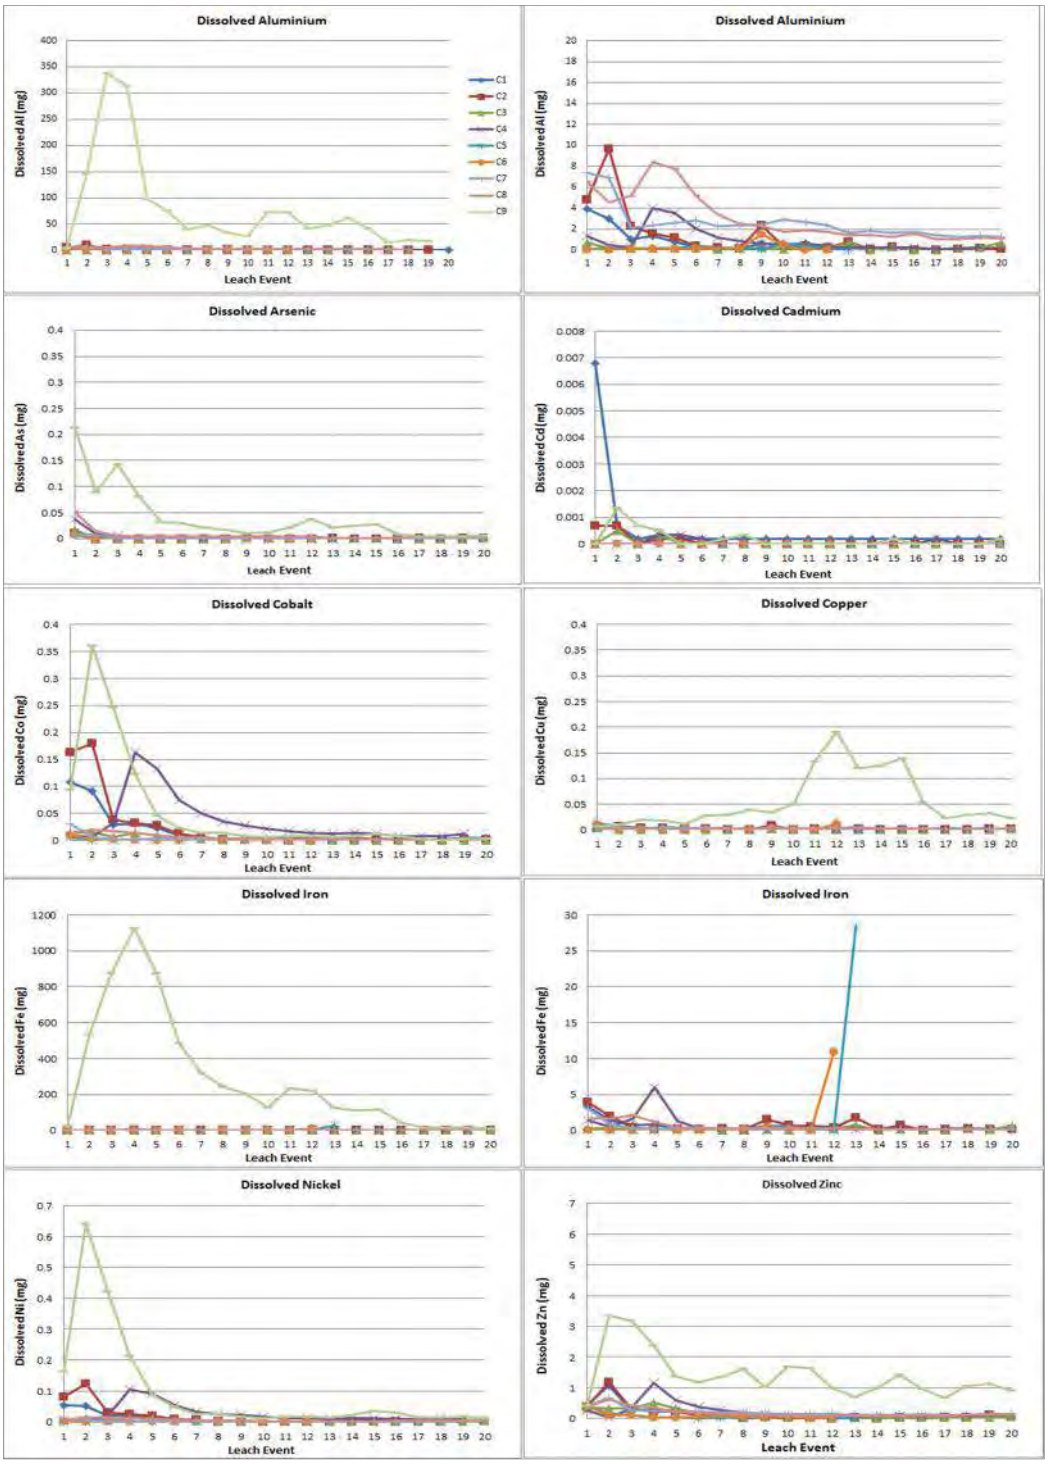

Figure 1 Comparison of dissolved metal concentrations in leachate.

XRF/XRD Analysis

Based on the results of the XRF analysis, the leached samples predominantly comprised silica (SiO_2) with lesser amounts of Aluminium Oxide (Al_2O_3; up to 9.55%), Iron Oxide (Fe_2O_3; up to 2.42%) and Potassium Oxide (K_2O; up to 1.46%).

Secondary iron minerals, such as jarosite and schwertmannite which commonly precipitate from iron-sulfate rich waters, were not identifiable within samples via XRD. This may be because they are only a minor component of the sample matrix (i.e. newly formed minerals). Alternatively they lack sufficient crystallinity to be detected. Freshly precipitated secondary minerals are likely to be highly amorphous and lack a regular crystalline structure.

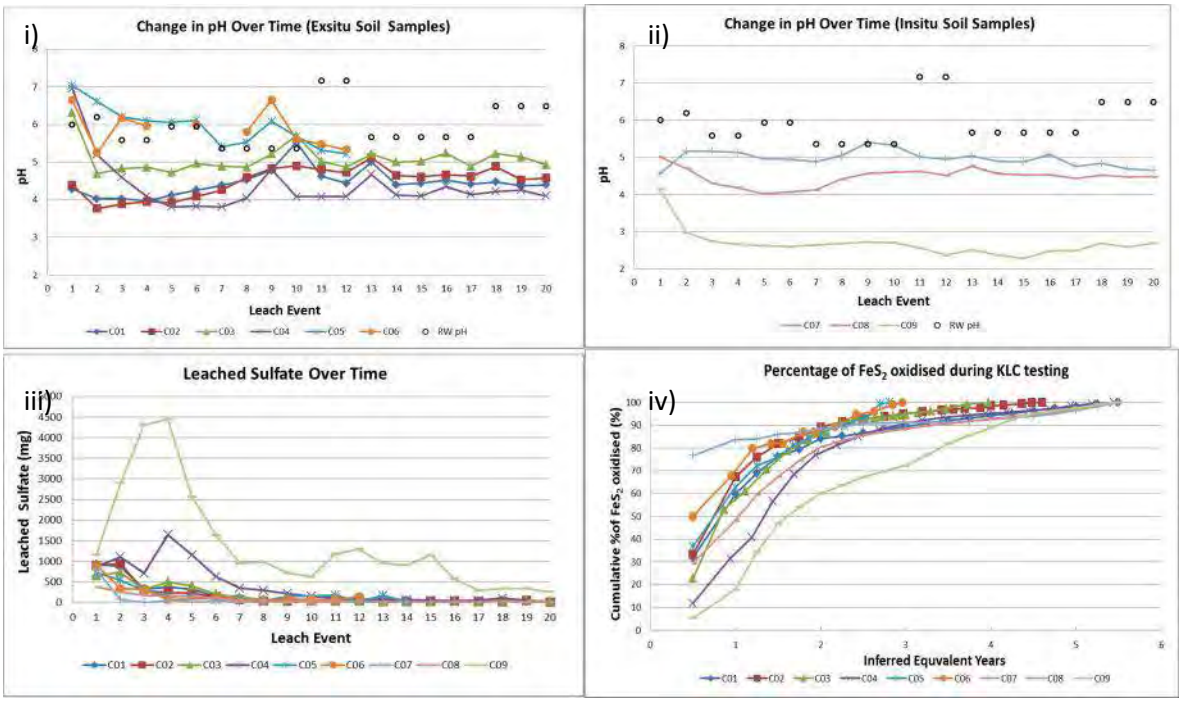

Figure 2 Change in pH over the leaching period for exsitu (i) and insitu (ii) samples. Rainwater pH (RW pH) also shown, iii) Sulfate export from the columns, iv) rate of sulfate generation / pyrite oxidation, assumes 100% of sulfate was leached during experiment.

Pyrite Oxidation Rates

Preliminary pyrite oxidation rates were calculated using the static and kinetic leach testing results. The assumptions used during this assessment are summarised as follows: (i) the samples are representative of the material in the constructed dunes; (ii) total pyrite content is calculated from the sum of sulfate in the leachate; (iii) the role of Fe(III) in the pyrite oxidation is limited given the low Fe concentration in waters at the site; (iv) by leach event 20, all of the pyrite has oxidised.

The cumulative percentage of FeS_2 oxidised over the course of the experiment was calculated through measurement of the sulfate generation over time and assuming oxygen as the primary oxidant. The rate of pyrite oxidation was plotted against the inferred equivalent field time (based on volume of leachant), as shown in Figure 2 (iii) and (iv).

It was noted that the oxidation rate decreased at approximately the 2.5 year mark, thus the assessment of acid loads to the environment two rates were used: within the first 2.5 years of oxidation, and following 2.5 years of oxidation. The oxidation rates for soil collected from the site are summarised as follows; oxidation rate within 2.5 years of disturbance, was estimated to range between 2 x 10-7 to 1.3 x 10-6 % pyrite oxidised per second. Oxidation rate following 2.5 years of disturbance, was estimated to range between 1 x 10-7 to 3.6 x 10-7 % pyrite/ sec. These rates are within the range reported in the literature (1 x10-7 to 2 x 10-4 % pyrite/ sec, (Hipsey and Salmon, 2008).

CONCLUSION

Based on the pyrite oxidation rates estimated during these works, the risks to groundwater from the oxidation of pyrite (within insitu and exsitu ASS) was most significant during the first and second year of soil disturbance and dewatering (2009 and 2010). However, based on groundwater monitoring (Dannatt and Wallis, 2014), the acid load released to groundwater during this time may not have caused acidic conditions to form; the construction period being as long as the acid generation period. Thus, the significant amount of high alkalinity construction materials (i.e. concrete) used at the site to potentially buffered the groundwater pH.

As the acid formation from the insitu and exsitu ASS is likely to reduce with time, as the rate of oxidation of pyrite stabilises and the potential acid load is significantly depleted, the long term risks to groundwater (i.e. following 2013) are likely to be limited. As a response to this, groundwater monitoring frequency has been reduced to quarterly events.

ACKNOWLEDGEMENTS

We would like to thank Dr Silvana Santomartino for her contribution to the project. Her expertise in the laboratory analysis of acid sulphate soils and data processing was most useful in the early phase of the project. We also wish to thank Dr Angus McElnea for his mentorship of Silvana.

Comparison of Actual and Calculated Lag Times in Humidity Cell Tests

ABSTRACT

It is common practice to run humidity cell tests on potentially acid generating rock or tailings samples to determine the amount of time it will take for acidic conditions to develop—often called "lag time". Defining lag time is important for understanding when management plans need to be in place for preventing or mitigating acid rock drainage. The lag time is a function of the amount of neutralization potential (NP) present in the rocks and rate of sulphide oxidation and therefore NP depletion. Although direct observations of lag times are possible, it is relatively rare for acidic conditions to develop over the course of a laboratory test. Therefore, lag times are more often calculated.

This paper explores the relationships between actual measured lag times versus calculated lag times for two groups of samples: 1) where acidic conditions developed following a distinct lag time, and 2) where acidic conditions should have developed, but did not develop despite an extended period of testing. The results show that actual lag times tend to be shorter than calculated lag times, demonstrating the importance of using conservative assumptions in the calculations of lag time as well as running some tests for an extended period of time to obtain site specific information on lag times. In addition the paper reiterates the importance of quantifying available NP rather than simply adopting measured NP results available from commonly measured NP procedures.

Keywords: Lag Time, Humidity Cell Test, Prediction, Management

INTRODUCTION

Generation of acid rock drainage (ARD) is a time dependent process in which oxidation of sulphide minerals results in the release of sulphate and acidity. Weathering of silicate minerals and/or dissolution of carbonate minerals may produce sufficient alkalinity to buffer the pH. In addition, reactions between sulphide oxidation products and carbonate and/or silicate minerals may further buffer the pH. In potentially acid generating mine wastes, the relative rates of acid production and acid consumption will determine: 1) whether acidic conditions will develop rapidly – due to insufficient rates of neutralization; or 2) whether there will be a delay in the onset of acidic conditions - due to a finite or limited amount of neutralization potential (NP). Along with rates of acid production, the amount and the availability of the NP will determine how long buffering reactions will persist.

Where present, the delay in the onset of acidic conditions is typically referred to as the "lag time". Lag times are important for understanding when management plans need to be in place to prevent or mitigate the effects of ARD. For example, where lag times are sufficient to ensure neutral pH conditions can be maintained for a period of time, it may be possible to backfill, place covers, or freeze the material to prevent ARD from developing. Similarly, it may be possible to delay the construction of a treatment plant, and thereby defer some of the start-up costs for period of time.

The lag time is a function of the amount and availability of NP present in the rocks and rate of sulphide oxidation and therefore NP depletion occurring as these rocks are exposed to air and water. Although direct observations of lag times are possible, it is relatively rare for acidic conditions to develop over the course of a laboratory test – even in samples that are potentially acid generating. More often, acidic conditions develop very early in the lab test due to insufficient rates of neutralization, or they don't develop at all due to slow rates of NP depletion. Therefore, lag times are more often calculated using data from humidity cell tests. Although the calculations are based on reasonably straightforward inputs, they are subject to a number of uncertainties, including the accuracy of measuring the NP and the rates of sulphide oxidation and NP release, the availability and reactivity of the NP, and other factors such as deposition of secondary minerals on mineral surfaces which may reduce the availability of the NP or result in reduced reaction rates. Estimates of lag times are also typically adjusted to reflect field conditions such as differences in temperature which can reduce reaction rates and further delay the onset of acidic conditions.

To better understand the magnitude of uncertainty in estimating lag times in the laboratory setting, we compiled data from a number of long term humidity cell tests and explored the relationship between actual versus calculated lag times in two groups of samples: 1) where acidic conditions developed following a distinct lag time, and 2) where calculations indicated that acidic conditions should have developed, but didn't develop despite an extended period of testing.

METHODOLOGY

SRK has compiled an inventory of results from over 229 humidity cell tests representing 33 sites internationally. Of these, 42 tests from 15 of these sites were identified as possible candidates for this study either because acidic conditions developed after distinct lag time to onset of acidic conditions, or acidic conditions had not developed, but the predicted lag times were reasonably close to or less than the test duration, indicating that acidic conditions could have developed. Key static and kinetic test results for each of these samples were compiled, and the calculations of NP

depletion were checked to ensure that consistent calculation methods were applied. On further review, 12 of the non-acidic tests were eliminated because the calculated lag times exceeded the test duration (i.e. there was no reason to expect that acidic conditions should have developed). The final dataset was comprised of 30 tests from 14 sites, with test durations ranging from 80 to 520 weeks. Thirteen of these tests are still operating.

Due to the large number of programs and the time frame over which these tests were completed – dating back almost 20 years, there were some minor variations in the static and kinetic testing methods. Most of the ABA tests included analysis of total inorganic carbon (TIC), and either Modified Sobek NP (MEND 1991), Sobek NP (Sobek et al., 1978), or with the European Standard EN15875 (CEN, 2011) procedure which itself is based on the Modified Sobek NP procedure. All of the humidity cell tests were completed using either flood or trickle leach variations of the MEND or ASTM method for humidity cell tests (ASTM 2001, MEND 1991). Lastly, the mineralogy was characterized using petrographic analysis and/or Reitveld XRD for most of the samples.

The actual lag time was defined as the point in time where the pH dropped below a value of pH 5, as shown in Figure 1. This pH was selected to ensure that acidic conditions were due to sulphide oxidation, rather than equilibrium with atmospheric carbon dioxide.

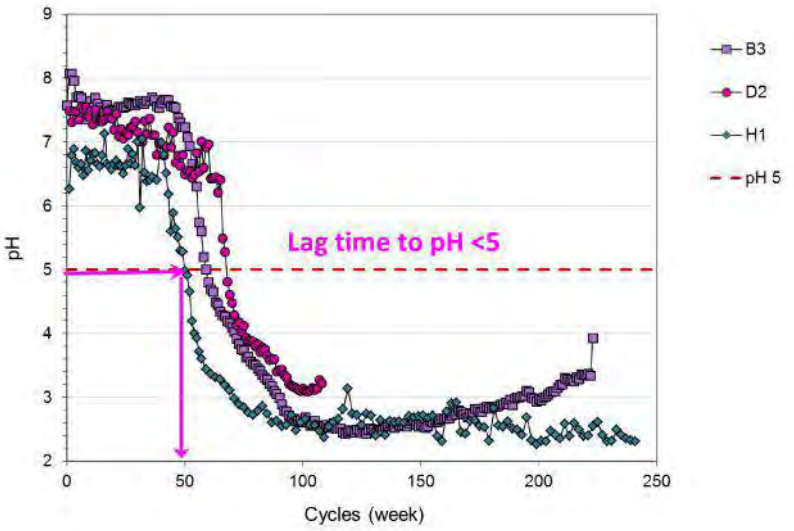

Figure 1 Definition of "actual lag times" used in this study

Calculated lag times were determined using the following two methods:

$$Time\ to\ NP\ depletion\ = \frac{NP*}{(Ca+Mg)\ release\ rate} \qquad \text{(equation 1)}$$

or,

$$Time\ to\ NP\ depletion\ = \frac{NP*}{SO_4\ release\ rate} \qquad \text{(equation 2)}$$

Where: NP* is the available NP in units of kg $CaCO_3$ eq/t (described below)

(Ca+Mg) and SO_4 release rates are the steady state non-acidic release rate from the humidity cell test in units of kg $CaCO_3$ eq/t/year.

For most of the samples examined in this study, these two calculation methods gave similar depletion times because the molar ratios of SO4/(Ca+Mg) in the humidity cell leachate were close to unity.

The available NP (NP*) was estimated based the TIC or NP titration method (Sobek, Modified Sobek or EN15875) that was considered to be most appropriate for the sample or project site, and further adjustments to account for limitations on the availability and/or reactivity of the NP. The following types of adjustments were made to account for these limitations:

- Site specific "unavailable" NP was estimated based on the TIC or NP found in samples with acidic paste pH values, and was subtracted from the TIC or NP.
- TIC was multiplied by a factor that represented the Ca+Mg content of the carbonates (Day 2009).
- TIC or NP was divided by a factor representing the relative availability of NP/AP (NP/AP_{crit}) established through kinetic testing. (NP/AP_{crit}) is typically a value between 1 and 1.5.
- For sites where there was no specific information as to whether TIC or NP was more appropriate for a site, or where site specific correction factors could not be established, the lesser of the TIC or NP value was selected and this was divided by an NP/AP_{crit} factor of 1.5.

For one site (Site N), NP was measured using both the normal EN15875 method in finely pulverized material, and an alternative method on samples with a particle size distribution equivalent to that used in the humidity cell test – without size reduction, making it possible to determine the amount of NP that was physically available in the humidity cell test. The results ranged from 0.34 to 0.66 (average of 0.53), indicating that roughly half of the NP was physically available. However, for consistency with the other data sets which did not have this type of data, these results were not explicitly considered in determining of NP* for these tests.

The (Ca+Mg) and SO_4 release rates were based on the steady state release rates established for the period of the test prior to the onset of acidic conditions. This is an important point because these rates often increase in response to decreasing pH conditions, and since the point of the calculation is to determine the time to onset, rates must reflect the period prior to onset of acidic conditions. Additionally, it was important to establish that these rates were not governed by dissolution of primary gypsum or anhydrite in the samples or by gypsum precipitation – which can occur in samples with very high oxidation rates and large amounts of calcite.

The comparisons of actual and calculated lag times inherently consider the combined effects of the variables that are included in these calculations – notably NP* and the (Ca+Mg) or SO_4 release rates. To explore secondary relationships, regression analysis was used to establish the relationship between actual and calculated values, and the residuals were plotted against other variables, including the rate of acidification (i.e. pH unit/week), the difference between NP* and TIC, (Ca+Mg)/SO4 release rates, sulphur content and sulphate production rates. A more qualitative approach was used to assess potential influences of mineralogy on the results.

RESULTS AND DISCUSSION

Sample Characteristics

Table 1 presents key results from the static and kinetic tests, and the actual and calculated lag times for each of the samples.

The ABA results (Table 1 and Figure 2) indicate that the majority of these samples had very low TIC and NP and high AP, with TIC/AP and NP/AP ratios consistently well below 1, indicating that they were all samples with a strong potential for ARD. As indicated previously, these samples represent a relatively small portion of the total number of samples in the kinetic test inventory, which suggests that delayed onset to acidic conditions is relatively rare and almost always occurs in material with very low NP and relatively high sulphide contents.

The pH profiles from the humidity cell tests (Figure 3) show a range of patterns. In some tests (Figure 3a), there is a distinct period when pH conditions are maintained at constant levels in the range of pH 6.5 to 8, and then a rapid drop in pH. In some (Figure 3b, 3c), there is a distinct period with constant pH, but then a more gradual drop in pH that is sometimes accompanied by large oscillations in pH over an extended period of time. In others (Figure 3d), the pH starts to drop early on in the test, but decreases very gradually, resulting in effective delays of more than 20 weeks before dropping below a pH of 5. Arguably samples from this last group does not show a distinct lag to onset of ARD, but were retained for use in the study to see if they would provide further insights in the determination of lag time.

Calculated versus Actual Lag Times

Comparisons of calculated versus actual lag times are shown in Figure 4. The results indicated that a small number of tests (5/30) had calculated lag times that were shorter than actual lag times. However, in most tests, calculated lag times were longer than actual values, and there was a reasonable relationship between these values (r = 0.62 and 0.67 for the two calculation methods respectively). A small number of tests were also treated as outliers because they had calculated lag times that were much longer than actual values. Further discussion of the outlier results is provided in the following section.

Although we expected to find a number of tests where the acidic conditions should have developed but didn't develop over the course of the test, only one test met this criterion (plotted on Figure 4 using test duration in lieu of actual lag time). This also supports the conclusion that acidic conditions tend to develop more rapidly than expected based on standard calculation methods used to assess lag times.

Linear regressions on these relationships indicate that, on average, predictions of lag time would be improved if the calculated lag times are multiplied by a factor of 0.73 (based on the calculation shown in equation 2). In other words, predicted lag times should be calculated as follows:

$$predicted\ lag\ time\ = 0.74 \times \frac{NP*}{SO_4\ release\ rate} \qquad \text{(equation 3)}$$

Interestingly, this factor is reasonably close to the "physical availability" that was measured in samples from Site N, suggesting that more rapid onset of acidic conditions could be, in part, a function of reduced NP availability in coarser particles in these samples.

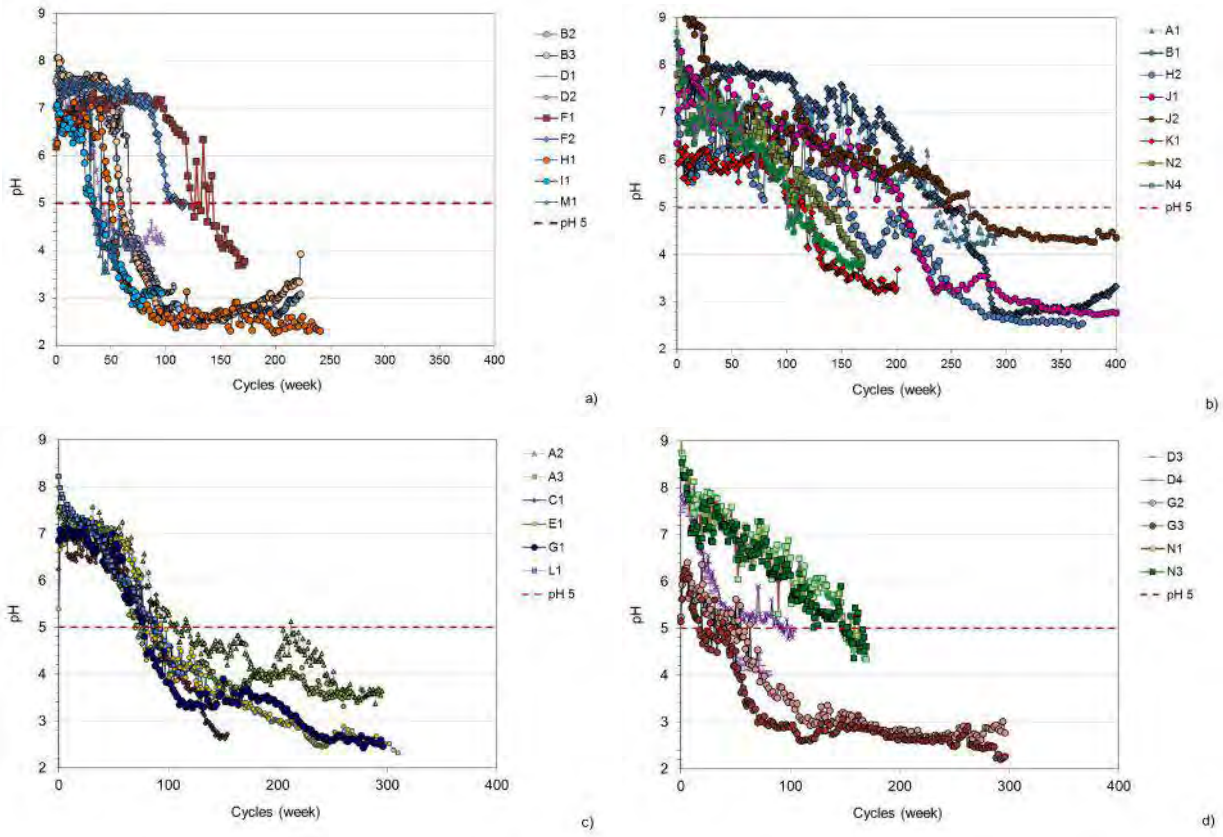

Figure 3 pH profiles from humidity cell tests.

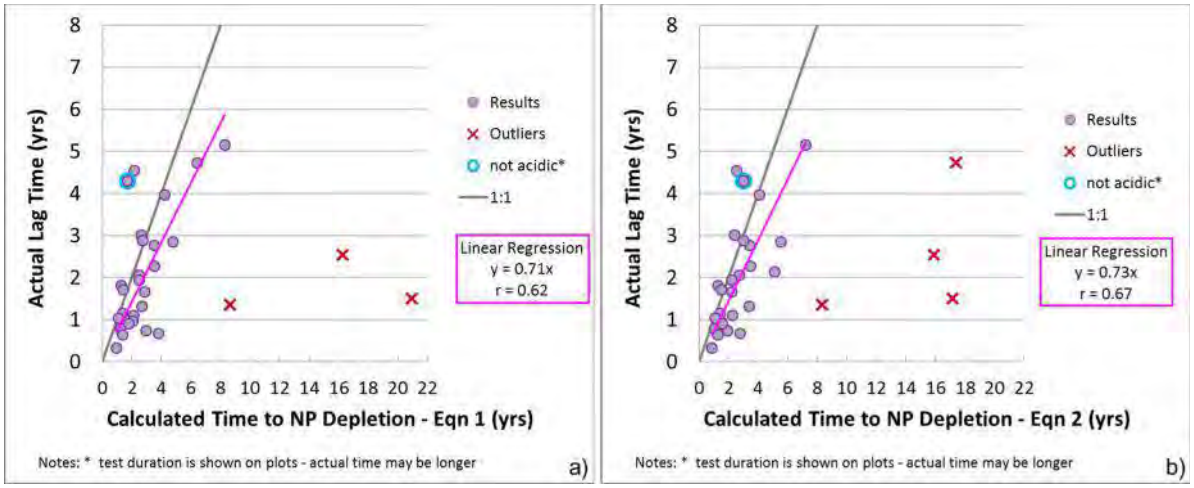

Figure 4 Comparison of actual versus calculated lag times a) using NP release rates (equation 1), b) using SO4 release rates (equation 2).

To assess the potential effects of other variables, the difference between actual and predicted lag times (equation 3) was calculated, and these residuals were plotted against other variables, including the rate of acidification, the difference between NP and TIC, (Ca+Mg)/SO4 release rates, sulphur content and sulphate production rates. The results are summarized as follows:

- The rate of pH change showed the strongest secondary relationship explaining 25% of the remaining variance (r^2 = 0.25) (Figure 5a). Samples that exhibited more gradual (slow) acidification tended to show longer than expected lag times, while samples that exhibited faster acidification tended to show shorter than expected lag times. This may be explained in part by the choice of pH used to define lag time in this study. If a higher pH threshold had been selected, actual lag times would be much shorter in the samples with slow pH changes, and essentially unchanged for the samples with more rapid pH changes.
- Samples with large differences between NP and TIC also tended to show longer than expected lag times (Figure 5b). However, this is based on only two samples with large differences between NP and TIC, and may not be statistically significant. In these samples, the TIC may have been contributing some buffering capacity not accounted for by the NP titration, or the discrepancy could indicate that the NP was underestimated.
- There was essentially no relationship between the residuals and ratios of (Ca+Mg)/SO4, total sulphur content or sulphate production rates.

A more qualitative approach was used to evaluate potential relationships with mineralogy, specifically the presence of calcium magnesium carbonates, iron carbonates, and calcium magnesium silicate minerals. Samples with relatively low carbonate, but with favorable silicate minerals tended to have longer than expected lag times, and samples with iron carbonates tended to have longer than expected lag times. However there were several exceptions and no clear patterns were evident. We also note that samples with shorter than expected lag times had NP measurements that were inconsistent with mineralogy or TIC, suggesting that the differences could have been due to analytical variability. Given that this dataset tended to have such low NP, it is not surprising that variability in lab measurement could be an important factor.

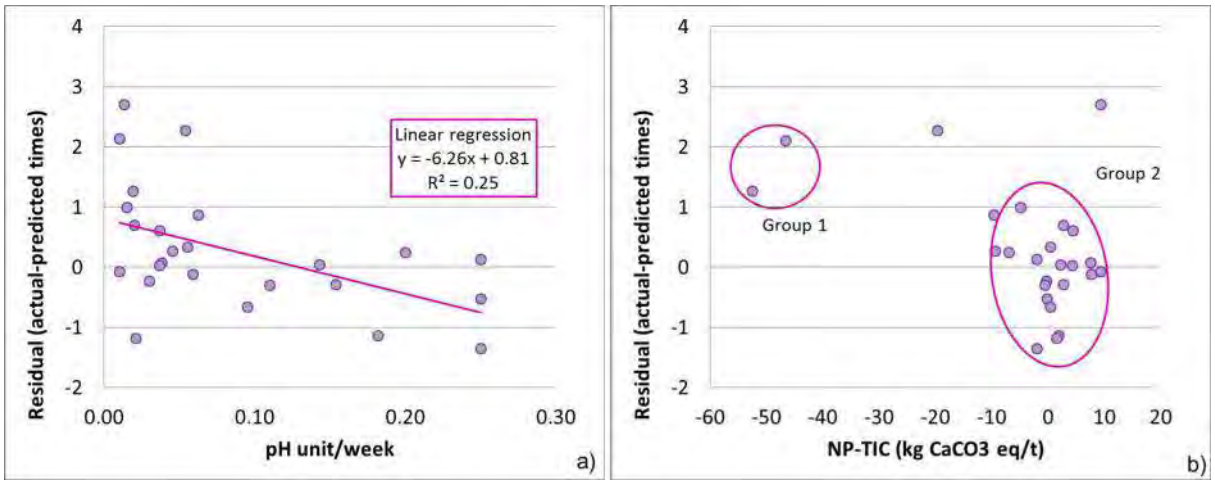

Figure 5 Relationships between residuals and a) rate of pH change and b) NP minus TIC

Outliers

Both calculation methods resulted in a small number of samples with calculated lag times that were substantially longer than the lag times actually observed in those tests. The calculated lag times based on equation 1 produced three outliers, while the calculated lag times based on equation 2 produced four outliers. The outliers were all from different sites. The outliers were closely examined to determine whether there were any unique features that could explain the large discrepancies between calculated and actual lag times, however, none were identified. Although it is believed that these differences could be due to inaccuracies in the quantification of available NP, they do suggest that calculations of lag time can lead to erroneous results. This finding emphasizes the importance of considering a range of samples in the determination of lag time, conducting quantitative mineralogy to provide independent verification of chemical determinations and having thorough QA measures in place to validate analytical results through duplicates and re-checks.

CONCLUSIONS

Data were compiled from a number of long term humidity cell tests to explore the relationship between actual versus calculated lag times. These number of tests in which lag time can be measured is rare and represents a relatively small portion of the total number of tests that were reviewed (30 out of 229 tests). The vast majority of samples that showed a distinct lag time prior to onset of acidic conditions had very low NP and relatively high sulphide concentrations. Key findings of this study are as follows:

- Calculated lag times were typically longer than actual lag times, but were significantly correlated ($r = 0.67$).
- Estimates of lag time can be improved by selecting the most appropriate NP (usually the lesser of TIC or NP), and by applying correction factors to account for availability/reactivity. These may be further improved by considering limitations on the physical availability.

- Tests with the longer than expected lag times showed a relatively gradual change in pH.
- The results emphasize the value of running some tests for an extended period of time either to determine actual lag times or to demonstrate that there is a prolonged period of neutral pH conditions in cases where the lag times are expected to last for an impractically long time.

It is emphasized that these conclusions may not be appropriate for samples with higher NP and/or lower sulphide content. However, there is insufficient data on lag times for those types of samples due to the long times required to measure onset of acidic conditions. Estimation of lag times in the field present further challenges and should be verified through appropriate monitoring programs.

ACKNOWLEDGEMENTS

Data used in this study was from a number of geochemical characterization programs that were completed by SRK in support of mining or mine development projects. We would like to acknowledge and thank the many companies that funded these programs and allowed us to use the data. Additionally, we are grateful for the support provided by our colleagues at SRK that helped to prepare the sample inventory and identify candidate tests for this work.

NOMENCLATURE

AP	acid potential
ARD	acid rock drainage
NP	neutralization potential
NP*	available neutralization potential
TIC	total inorganic carbon (a measure of carbonate content)

ABSTRACT

Data from humidity cell tests (HCTs) are often used during mine development to design appropriate rock management plans and engineered systems, and can provide critical source terms in the predictive modelling of mine-impacted water quality. Information on reproducibility and repeatability of HCTs, in general, can be useful in providing a basis of reference during both the design of the HCT programs, and in the review of the quality of data used for making decisions, or forming inputs to the predictive models. Lapakko and White (2013) conducted repeatability and reproducibility analyses of duplicate HCTs on several rock types, including gabbro from the Duluth Complex with sulfur content ranging from 0.56% to 1.39%. An ongoing geochemical characterization program for a project in development to mine Duluth Complex rock presents an opportunity to augment this previous study with additional data from HCTs. As part of a characterization program, seven duplicate humidity cell tests (representing 14 individual tests) were conducted on Duluth Complex rock with total sulfur content from 0.04% to 3.79%, following the ASTM standard method D 5744-96 (Reapproved 2001) (ASTM, 2001). Results from this study indicate that for duplicate HCTs, maximum difference from the mean for pH varies between 0.05 and 0.18 units, while average difference from the mean for constituent release rates for sulfate, calcium, and magnesium were mostly within 15%. Variability in release rates for copper and nickel were greater, with average difference from the mean ranging from approximately 15-29%.

Keywords: Humidity cell tests (HCT), repeatability, precision, Duluth Complex

INTRODUCTION

Data from humidity cell tests (HCTs) are routinely used to estimate the rates by which constituents will be released during subaerial weathering of waste rock. These estimates may then be used as inputs to predictive geochemical models that serve as the technical bases for making decisions related to environmental assessment, mine design, and financing for mining projects. The U.S. Environmental Protection Agency Guidance for Quality Assurance Project Plans (USEPA, 2012), a guidance on quality assurance for environmental data, including data produced from models, recommends that a systematic planning process is used to establish criteria for the "Data Quality Indicators" (DQIs) that are consistent with the overall "Data Quality Objectives" (DQOs) for the project. DQIs for environmental data include properties such as precision, bias, representativeness, completeness, and sensitivity. Following from the above, characterizing the precision of HCTs may be a key component in evaluating whether geochemical model outcomes meet the DQOs for the overall project. In addition, knowledge of the precision of HCTs is required to assess representativeness and accuracy of the dataset. For the purpose of this paper, precision is defined as "an evaluation of agreement among replicate measurements of the same property under similar conditions; also referred to as random error or measured variability" (USEPA, 2012) whereas accuracy is defined as "a measure of the closeness of an individual measurement to a known or reference value" (USEPA, 2012) and is measured through both precision and bias. There is currently a limited amount of published data on repeatability and reproducibility of HCTs, factors that are used to quantify the overall precision. The current study aims to augment this existing body of information by opportunistic evaluation of the HCTs conducted for the quality assurance/quality control component of the ongoing geochemical chemical characterization program for a potential future mining project located in Duluth, north-eastern Minnesota.

Lapakko and White (2013) conducted repeatability and reproducibility analyses of duplicate HCTs on several rock types, including Duluth Complex gabbro (sulfur content ranging from 0.56% to 1.39%). The results of this study were used as a basis for the precision parameters in the present ASTM standard (method D 5744-96). Consistent with ASTM protocols (ASTM, 2011), repeatability refers to precision under conditions where the same test is performed by the same operator in the same lab within short periods of time, whereas reproducibility reflects precision when the test is performed by different operators at different labs. The majority of the repeatability HCTs analyzed by Lapakko and White (2013) were conducted over 59 weeks with a few extending up to 265 weeks. Comparisons were based on pH and release rates for sulfate, calcium, and magnesium. The maximum difference of the mean was used to compare drainage pH values whereas the percent difference from the mean was used for sulfate, calcium, and magnesium rate comparisons. The equations for both values are listed below:

(1) Maximum Difference of the Mean pH = maximum value for $|pH - pH_{ave}|$ where $pH_{ave} = -\log[(10^{-pH_1} + 10^{-pH_2})/2]$

(2) Percent Difference from the Mean = $100 * |rate - rate_{ave}|/rate_{ave}$

The percent difference from the mean was calculated for each individual rinse cycle and the mean and standard deviation of the percent difference was reported.

ASTM method D5744-96 includes two protocol options (Options A and B). Option A involves weekly cycles of three days of dry air followed by three days of water-saturated air pumped through the sample, with a water leach on the last day. Alternatively, Option B has six days of

controlled and constant temperature and humidity and oxygen is supplied via diffusion (and possibly advection), not pumping, followed by a water leach occurring on the last day (ASTM, 2011). Lapakko and White (2013) evaluated both of these options. For Option A, both leaching alternatives were evaluated (drip and flood) for repeatability and reproducibility analyses whereas for Option B the drip and flood leach alternatives were only evaluated for the repeatability analysis (Lapakko and White, 2013).

Lapakko and White (2013) found that for the Option A drip alternative gabbro samples, repeatability of each laboratory was satisfactory. Two-thirds of the duplicate samples had a pH within 0.10 units of the mean. Similarly, sulfate, calcium, and magnesium rates were within 10% of the mean for over three-quarters of the samples. Deviations from the mean increased the longer the HCT was conducted. Reproducibility of the drip alternative for Option A were similar to that of the repeatability analysis during the first 125 weeks and as the length of testing increased, the percent difference from the mean increased as well. The increases were ultimately attributed to elevated temperature of the reaction environment resulting in an increase in sulfate release and lower drainage pH. Seasonal temperature changes resulted in differences in sulfate rates, most notably with increased rates in the summer months; increased oxidation rates also resulted in a lower pH. Similar trends were observed in the Option A flood alternative samples, as well as slightly lower pH values. One gabbro sample was run using each Option B method (drip and flood); initial results were similar between the leach alternatives and did not deviate with increasing time, presumably resultant to the stable temperature reaction environment (Lapakko and White, 2013).

The HCTs evaluated for the present study also contain rock from the Duluth Complex which enabled a direct comparison to Lapakko and White (2013). However, an expanded range in sulfur content was considered (duplicate HCT's use samples with sulfur content of 0.04-3.79%).

METHODOLOGY

An ongoing geochemical characterization program for a project in development to mine Duluth Complex rock presents an opportunity to augment this previous study with additional data from humidity cell tests on similar rock. This program was designed in cooperation with the Minnesota Department of Natural Resources Lands and Minerals Division and included seven duplicate HCTs (fourteen total) conducted on samples with a sulfur content ranging from 0.04% to 3.79% (Table 1) for 198 weeks. All humidity cells were analyzed by a single laboratory, allowing for the evaluation of the repeatability of the data only. Lithological designations for the Duluth Complex rocks are based on modal percentages of plagioclase, olivine, and pyroxene minerals present, using the classification scheme created by Phinney (1972). Humidity cell tests used in this study were conducted in accordance with ASTM standard method D 5744-96, Option A, flood leach. Sulfur content was determined using a LECO furnace. Aqueous metal concentrations were analyzed using ICP-MS and ICP-OES (alternating) bi-weekly. The ICP-OES was conducted to evaluate trends in major elements and provided trace metal concentrations, but at higher detection limits than the ICP-MS. pH was collected weekly. Results were recorded as mg/L and all non-detect data were recorded at the detection limit. For the purpose of this paper, only calcium, copper, magnesium, nickel, sulfate, and pH were evaluated.

Table 1 Duplicate HCT details

Sulfur Content	Lithology
0.04%	Anorthositic
0.04%	Troctolitic
0.06%	Ultramafic
0.09%	Anorthositic
0.25%	Troctolitic
1.68%	Troctolitic
3.79%	Virginia/Graywacke

Repeatability of the HCT samples is evaluated in a manner consistent with Lapakko and White (2013), as follows:

- pH: the difference from the mean (negative logarithm of the average hydrogen ion concentration) is determined by calculating an average pH between the duplicate HCTs (or group of non-duplicate, similar sulfur HCTs) for each weekly test cycle and the difference between the pH of individual HCT and the average. The maximum and average difference from the mean were determined and reported for each duplicate and similar sulfur content, non-duplicate groups.
- Release rates: the percent difference from the mean is determined by first converting concentration of ions to a release rate (µmol/kg/wk). Then, an average release rate is calculated for each test cycle and the difference between individual HCT analyses and the cycle average is calculated. The average of these differences for each test cycle is expressed as a percentage of the mean release rate for each cycle ("the percent difference from the mean"). The average percent difference from the mean is reported here for each duplicate set and similar sulfur content, non-duplicate groups.

The method of calculation conducted by Lapakko and White (2013) assumes a normal distribution. Additional analyses were conducted on sulfate and pH to determine to actual distribution as well as the upper confidence limit (UCL) of the mean concentration based on that distribution. The statistical software program ProUCL 5.1.00 was used to determine the data distribution and UCL mean concentrations (Singh et al., 2013). The non-detect values are easily identifiable in ProUCL and are input at the detection limit.

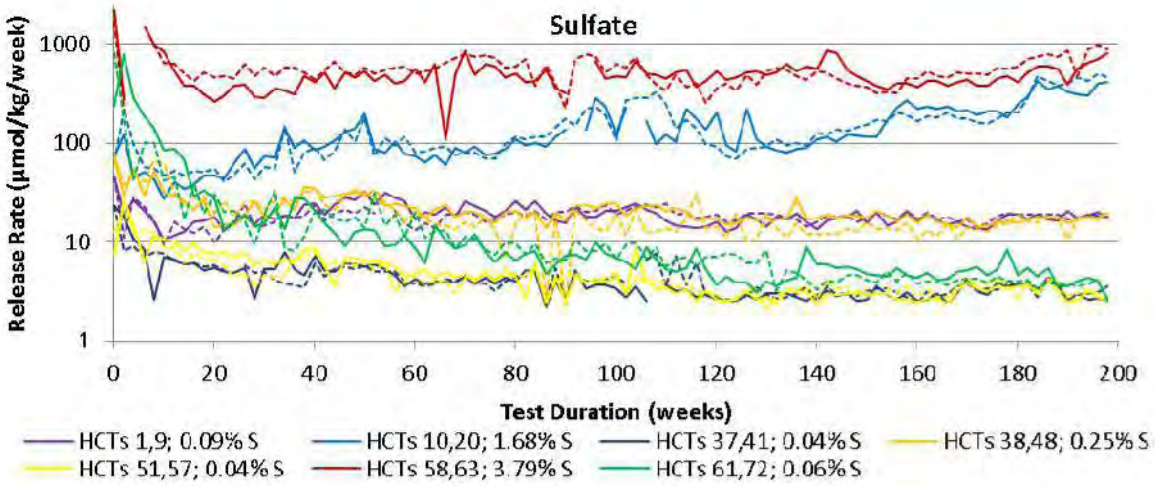
RESULTS AND DISCUSSION

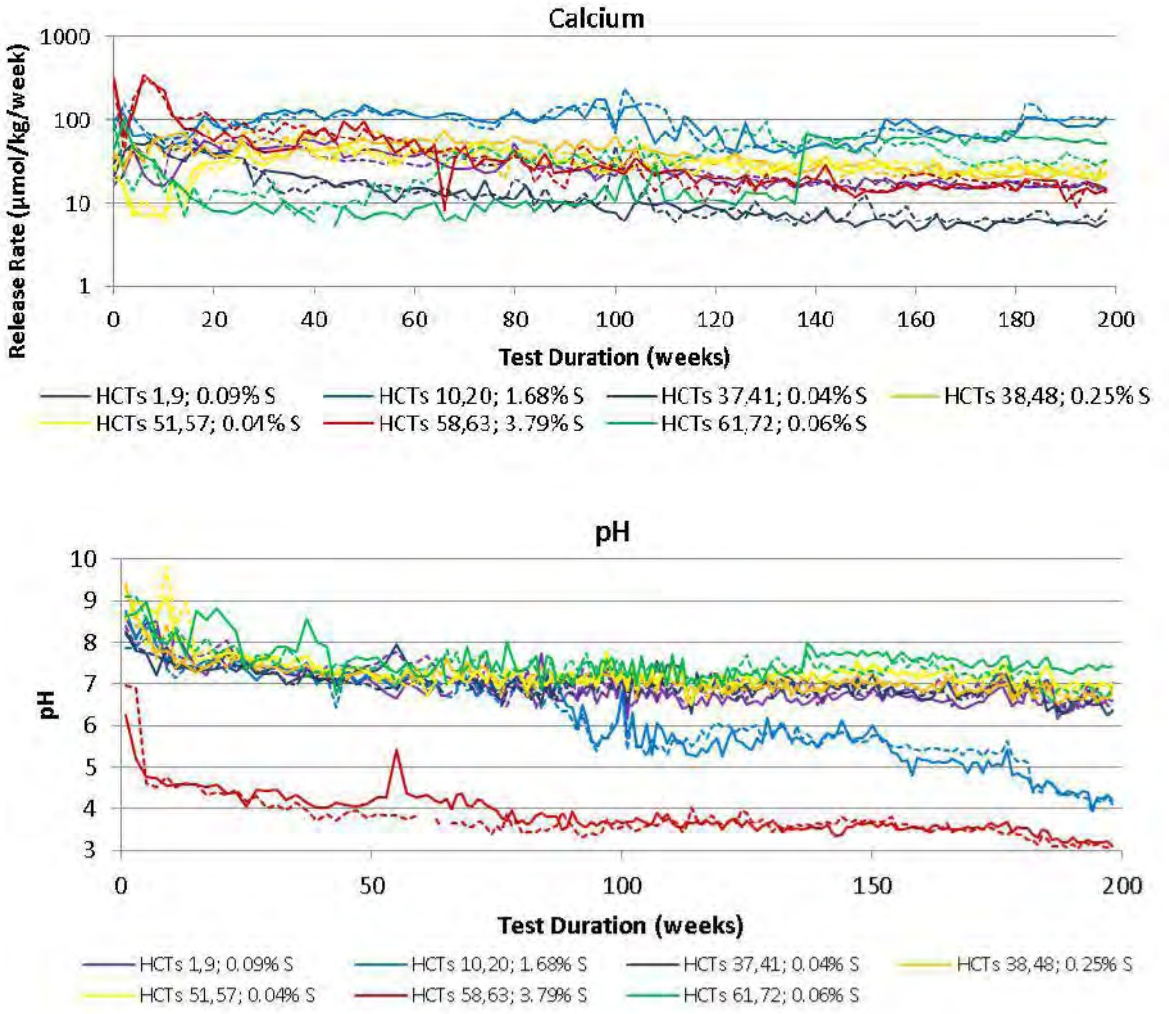
Results of the repeatability analysis of the duplicate HCTs are shown in Table 2. For sulfate, calcium, and magnesium, the average percent difference from the mean for release rates was less than 15%, except for the duplicate samples run on ultramafic material. For pH, the maximum difference from the mean was found to be between 0.05 and 0.18. These results are slightly higher, yet consistent, with findings reported in Lapakko and White (2013) Duplicate HCTs with less than 0.10% S are closer to the findings of Lapakko and White (2013) than those with more than 0.25% S, except in the case of ultramafic samples. Figures 1-3 portray the time sequence of release rates for duplicate HCTs for sulfate, calcium (trends for magnesium release rates are similar to calcium) and

pH. For individual pairs of duplicate HCTs, there are no obvious trends in the difference from the mean, either in terms of test duration (i.e., the difference from the mean did not consistently increase or decrease as the HCT progressed) or relationship to the analytical detection limit (analyses closer to the detection limit did not show consistently greater differences than those far away).

Table 2 Repeatability of duplicate HCTs: maximum difference from the mean (pH) and average percent difference from the mean (SO_4, Ca, Mg release rates)

HCT IDs	Sulfur Content	Lithology	pH	SO4	Ca	Mg
37, 41	0.04%	Anorthositic	0.12	7.9%	11.2%	10.0%
51, 57	0.04%	Troctolitic	0.05	8.7%	8.9%	9.6%
61, 72	0.06%	Ultramafic	0.18	17.1%	35.0%	34.1%
1, 9	0.09%	Anorthositic	0.17	7.5%	8.7%	8.3%
38, 48	0.25%	Troctolitic	0.08	13.4%	12.6%	8.4%
10, 20	1.68%	Troctolitic	0.12	12.1%	8.9%	9.2%
58, 63	3.79%	Graywacke	0.12	12.8%	12.3%	14.0%





Figures 1-3 Sulfate and calcium release rates and pH for duplicate HCTs (shown by solid and dashed lines of the same color) throughout the 198 weeks of testing

Two different analytical methods, ICP-OES and ICP-MS, were used to measure constituent concentrations in HCT rinseate. The ICP-OES analyses, with detection limits up to two order of magnitude greater than the ICP-MS, were often dominated by analyses less than the detection limit for copper and nickel; therefore, only the ICP-MS data were used in the evaluation of copper and nickel repeatability. Repeatability of copper and nickel release rates using ICP-MS data are shown below in Table 3. The average percent difference from the means for all duplicate pairs are approximately 15% or greater for both copper and nickel release rates. For the duplicate HCTs, there does not appear to be a direct relationship between percent difference from the mean and closeness to the analytical detection limit. While repeatability was weaker for these trace metals than the major ions, trends in metal release was the same for duplicate pairs and distinctive differences between tests were maintained.

Table 3 Duplicate HCT repeatability analysis results: average percent difference from the mean for copper and nickel release rates

HCT IDs	Sulphur Content	Lithology	Cu	Ni
37, 41	0.04%	Anorthositic	22.2%	14.7%
51, 57	0.04%	Troctolitic	22.6%	16.3%
61, 72	0.06%	Ultramafic	26.2%	25.1%
1, 9	0.09%	Anorthositic	18.2%	18.2%
38, 48	0.25%	Troctolitic	21.2%	18.7%
10, 20	1.68%	Troctolitic	17.5%	21.5%
58, 63	3.79%	Virginia/Graywacke	29.4%	16.8%

The distribution of sulfate release rates and pH values for the duplicate humidity cells were conducted on results after the first 52 weeks of study using ProUCL. Significant variability occurred within the first 52 weeks and may not be indicative of long-term conditions encountered. Additionally, as previously mentioned, the Lapakko and White (2013) study based their analysis on the data being normally distributed, however, further analysis indicated that only 36% and 57% of the humidity cells sulfate release rates and pH values, respectively, were characterized as being normally distributed. The 95% UCL of the mean for each humidity cell was determined based on distribution criteria outlined in Singh et al. (2013).

Table 4 Repeatability of duplicate HCTs based on statistically determined distribution: maximum difference from the mean (pH) and average percent difference from the mean (SO_4 release rates)

HCT IDs	Sulfur Content	Lithology	pH		Sulfate	
			95% UCL	Max. Diff.	95% UCL	Ave. Percent Diff.
37	0.04%	Anorthositic	6.9	0.06	3.9	5.7%
41			7.0		3.5	
51	0.04%	Troctolitic	7.2	0.01	3.8	0.7%
57			7.2		3.8	
61	0.06%	Ultramafic	7.3	0.07	7.5	6.3%
72			7.5		6.6	
1	0.09%	Anorthositic	7.0	0.13	19.0	0.8%
9			6.7		19.3	
38	0.25%	Troctolitic	7.0	0.01	19.4	10.1%
48			7.0		15.8	
10	1.68%	Troctolitic	5.9	0.01	200.8	4.1%
20			5.8		217.8	
58	3.79%	Graywacke	3.6	0.07	582.9	4.8%
63			3.7		529.8	

The recalculated maximum difference from the mean pH value was approximately one-half of those assuming normal distribution for all the samples. Similarly, the recalculated average percent difference from the mean sulfate release rates were 2 to 10% lower than those previously determined. Therefore, it is possible that with more rigorous statistical analyses, with particular attention on the distribution of the data as well as long-term stability of the dataset, the repeatability of the HCT improves.

CONCLUSION

Humidity cell test data is key input for predictive modelling of the quality of mine-impacted water. Understanding the repeatability of that data is necessary for accessing the quality of data being used for these models. Results from this study indicate that for duplicate HCTs, pH varies between 0.05 and 0.18 units from the mean, while constituent release rates for sulfate, calcium, and magnesium were within 15% of the mean, except for the ultramafic duplicate samples. This is consistent, although slightly higher, than precision parameters published in the ASTM method. Duplicate HCTs with less than 0.10% S are more consistent with the findings of Lapakko and White (2013) than those with more than 0.25% S, except in the case of ultramafic samples. The average difference from the mean for copper and nickel was greater than that of the major ions. Trends were not observed between either test duration or closeness to the detection limit and precision. Statistical analyses of the distribution of pH and sulfate release rates for data collected after the first 52 weeks of testing resulted in lower differences from the mean and therefore increased apparent repeatability of the humidity cell testing.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge permission from the mining company to publish these results. Interpretation of the test work results have benefitted from numerous discussions with individuals at both MDNR-LAM and the company. The authors would also like to acknowledge the contribution of two anonymous reviewers whose comments resulted in a much improved manuscript.

ABSTRACT

For operations and closure planning, understanding lag times to the potential development of acidic conditions is critical for management of a tailing storage facility (TSF). While this is important for many mines, for the site presented herein (and similar projects) the climatic and hydraulic conditions expected for TSFs in the extreme arid climate of the Atacama Desert present specific challenges for prediction of lag times to acidic conditions and subsequent metals leaching.

Long term humidity cell testing (up to 151 total cycles) was undertaken for several fractions of pilot plant tailings for a copper porphyry deposit. Modified humidity cell tests were also utilized with weekly cycles of humid and dry air and rinses every 20 cycles. The delayed rinse cells were used to provide insight for conditions where wetting of tailings will occur very infrequently following deposition.

Tailings evaluated had total sulfur contents near 1.0% and low neutralization potential. While predicted to be acid generating by static testing, extended lag times were observed. Long term humidity cell testing indicated a lag time of 40 cycles to significant acid generation and a slow process of acidification (reaching stable final pH values near 2.5 took almost 115 cycles). Metals leaching, as expected, increased with acidic conditions. The delayed rinse cells indicated longer lag times to acidification and reduced loading rates for key metals.

Evaluation of the potential development and timing of onset of acidic conditions in the TSF considered the results of the long-term and delayed-rinse testing, pre- and post-testing mineralogy, as well as the hydraulic conditions expected in the TSF under the extreme climate conditions. These include: high evaporation rates, salt migration, and hardpan formation. This paper describes the test work, results, and how the results were used to guide design efforts for both operations and closure planning.

Keywords: Closure planning, arid climate, humidity cell lag time, prediction

INTRODUCTION

While mine wastes may be predicted to be potentially acid generating (PAG), the lag time to the generation of acidic conditions in the field has important implications for mine and closure planning. The lag time may dictate how the material may be handled, stored, or treated prior to acidification. Understanding lag times, and the factors that affect them, is critical in order to effectively design, operate, and prepare for closure of a mine. There are a number of factors that may affect a lag time, including geochemical factors (such as sulfide content, sulfide mineral availability and morphology, secondary mineral coating, available neutralization potential) and physical factors (such as exposure time, grain size and surface area, and moisture content).

Understanding the timing to the onset of acidic conditions is important for facility design, operation, and closure because once acidic conditions are initiated they can persist over the long term. Acidic conditions may require a spectrum of water management practices, water treatment needs, or mitigation strategies, all of which may also evolve with time from operations to closure. For tailings storage facilities (TSFs), these measures may include: seepage capture systems, water treatment facilities, water management for run-on and runoff, amendments, and closure covers. Implementation of these strategies is generally more costly and difficult to perform without preparation or in a retroactive fashion; therefore, it is important to understand these needs as early as possible in the design of a TSF (INAP 2009).

For tailings, the overall dynamics for acid generation are generally well understood. Highest oxidation generally occurs shortly after tailings deposition ends (Blowes et al. 2003). Oxidation rates are generally the highest at the initiation of oxidation and the majority of acid generation occurs during the early stages of acid generation (e.g., MEND 1997). Oxidation occurs at the surface of the TSF and an oxidation front typically progresses downward from the TSF surface. This process results in a profile that includes an upper oxidized zone where sulfides have oxidized, an oxidation zone, where oxidation is occurring, and an un-oxidized layer underneath (e.g., Blowes et al. 2003). The location of an actual acidic front within this profile is dependent on the infiltration rates and the balance of acid generation versus neutralization potential. The acidic front will either remain within the upper zones of the profile or be carried downward by infiltration and, if it overwhelms the neutralization potential below, acidic seepage can result.

The depth and development of the oxidation profile and acidic front is dependent on a range of factors, such as the tailings' acid-base characteristics, saturation state, oxygen diffusion, and age of the facility. Saturation state of the tailings is considered a key parameter for tailings facilities, as higher saturation will restrict oxygen entry, limit oxidation, and subsequently control the development and location of acidic conditions.

In the Atacama Desert, the saturation state of the tailings is an important parameter for consideration of the generation of acidic conditions. The Atacama Desert is one of the driest places in the world with annual average precipitation under 15 millimeters (mm) for an average year and on the order of 100 millimeters per year for a 100 year return period. Coupled with this, evaporation is high, with an annual average evaporation near 2500 mm per year. In addition, precipitation is infrequent with many successive years registering zero precipitation. When precipitation does occur it is typically concentrated in one larger event. The extreme arid climate will affect geochemical and hydraulic factors of the oxidation profile and warrant consideration in the design, management, and closure planning for TSFs in arid climates.

As a part of permitting and design of a TSF in the Atacama Desert for development of a copper porphyry deposit, a kinetic testing program was undertaken for several fractions of pilot plant tailings. The kinetic testing program included long-term (up to 151 cycles) humidity cells and modified humidity cells with extended time between rinse cycles. The objective of the modified humidity cells was to evaluate the lag time under dry conditions with infrequent wetting and rinsing, as found at the climate of the site. The testing program was designed to meet both permitting requirements and informational needs to provide inputs to engineering design, operations planning, and closure planning activities.

METHODOLOGY

Three tailings samples were included in the kinetic testing program, including whole tailings, underflow tailings, and overflow tailings. The whole tailings sample represents materials from a process plant mill that will then be cycloned to produce the overflow (two stages, combined for this sample) and underflow materials. The underflow sample represents the sands that will be used to build the dam for the TSF. A combination of whole tailings and overflow tailings are planned to be placed in the TSF. All tailings samples were produced by a metallurgical pilot plant.

A standard and complete static testing program (e.g., INAP 2009, MEND 2009) was performed on all tailings samples, including acid base accounting (ABA), mineralogy by x-ray diffraction (XRD) with Rietveld refinement, elemental content, grain-size distribution, net acid generation testing (NAG), and short term leach testing. Pertinent ABA and mineralogy results are provided in Tables 1 and 2, respectively. All tailings have moderate amounts of sulfur (0.78 to 1.1 wt. %) and are estimated to be potentially acid generating (PAG) from the results of both ABA and NAG testing (using criteria presented in INAP (2009) and MEND (2009)). These results are confirmed by the mineralogical testing that indicates moderate pyrite content (between 1.3 and 2.0 %) and limited minerals with neutralization potential.

Kinetic testing was performed utilizing two types of humidity cells. The first was based on the standard humidity cell test (ASTM D5744-07), utilizing standard cycles of humid air and dry air during a week, followed by a week-end leach. However, these humidity cells were run for extended periods, including 60, 130, and 151 cycles for the overflow, underflow, and whole tailings samples, respectively.

The second test was a modified humidity cell, referred to herein as a delayed humidity cell. In this test, the standard procedure was modified so that that leach cycle was performed every 20 cycles rather than weekly. The weekly dry and wet air cycles were still performed. Delayed humidity cells were performed for two samples, the whole tailings and the underflow tailings. Delayed humidity cells were run for 80 cycles and were leached 4 times during the testing period.

At the termination of the humidity cell tests, splits from the humidity cells were tested for post-testing ABA and mineralogy (Tables 1 and 2, respectively). Post-testing ABA results indicate a depletion of sulfides and neutralization potential during kinetic testing. Post-testing mineralogical results indicate depletion of sulfides and the presence of reaction products such as jarosite and gibbsite, as expected. This is also consistent with post-testing ABA results as well. An increase in carbonates (calcite and ankerite) was detected in the post-testing XRD analysis, inconsistent with both the expected depletion and the ABA results; this result is considered likely due to heterogeneous materials.

Table 1 ABA results

Parameter	Units	Whole		Overflow		Underflow

RESULTS OF THE KINETIC TESTING PROGRAM

Results for the leachate pH values with time for all kinetic test types are shown in Figure 1a. Concentrations of sulfate are shown on Figure 1b and concentrations of copper are shown on Figure 1c. The humidity cell leachates initially have near neutral pH values for all tests and a typical first flush of elevated sulfate concentrations and metals is observed. Following the first flush, an extended lag time to acidic conditions is observed for all tailings samples under the test conditions, during which pH values remain above 7 and sulfate concentrations steadily decrease.

Following the lag period, sulfide oxidation and subsequent acid generation occurs. For the whole tailings sample in the standard humidity cell, increasing sulfate concentrations (indicating sulfide oxidation) and increasing calcium concentrations (indicating dissolution of calcite) are observed starting at cycle 35. The pH begins a steady decline following this in cycle 40. The pH continues to drop with subsequent cycles to cycle 116 when the pH stabilizes near a value of 2.5, which is maintained for the final 35 cycles of testing (151 cycles total). During the final acidic phase, calcium concentrations decrease (likely indicating depletion of carbonate) and a decrease in sulfate concentrations to between 300 and 450 mg/L occurs. Concentrations for metals are elevated, including: aluminum, barium, beryllium, cadmium, chromium, cobalt, copper, iron, lead, lithium, manganese, nickel, thallium, uranium, and zinc.

The lag time under testing conditions was greater for the cyclone fractions. The underflow fraction sample had the greatest lag time to initiation of sulfide oxidation and to initiation of acidic conditions (starting at approximately 83 cycles with a drop in leachate pH below 7 and an increase in sulfate concentrations). Additionally, the final stable pH for the underflow humidity cell test was higher, at a value near 5. For the overflow sample, sulfate concentrations followed a similar trend as the whole tailings sample, with increasing concentrations beginning near cycle 40 and an initiation of a decrease in pH beginning in cycle 58. Given similar behavior to the whole tailings, this test was terminated at this time.

For the delayed humidity cells, the lag time was not exhausted during the testing period. The pH values for the entire duration of testing were greater than 7. Additionally, a change in sulfate and overall metals mass loading was not generally observed in the leachate over time. Leachate sulfate and metals concentrations were generally elevated in the delayed humidity cell test relative to that of the standard test because removal of mass load from the cells only occurred every 20 cycles. Calculation of mass flux from the standard humidity cell compared to that of the delayed humidity cell at cycles 20, 40, 60, and 80 are presented for sulfate, copper, arsenic, and antimony on Figures 2a through 2d (results shown for whole tailings samples only).

DISCUSSION

The majority of the geochemical characterization data indicate that the tailings (whole and cycloned fractions) have potential to be acid generating under appropriate conditions, such as assuming the presence of sufficient moisture following desaturation of the tailings. With the onset of acid generation, pore water quality would be expected to have low pH values between 2.5 and 3 with elevated concentrations of sulfate and metals. For a copper porphyry deposit with sulfide tailings this is not an unexpected result. From a planning perspective for design, operations, and closure, the most pertinent results are those from the kinetic testing with respect to the lag time. A significant lag time is expected based on the results of the standard humidity cell test. The lag time was observed to vary between the different tailings fractions, with the shortest lag time for

initiation of acidic conditions observed for the whole tailings (40 cycles) and longest for the underflow (80 cycles). For this site, translation of laboratory lag times to the field is significant. One equivalent cycle under field conditions could take many years to occur as there can be successive years without precipitation or without precipitation sufficient to wet more than the surface of the tailings due to the high evaporation rate.

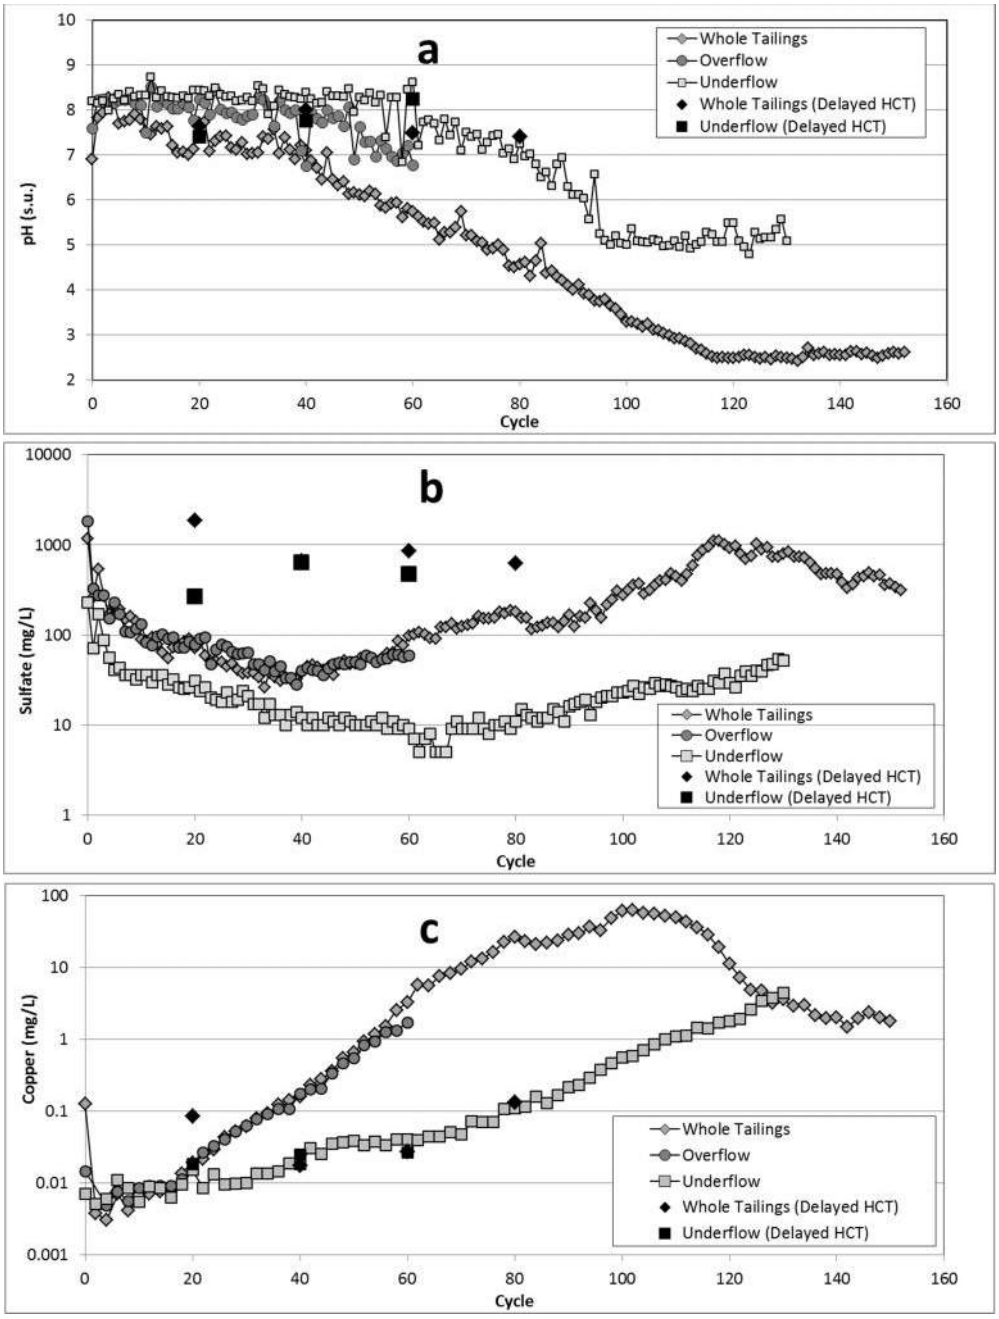

Figure 1 Leachate a) pH, b) sulphate and c) copper concentrations with time

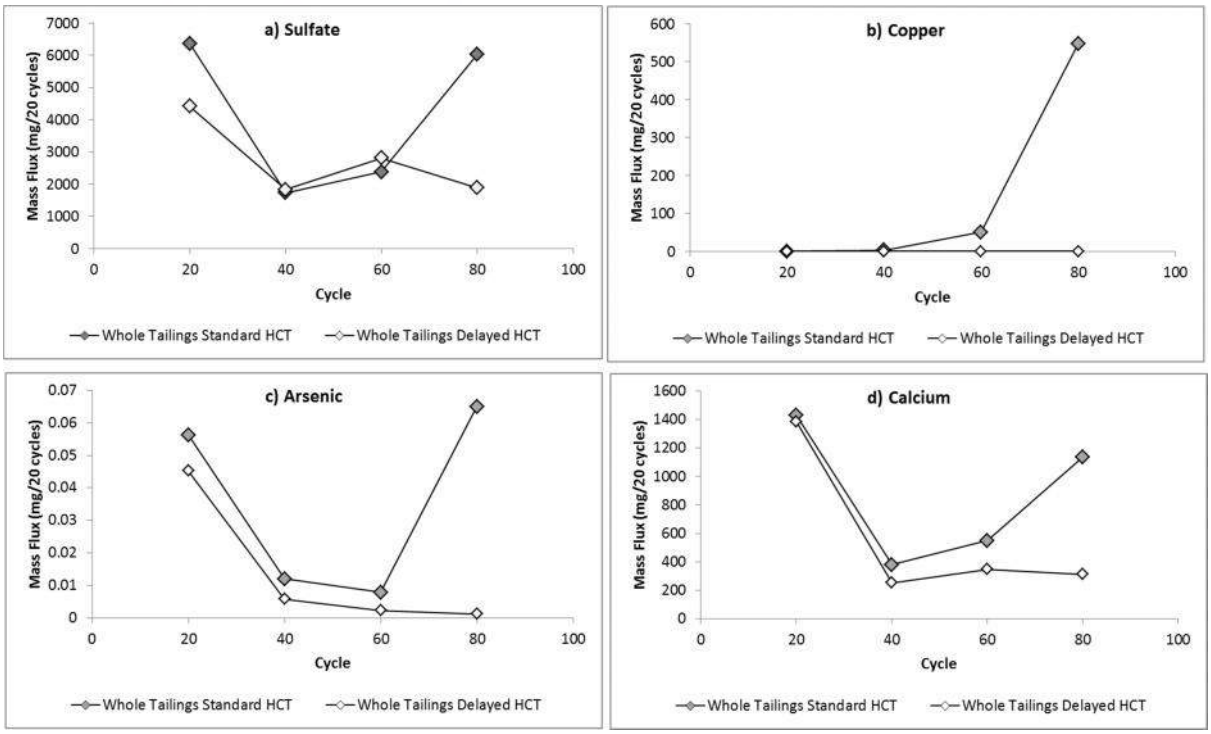

Figure 2 Mass flux from standard and delayed humidity cells over 20 cycles for: a) sulfate, b) copper, c) arsenic, and d) calcium

The results of the delayed humidity cells confirm the lag time and indicate that the lag time may be extended further with less frequent wetting as expected in drier conditions. The pH of the delayed humidity cells remained constant through testing (80 cycles) and no increase in sulfate or metals concentrations is observed. This indicates that initiation of sufficient oxidation to affected leachate water quality is postponed in the absence of weekly rinsing cycles.

Trends of mass flux from the standard humidity cells compared to that of the delayed humidity cells provide greater insight into the oxidation behavior. Mass flux for sulfate (Figure 2a) and most metals (similar to that of copper and arsenic, as shown on Figures 2b and 2c) are similar for the standard and delayed humidity cells for the first 40 cycles, indicating similar rates of oxidation and metals release up to this time. Following the initiation of sulfide oxidation just before 40 cycles in the standard humidity cells, a slight increase in cumulative loading is observed for the standard humidity cells, resulting in higher loading rates compared to the delayed humidity cells at 60 cycles. At 80 cycles, the pH values of the standard humidity cells have dropped below 5, sulfate and metals mass flux increases dramatically. In comparison, mass flux of metals and sulfate from the delayed humidity cells remains relatively constant between cycles 40 and 80.

The mass flux trends indicate that whole tailings in both the standard and delayed humidity cells had similar oxidation and metals release during the initial phases of the test (i.e., the first 40 cycles). Because the mass flux changes for the standard cells, but not the delayed humidity cells, this implies that the initiation of significant oxidation is delayed by less-frequent wetting and it is not a mechanism of neutralization that delays acid generation. Calcium mass flux (Figure 2d), which

would provide an indication of calcite dissolution, is also similar between the standard and delayed humidity cells until significant oxidation and acidic conditions are apparent in the standard cell.

The delay in the initiation of oxidation could be due to factors such as an initial surface coating of sulfide surfaces with secondary minerals that may form during initial processing (e.g., Jambor 1994; Thomas et al. 1998) or throughout the testing, sulfide mineral availability, initially available neutralizing minerals, or buffering capacity of initial process solutions. The limited flushing in the delayed humidity cell test may not sufficiently remove oxidation products from the pyrite surface, thereby further limiting initiation of significant oxidation (e.g., Blowes and Ptacek 1994, Jerz and Rimsdit 2004, Huminicki and Rimstidt 2009).

A second pertinent result from a TSF design and planning standpoint is that following initiation of sulfide oxidation and depletion of the neutralization potential, the development of fully acidic conditions was gradual under the test conditions. While terminal pH values were near 2.5 with elevated metals concentrations, it took greater than 75 cycles to reach these conditions after sulfide oxidation initiated between cycles 35 and 40 (based on the increasing sulfate concentrations at this time). Peak sulfide oxidation rates (based on sulfate release) are reached in cycle 116, as a pH of 2.5 is reached, and then sulfide oxidation rates decrease through the conclusion of the test at 151 cycles. The greatest sulfide oxidation rates are expected for tailings at the beginning of acidic conditions (e.g., MEND 1997). In this case, a similar result is observed, but only after fully acidic conditions were attained (i.e., at the start of consistent pH values near 2.5). While the neutralization potential of the tailings was expected to be limited based on initial ABA and XRD analyses, sufficient available neutralization potential from the tailings (and possibly process solutions) was available to slow the acidification process.

Implications for Design

The results of the geochemical testing program, while initially developed for permitting using standard characterization tests, were incorporated into the design and planning for the facility, considering both operations and closure. The design and planning process also considered the extreme arid climate, combined with its implications on the hydraulics of the TSF, in light of the geochemical characterization results. Additional hydraulic considerations included the high evaporation rates, salt migration, and hardpan formation which may also affect saturation state. All of these factors warrant consideration in the design, management, and closure planning for TSFs in the Atacama Desert, as well as site in other arid climates.

Operations

Given the extended lag time for the tailings and the saturation state of freshly deposited tailings, acidic conditions will not develop in the TSF during operations. Tailings will be deposited wet, in lifts by spigots. The upper portion of a lift will undergo drying; however, it will be re-wetted to a limited extent as it is subsequently covered by a fresh layer of tailings. However, due to the arid climate, limited rewetting is expected, with infiltration modeling indicated that infiltration and rewetting will be interrupted after 5 to 8 days by evaporation processes. The results of the delayed humidity cells indicate that the limited wetting and drying will further extend the already significant lag time to the initiation of significant oxidation (a minimum of 40 cycles based on the standard humidity cells) and development of full acidic conditions (a minimum of 116 cycles in the standard humidity cells). Furthermore, one cycle in the laboratory scaled to an equivalent wetting

and drying cycle in the field following cessation of deposition may represent many years at the site location due to the climate conditions.

The long lag time and slow development of fully acidic conditions with peak oxidation rates has other implications for TSF management. Given acidification either may not occur at all due to the climate or it will take a very long time to develop acidic conditions, monitoring of any seepage from the tailings facility will provide a long lead time to develop and implement mitigation measures.

From an oxidation potential perspective, underflow sands in the dam can be a concern due to their grain size and position in the dam that allows for drainage and lower moisture contents. Cycloning tailings can also result in concentration of sulfides in the underflow sands. However, in this case, the latter was not observed with similar sulfide contents in the whole and underflow tailings as measured by both ABA and XRD. Additionally, the grain-size distribution for underflow sands is generally larger, resulting in a lower specific reactive surface area. The lower specific surface area and similar sulfide content resulted in less reactive underflow tailings in this case. The underflow sands exhibited a longer lag time and the terminal pH values were relatively high (values near 5) with corresponding lower concentrations of sulfate and metals. As such, significant acid generation from the underflow sands is also not expected during operations.

Given these observations, the TSF design was focused on water conservation as water quality is not expected to be a concern. These factors, combined with the expected geochemistry of the tailings, indicate a very low risk of water quality impacts during operations.

Closure

Following closure, the upper tailings will be unsaturated, allowing oxidation and acidification. However, the significance of acidification will be limited due to several factors. The most important is that following cessation of operations and deposition of tailings, the climate conditions will not provide sufficient water to mobilize seepage through the facility. Secondly, as described, a delay to acidification is expected and the dry climate will limit wet and dry cycles and mobilization of acidity. The delayed humidity cells demonstrate that persistent dry conditions and lack of flushing will increase the lag time. A lack of mobilization of constituents from the oxidized zone may also limit oxidation as secondary products may blind off reactive surfaces. Finally, while a significant unsaturated zone at the surface of the TSF is expected due to the climate, formation of a hardpan is also expected by natural and secondary salts (e.g., Coggans et al. 1999) that may limit oxidation diffusion. Natural hardpans are currently present at the site due to the climate, providing an analog for expected future conditions, and hardpan formation was observed in geotechnical laboratory studies for the tailings. Given the above considerations, limited or no water management requirements are expected following closure of the TSF to be protective of the environment.

Pyrite Oxidation in Well-Constrained Humidity Cell Tests

Mark Williamson
Geochemical Solutions, USA

ABSTRACT

Owing to its significance in the formation of acid mine drainage, the rate of pyrite oxidation has received persistent attention for many years. The vast majority of experimental rate measurements have been made under saturated (liquid) conditions (no gas phase), and a few are available for the reaction in vapor-only (humid oxygenated air) conditions. However, in field settings, either naturally occurring or associated with mineral extraction activity, liquid+vapor conditions with moist air and water present are perhaps the most common.

As part of environmental permitting programs, the mineral industry has come to rely on empirical measurements of pyrite (and other sulfide mineral) reaction rates using the Humidity Cell Test (HCT). This laboratory test exposes crushed mine rock samples to liquid+vapor water in the presence of atmospheric oxygen, provided in excess. The HCT is a standardized test method that has been evaluated for reproducibility, but limited effort has been made to assess rates, specifically pyrite, relative to existing geochemical literature.

In the present work, a series of well-constrained HCT experiments have been and are being conducted using simple mineral assemblages, with known mineral grain sizes/reactive surface area. Tests have been conducted using pyrite + quartz and pyrite + quartz + calcite. Additional testing has been conducted using two separate pyrite grain sizes. Though difficult to constrain, the proportion of liquid to vapor water in the system has also been investigated by altering the established procedure to increase the vapor relative to liquid phase (vapor-enhanced).

Results to date indicate that the rate of pyrite oxidation slows with time. Initial rates are significantly faster than in liquid-only experiments (Williamson and Rimstidt, 1994), and diminish with time. Results were consistent with trends observed in vapor-only laboratory experiments. Terminal, near steady-state rates of pyrite oxidation approached the same value for all test conditions, and were consistent with well-stirred liquid-only initial rates. Thus, hypothetical retention of reaction products that might explain the both the reduction in rate and the similarity among tests seems improbably. Terminal rates showed no relationship to rate of water supply (flushing). Rates scaled directly with pyrite reactive surface area, but sulfate production (concentration) did not scale directly with grainsize.

Keywords: pyrite oxidation, HCT, kinetics

INTRODUCTION

Owing to its significance in the formation of acid mine drainage, the rate of pyrite oxidation has received persistent attention for many years. Understanding has grown from a characterization of oxygen, temperature, sulfide mineralogy and bacterial action as reaction drivers of pyrite oxidation (Caruccio, 1968) through development of quantitative rate expressions that identify the significance of reactive surface area of pyrite. Currently, rate expressions for pyrite oxidation have been developed for water-saturated conditions (Williamson and Rimstidt, 1994) and water vapor-only conditions (Williamson, 2013). However, in field settings, either naturally occurring or associated with mineral extraction activity, liquid+vapor water conditions are the most common.

As part of environmental permitting and mine waste management programs, the mineral industry has come to rely on empirical measurements of pyrite (and other sulfide mineral) reaction rates using the Humidity Cell Test (HCT). This laboratory test exposes prepared mine rock samples to liquid+vapor water in the presence of atmospheric oxygen, both provided in excess. Initially, the HCT was thought to be an accelerated weathering test, as it was thought that the procedure removed reaction products from the test cell that would otherwise impede reaction progress (Sobek, et al, 1978). The HCT is a standardized test method (ASTM, 2012) that has been evaluated for reproducibility, but limited effort has been made to assess reaction rates relative to existing geochemical literature.

Only a few studies have tried to quantify the rate of pyrite oxidation in a two-phase water system (liquid+vapor). Of these, only a limited number of studies have been conducted for which the reactive surface area of pyrite is known or estimated. Lappakko and Antonson (2006) report rates of pyrite oxidation present in Duluth Complex rock matrices determined in an HCT; Watzlaff and Hammack (1990) made measurements in a vertical column with continual air flow and a weekly leach; and Leon, et al (2004) present results of batch-style tests with limited amounts of liquid water present in an otherwise humid environment without forced airflow. Data from other two-phase studies are reported in the literature, but reactive surface area and/or grainsize is either unknown or beyond estimation.

The worldwide database of two-phase (presence of moist air plus liquid water) results is overwhelmingly for mine rock using the HCT. These materials often represent complex mineralogy and virtually never report reactive surface area for pyrite, although the test procedure itself does restrict the grain size of the material with which the cell is charged. Thus, it is impossible to reliably compare and contrast pyrite oxidation rates with fundamental geochemical understanding, or compare other tests on various mine rock samples. The purpose of the present study is to employ a simplifying approach to begin to study simple systems that will eventually lead to the defensible interpretation of specific reactions in humidity cell tests and support reliable predictive modeling.

METHODOLOGY

In the present work, a series of well-constrained HCT experiments have been conducted using simple mineral assemblages, with known mineral grain sizes/reactive surface area. Tests have been conducted using test cell charges comprised of pyrite (py) + quartz (qtz) and pyrite + quartz + calcite (cal). Testing has been conducted using two separate pyrite grain sizes. Though difficult to constrain or quantify, the effect proportion of liquid to vapor water in the system as well as rinsing has also been investigated by altering the established HCT procedure (ASTM, 2012) to increase the

vapor relative to liquid phase (vapor-enhanced).

Approach

In contrast to the inherently more complex situation when testing poly-mineralic materials (i.e. mine rock, tailings), with a restricted but wide range in grainsize (with unknown reactive surface area), and fixed rate of water supply, the present work has taken a decidedly reductionist approach. The study has utilized a simple mineralogic composition (pyrite, calcite and quartz) with restricted grainsize, known reactive surface area. Two distinct values of reactive surface area for pyrite were examined and the rate of water supply was varied by a factor of about two. Table 1 summarizes the four tests currently being conducted, and provides a statement of test objective for each. All tests were run at 22 ± 1.5 C.

Table 1 Summary of experimental conditions.

Test Cell ID	Cell Charge (gm)			Flushing Frequency	Test Objective
	Pyrite	*Calcite*	*Quartz***

* Grain size = 0.4 mm (0.297 mm < sample < 0.5 mm) = 70 m^2/gm (Foust et al., 1980)

** Grain size = 2.4 mm (2 mm < sample < 2.83 mm) = 19 m^2/gm

*** Grain size = 0.85 mm (0.85 mm < 93.6% < 1 mm sieve)

Materials

The pure pyrite (FeS_2) used in this study was sourced in Peru, and is the same material used by Williamson and Rimstidt (1994) and Jerz and Rimstidt (2004). The sieved pyrite was washed with alcohol to remove fine-grained material as much as possible. Pure calcite ($CaCO_3$) was obtained from Ward's Scientific (optically clear; variety Iceland Spar) and was sieved to collect the 0.5 mm fraction as described above for pyrite. Silica sand (SiO_2) was purchased commercially, sourced in Wedron, Illinois, with a reported assay of 99.7% SiO_2 and less than 0.01% calcite. Mineral mixtures were loaded carefully into the test cells to avoid any gravity separation effects.

RESULTS AND DISCUSSION

Analytical Results

Analytical results for test cells' leachate over time are presented in Figures 1 to 4. Figure 1 illustrates the mass of water retained by each cell following the leach cycle. Of particular note are the results for HCT-4, which was only rinsed bi-weekly, showing the cell essentially drying out between leaching. Other cells display a loss of entrained water, but clearly maintain the presence of liquid water (not dried out) and moist vapor during the experiment.

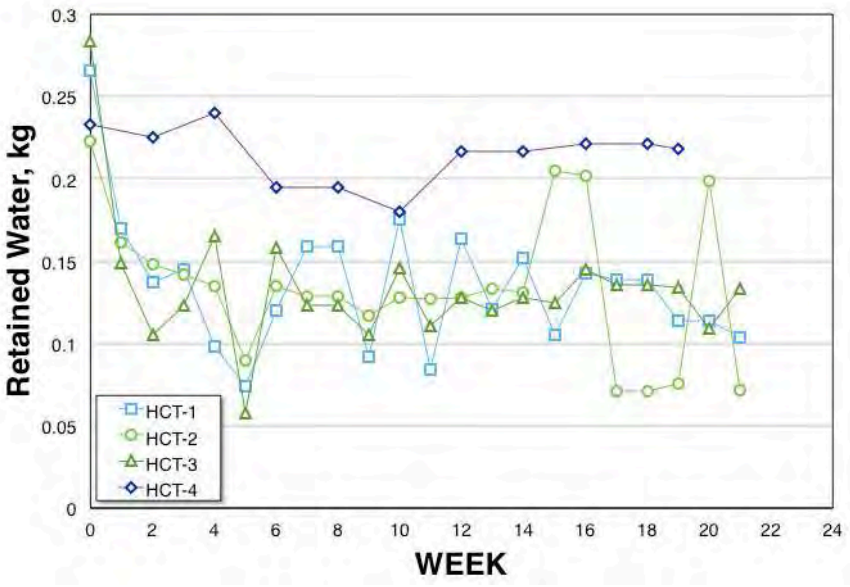

Figure 1 Cell water retention over time

Figure 2 is a graph of pH over time, and shows an expected decrease for two of three py+qtz cells. HCT-1 and HCT-4 (same pyrite grainsize, HCT-4 flushed bi-weekly) begin an immediate, but not instantaneous drop, reaching a value of 4 after 24 weeks. Oddly, HCT-3 (larger pyrite grainsize) remained generally steady for about 18 weeks, and then became more erratic, and trending toward lower values. As expected, the test containing calcite remained near neutral, but significantly below a value of about 8.2 that would be expected for qtz+cc without pyrite. The blank cell maintained a pH ranging from 5.7 to 6.3 throughout.

Figure 3 present results for sulfate, which shows an immediate and significant decrease over the first four weeks. All tests are generally steady after six weeks. Iron (Figure 4) shows an increase in tests where pH decreases. Sulfate and iron analyses for the blank cell produced were determined to be zero throughout.

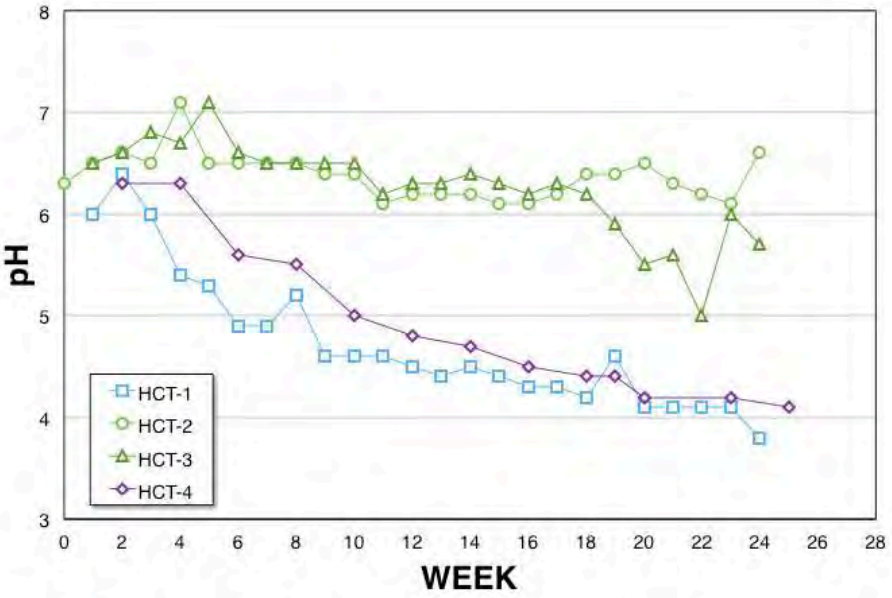

Figure 2 Leachate pH variation over time

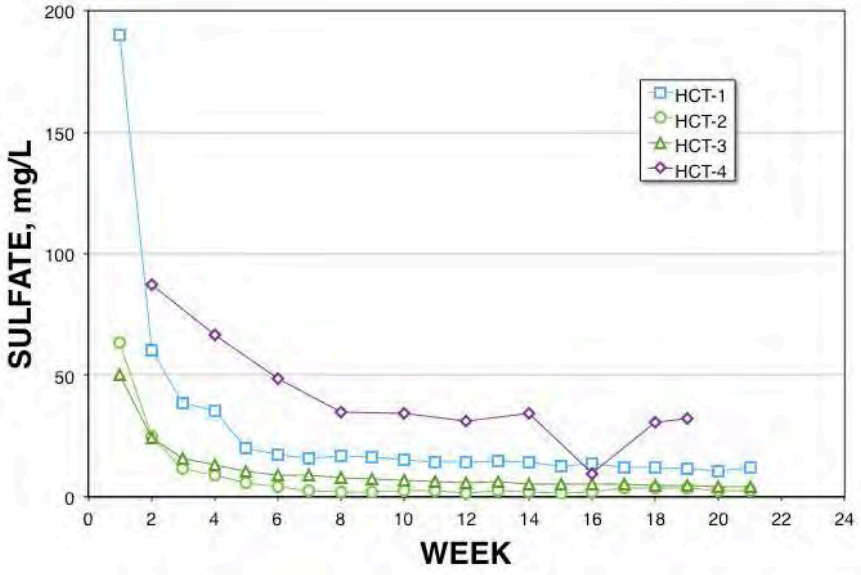

Figure 3 Leachate sulfate concentrations over time

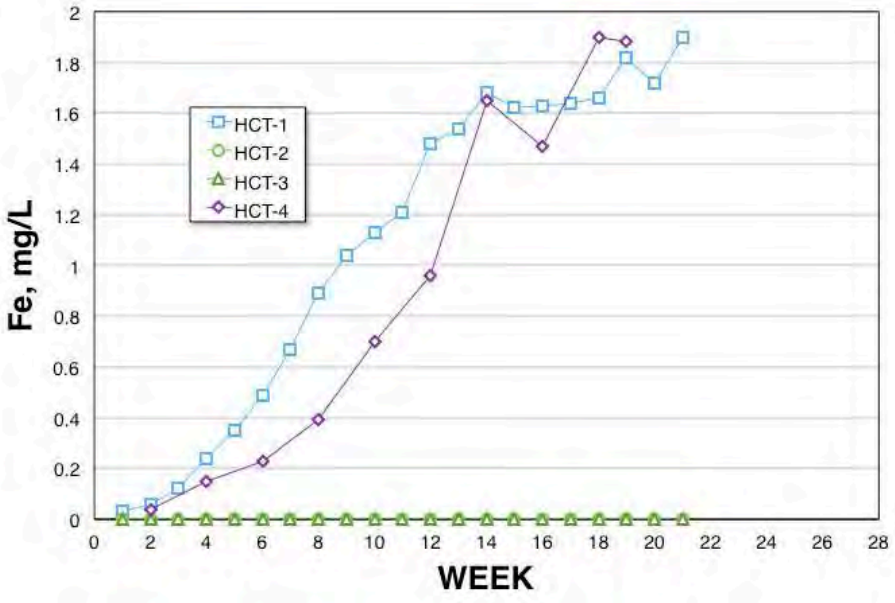

Figure 4 Leachate iron concentrations over time

Discussion

As expected, in py+qtz experiments, acidity is immediately produced by pyrite oxidation and the pH of leachate solutions begins to drop. However, despite the basic absence of acid neutralizing minerals (calcite), the pH decreases more gradually than might be expected. One py+qtz experiment, with larger grainsize pyrite, maintained near-neutral pH for about 18 weeks before it displayed a (slight) trend toward acidic conditions.

Consistent with common convention of reporting the results of HCT work, Figure 5 is a graph of the cumulative sulfate production in each test cell. In this case the sulfate production has been normalized to the mass of pyrite in the cell and not the total mass in the cell (1 kg). If the end-point of each test is used to calculate the overall rate of pyrite oxidation, the bi-weekly rinse test (HCT-4) produces less sulfate than the base case (HCT-1) and, therefore, might be interpreted to represent a slower rate of reaction. Similarly, the larger grainsize pyrite test (HCT-3) would also appear slower than the base case. However, a more appropriate basis upon which to compare rates of reaction, both between tests and with established literature is that of moles of pyrite destroyed, per meter squared, per second (mol py/m^2/s; Williamson and Rimstidt, 1994, Lappakko and Antonson, 2006), and can be calculated for each point (week) during the test.

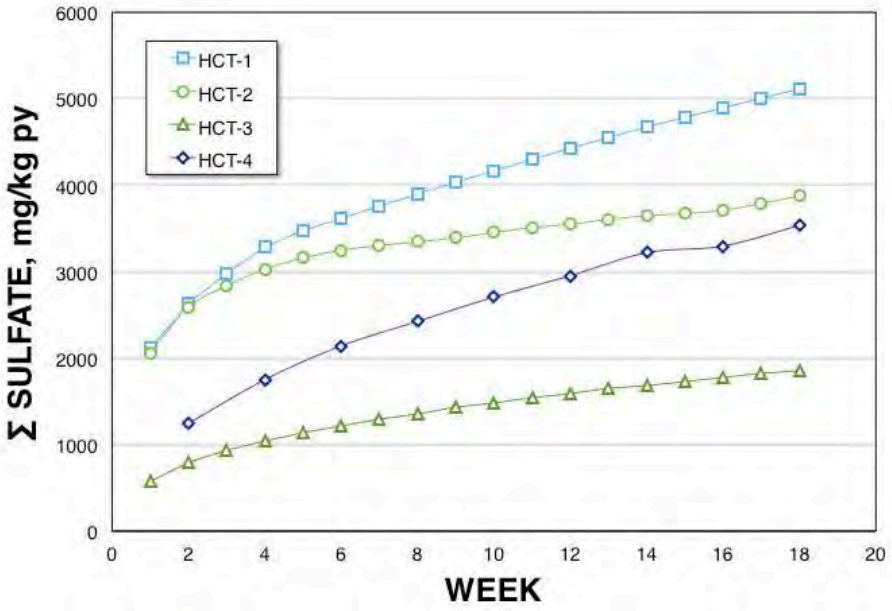

Figure 5 Cumulative sulfate production over time

When data are recast to mol py/m²/s, calculated for each period of measurement (either one week or two), the rates of pyrite oxidation show very consistent trends. Figure 6 illustrates the pyrite oxidation rates on this basis. Owing to the simple mineralogical composition and texture of the experiments, the data plot in a remarkably smooth fashion. All but one experiment (HCT-4) shows a relatively rapid initial rate that rapidly diminishes with time. All experiments converge to essentially the same fundamental rate. Thus, the presence of calcite and bi-weekly flushing ultimately appear to have little effect on the rate of pyrite oxidation. The agreement between cells with different grainsizes, confirms that the fundamental link between rate and reactive surface area applies under HCT conditions.

The observed rapid decrease in the rate of reaction (Figure 6) is consistent with literature for the oxidation of pyrite in vapor-only conditions. Over the course of many individual experiments, Jerz and Rimstidt (2004) observed the same basic trend. Figure 7 illustrates some typical data from one of their experiments. Like the rates in the current study, the initial rate is relatively fast, and rapidly diminishes to near steady rates with time. Jerz and Rimstidt (2004) attributed this observation to the build up of an adsorbed water layer that restricted oxygen transfer to the mineral surface via diffusion. Their estimates of the amount of pyrite destroyed did not lead to a conclusion of iron precipitate armoring of the pyrite grains. Such an effect may not apply to the current results, as the HCT provides for weekly rinsing However, a similar passivation may occur in HCT work as a result of armouring by weathering products (retention of iron) or a change in electrochemical properties of the pyrite itself (Williamson and Rimstidt, 1994). Although currently unavailable, on-going microscopic analyses intend to address these possibilities.

In the present experiments, each retained iron. This is shown clearly in Figure 4 for HCT-2 and HCT-3. Although the remaining two cells discharged iron, it was less than the stoichiometric amount expected from consideration of sulfate release. Thus, armoring by iron precipitates might be anticipated. However, in comparison with literature reports for pyrite oxidation in well-stirred,

liquid-only experiments, such armoring seems unlikely as reaction products are rapidly swept form the mineral surface.

Figure 8 illustrates the rate of reaction in the present test cells as a function of the pH, for each week. As described above, the rate drops rapidly and, in some cases, the pH decreases. The figure also shows the rate of reaction according to rate laws for liquid-only experiments (solid line; Williamson and Rimstidt, 1994) and for vapor-only rate laws for 100% relative humidity (Williamson, 2013). As shown, the present rates, over time, approach the rates for well-stirred liquid-only rates, (line for Williamson and Rimstidt, 1994 in Figure 8) where accumulation of iron precipitates is limited, to non-existent. Thus, the slowing of rates in the present test cells, despite retention of iron, does not appear to be explained by the accumulation of iron precipitates.

Lappakko and Antonson (2006) present a comparison of surface area corrected pyrite oxidation rates in their HCT cells with the rate laws of Williamson and Rimstidt (1994) and likewise conclude that there is close agreement, although the comparison is less favorable than the present cells. This difference is likely to be related to the great, but expected, difficulty in estimating reactive surface area for their clearly more complex test cell charges (rock).

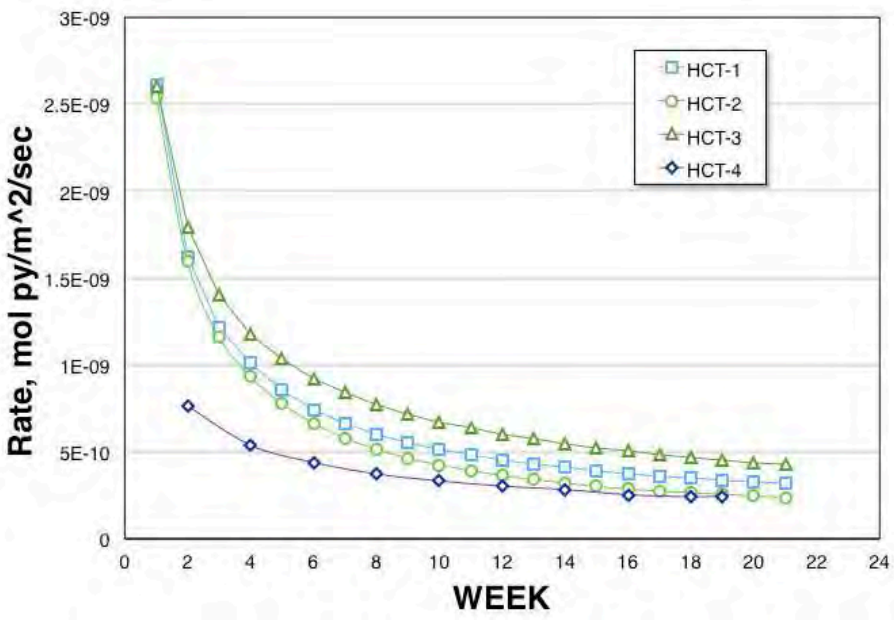

Figure 6 Rate of pyrite oxidation over time

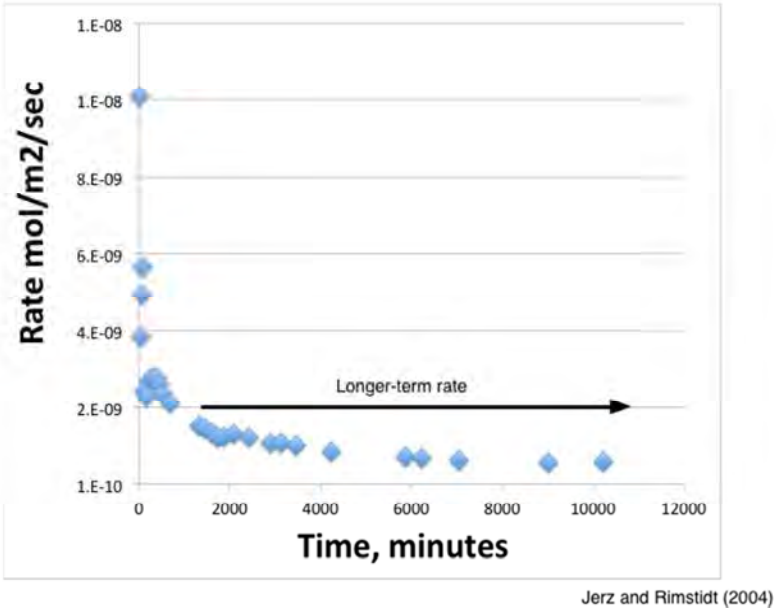

Figure 7 Rate of pyrite oxidation over time in vapour-only experiments

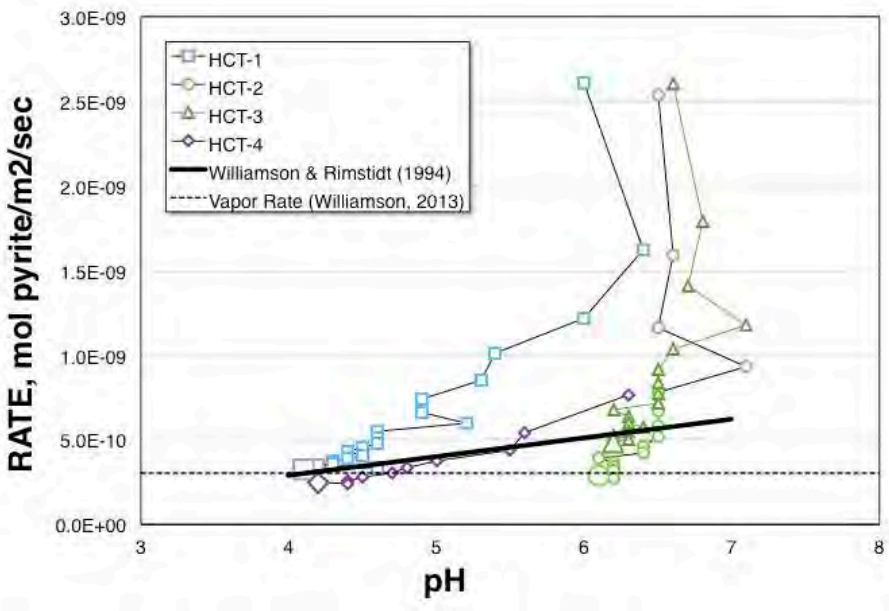

Figure 8 Rate of pyrite oxidation over time

CONCLUSION

The rate of pyrite oxidation in HCT liquid+vapor conditions, with routine flushing, is in close agreement with literature rates of reaction in liquid-only conditions and for vapor-only 100%

relative humidity. Although there is some thought that HCTs might retard the rate of reaction due to the retention of reaction products, it did not appear to be appreciable in the present test cells. There was only very limited difference in observed rate when pH was buffered by the presence of calcite, or for cells with pyrite of different reactive surface area, or indeed the rate of flushing.

ABSTRACT

Kinetic testing is one of the key tools for predicting the long-term weathering of mine waste materials and their potential environmental impacts. The standard methodology commonly undertaken for kinetic testing of mine waste is the ASTM D 5744 humidity cell test procedure. However, this test requires a significant time period to generate representative data, with typical test duration in excess of 40 weeks. In some cases, it may even require years before suitable information is obtained. This long lead time can have significant impact on mine development schedules especially if the data is required by environmental regulators for the permit application procedures. Due to the time constraints of mine development programs, it is highly desirable to identify complimentary test methods that are able to deliver the required data for water quality predictions in a shorter period of time. One of the more promising methods is the use of hydrogen peroxide (H_2O_2) leach test (a common variant being the Net Acid Generation or NAG tests). The resulting NAG leach solutions can potentially be scaled to field conditions to allow for a preliminary prediction of mine waste seepage water quality. This paper compares results from NAG testing and long term humidity cell testing, including correlations between the two data sets to show whether NAG leaching is an appropriate method for preliminary rapid assessment of mine site drainage water quality.

Keywords: NAG test; Humidity Cell; Seepage prediction

INTRODUCTION

Exposure of sulfide minerals during mining results in gradual oxidation of these minerals and the associated release of solutes and acidity to the environment. This is commonly referred to as acid rock drainage (ARD) and metal(loid) leaching (ML) or ARDML. ARDML can result in significant detrimental ecological impacts which makes the prediction of water quality from mine sites one of the most critical aspects of the evaluation of mine design for permitting and/or closure applications. Prediction of ARDML and associated water quality impacts have become mandatory for studies in many mining jurisdictions and/or where international bank financing is required.

One of the primary objectives of an ARDML study is to determine if contaminants will be released and to predict the rate at which they will be released from each mining waste type. In order to do this, it is necessary to undertake a series of characterization tests. These tests can generally be classified into two types (MEND, 2009):

- Static tests – rapid testing procedures that deliver information on the finite materials characteristics, for instance, if the material is potentially acid generating, if it is enriched in certain elements of concern, what the immediate mobility of such elements are, and the potential for long term release of certain elements if the samples are fully oxidized.
- Kinetic tests –laboratory or field column tests that are used to determine the rate at which acidity is generated and solutes are released. Kinetic tests require a longer time period than static testing, and are usually run for 40 weeks or more.

Kinetic testing methods vary based on the particular scenario that is being examined and the required test outcome. The most commonly used kinetic test is the ASTM D 5744 Humidity Cell Test (HCT) (ASTM, 2013). This is an optimized weathering test in which a sulfidic material is exposed to alternating dry and humid air cycles followed by weekly flushing with deionized water at a high liquid to solid ratio. The test is intended to ensure that appreciable oxidation and solute release is achieved and is not designed to directly simulate field conditions.

The long lead time between the initiation of the tests and the time at which the test matures i.e. when the data obtained from the test is suitable for use in long term water quality predictions, can be many months (eg. Sexsmith et al, 2015). This is especially applicable with materials which are slow reacting and demonstrate a significant lag time to the onset of persistent acidic leaching conditions at which solute mobility and release from the cell is at its highest and most representative of long term weathering.

In many cases, the significant maturation time of kinetic testing does not fit in with the mine development schedule where timely water quality predictions are essential in order to ensure that the most suitable and cost effective mitigation measures are designed into the project at the earliest possible opportunity. In order to avoid such situations, it would be beneficial to develop a complementary methodology that can be used to undertake preliminary predictions of water quality far in advance of that provided by kinetic tests.

One of the most promising methods to address these needs is the use of solute release data obtained from Net Acid Generation (NAG) test. NAG tests are commonly used as a complimentary method to Acid Base Accounting (ABA) for the confirmation of a materials acid generating potential. In a standard NAG test, a 2.5g portion of pulverized sample is leached in 250mL of 15% hydrogen peroxide (H_2O_2) solution. The NAG test intends to fully oxidize the sulfide minerals contained within the sample, generating acidity, releasing sulfide-associated elements into solution and reacting with fast-reacting acid buffering carbonate minerals. As well as providing information on

acid generating characteristics, multi-element analysis of the generated NAG solution can reveal significant information on potential release of metals, metalloids and salts from the sample after complete sulfide weathering.

The NAG procedure has been sequentially developed by a number of researchers over the past 40 years; Smith et al. (1974), Sobek et al. (1978), O'Shay et al, (1990), Stewart et al (2006) and references therein; but so far, the use of NAG test data in the preliminary prediction of water quality for mine sites has not been addressed. The most likely reason for this is that analysis of NAG solution chemistry is not widely practiced and a reliable empirical database comparing standard kinetic (HCT) release rates and mass release from standard NAG test data is not readily available.

The purpose of this paper is to make comparison between multi-element assay of the NAG solution and the HCT results from the perspective of using NAG data to make a preliminary prediction of water quality suitable for use in mining development studies as a complementary methodology to (rather than a substitution for) standard kinetic testing methods.

The potential benefits of using such static tests for early water quality predictions would be to allow for better costing of engineering designs early on in a feasibility study program to mitigate the potential impact of ARDML to the environment without inclusion of excessively cautious designs approaches.

Prediction of water quality through scaling of kinetic data

Although it can be argued that the use of HCT data for the prediction of mine site water quality is less than ideal (i.e. Sunkavalli, 2014), it is not the intention of this paper to examine this. Therefore in this study, kinetic testing refers to standard ASTM D-5744 HCT and the resulting solute release rates. However, the author acknowledges that elemental release rates can be obtained from a large variety of kinetic tests, some of which are arguably superior to HCT more closely simulating field conditions in terms of fluid flow, temperature or liquid to solid ratio.

In order to convert laboratory derived solute release rate (R*lab)* into field water quality predictions, it is necessary to upscale R*lab*, to take into account such factors as oxygen availability, particle size distribution, and field temperature variation to give a primary field release rate (R*field*). Once R*field* has been calculated, it is then possible to estimate a concentration in pore water by taking into account the difference between laboratory and field liquid to solid ratio. The solute concentrations calculated using this method then need to be equilibrated using a thermodynamic equilibrium code (such as PHREEQC, Parkhurst and Appelo, 2013) to take into account such things as mineral saturation and adsorption to mineral surfaces. The resulting solutions 'source term' concentration can then be incorporated into site wide water quality predictions and / or assessed against relevant water quality guidelines, and used to develop suitable mitigation controls in the design and cost estimates prior to mine development.

Alternative methods of water quality prediction may also be undertaken such as deriving water quality from primary mineral weathering rates (effectively from first principals i.e. Linklater et al (2005) and references therein). However, these methods are complex and require data that is usually difficult to obtain during a mine development study. In addition, the first principal method of modeling commonly does not take into account all of the contaminants released from a deposit which would be included if scaling of kinetic test data is included. It is also possible to make a preliminary prediction of water quality from empirical relationships and analogue sites. This is often a very useful first approach (MEND, 2009) but again, does not take into account intricacies and variations that can be obtained through the scaling of leaching test data.

Potential for substitution of kinetic "rates" with static test release data

It is plausible that R*lab* obtained from kinetic testing can be substituted for an alternative rate derived from static testing methods. However, static tests generate only a mass release (usually referred to in mg/kg) and thus a release rate has to be assigned - for example, by assuming that all of the sulfide-S content of a sample is released as sulfate equally over a given time period. Furthermore, in the case of water leaching tests such as EN12457 or MWMP tests, the mass released often represents only the dissolution of soluble salts that are rinsed from the sample surface and do not take into account the release of solutes due to the oxidative dissolution of sulfides, and associated acidity driven dissolution.

The NAG test has the benefit of being able to determine (i) the solute release attributed to sulfide oxidation though the reaction of hydrogen peroxide (H_2O_2), and (ii) the solubility of the solutes at the pH of the final NAG solution. Therefore this method shows the most promise for use in rapid prediction of long-term weathering water quality. However, due to the very rapid reaction of H_2O_2 with the sulfide minerals within a mine waste sample, complete oxidation is commonly achieved within a matter of hours. Although attempts have been made to measure NAG release rates (Kinetic NAG), the exothermic breakdown of H_2O_2 during the test often results in very high temperatures which make measurement of a sulfide oxidation rate difficult.

Any rate used to substitution for R*lab* (HCT) must be derived in some way from the total mass release. The NAG tests simply gives a bulk release of sulfide-associated elements, an average for the entire humidity cell release if it were to be run to sulfide exhaustion. Additionally, NAG tests suffer many additional complications. For instance, incomplete oxidation of sulfides is often observed in samples due to the decomposition of H_2O_2 during the test. This is promoted by increasing pH and by the presence of catalytic metal ion, such as Mn, Fe and Cu or, in alkaline solution, by the presence of the carbonate ion (Liochev and Fridovich, 2004 and references there in) and in some cases simply by the method employed for the analysis (Charles et al, 2015). Despite these drawbacks, NAG tests may represent one of the most favorable static tests for rapid determination of water quality impacts.

Comparison of NAG data with HCT data

Eight samples of moderate to high sulfur waste rock materials were subjected to long term (greater than 160 weeks) ongoing HCT testing, details of the ARD characteristics of the samples are given in **TABLE 1.** The deposit utilized for the testing is a magnetite resource within an Iron Oxide Copper Gold (IOCG) style of mineralization. The deposit is characterized by a moderately elevated coarse grained sulfide (pyrite / pyrrhotite / chalcopyrite) content hosted in quartz veins within amphibolites, diorites and schists lithologies. Total sulfur (almost all present as sulfide sulfur) is in the range of 0.1 to 5 wt.%. In addition to sulfides, the deposit also has a relatively uniform but low magnitude carbonate mineral assemblage with inorganic carbon consistently between 0.05 - 0.5 wt.% and averaging 0.08 wt.%. All the static testing undertaken on the samples demonstrated them to be acid generating and all NAG tests produced pH conditions below pH 4.5.

Comparisons are made of data between times at which the HCTs were at circum-neutral pH and them later at acidic pH. It is important to note that within ARD systems, as pH decreases to < 4, dissolved Fe(III) becomes increasingly soluble and more important than O_2 as the (direct) sulfide oxidant. Laboratory data indicate that sulfide oxidation rates are circa one order of magnitude higher under acidic conditions than rates under neutral (O_2 dominated) pH conditions (cf.

McKibben and Barnes (1986); Olson (1991) and Rimstidt et al (1994). Observation made by the authors from previous kinetic testing have shown that, the ratio between sulfide oxidation rates at neutral pH and peak (maximum) sulfide oxidation rates under acidic condition may reach the factor of 10 and in some cases exceed this. However, this was generally only observed for a short duration (<10 weeks) and was not representative of average sulfide oxidation rates under acidic conditions. When the long term neutral and long term acidic sulfate release rates were compared, the ratio between neutral and acidic rates decreased significantly with a median ratio value of 4.87 and ranges between 1.8 and 8 (see inset graph in **FIGURE 1)**

Table 1 Summary of geochemical characteristics of waste material used in humidity cell testing

Sample No.	Material Type	Acid Base Accounting							NAG pH	Ave. week 151 – 160 HCT pH
		TIC	Total Sulfur	AP	NP from TIC	NP from Titr.	NNP Titr.	NPR Titr.

NPR	Neutralizing Potential Ratio (NP/AP)		

The main plot in **FIGURE 1** compares the rate of sulfate release at different periods within the HCT to the total sulfate mass release from the corresponding NAG tests. The red points represent early stage weathering (weeks 21 to 40) during which time pH of all HCT leach solutions was above pH 7 whilst ensuring that the early stage flushing of soluble sulfate salts had occurred. The second period is between weeks 151 and 160 which is the most recent data available and represents the cells at their lowest recorded pH and highest sulfate release (blue points). In both cases, a reasonable correlation can be drawn between the NAG release and HCT release rates with R^2 of 0.72 for weeks 21 to 40 and 0.93 for weeks 151 to 160, for linear best fit and zero intercepts. The slope of the correlation for weeks 21 to 40 is 0.0012 (1/776), whilst this is roughly double for weeks 151 to 160 at 0.0025 (1/391). This demonstrates the following:

1) That the rate of release in the HCT is proportional to the NAG sulfate release and likewise the total sulfur content of the samples. This is logical for samples such as these where sulfides (and their exposed surface area) are distributed uniformly through the sample.
2) That this proportionality between HCT S release rate and NAG S release is maintained at later stages of the HCT when pH is lower, albeit with higher HCT sulfate release rates.

3) That as with other literature, sulfide oxidation rates within the HCT increase as pH conditions become more acidic. In the example given here, the sulfate release rate has doubled between neutral and mildly acidic pH conditions of the test.

The upper orange line in **FIGURE 1** represents a 4.87 increase in the neutral oxidation rate as discussed above. Applying a factor of 4.87 to the week 21 to 40 rate slope of 1/776 gives a predicted sulfate release rate (under acidic conditions) / NAG sulfate release slope equal to 0.00635 (1/157.5) x the total NAG S. Or restated for clarity, after 157.5 weeks, the total sulfur content of the sample would be released at a fixed rate to exhaustion.

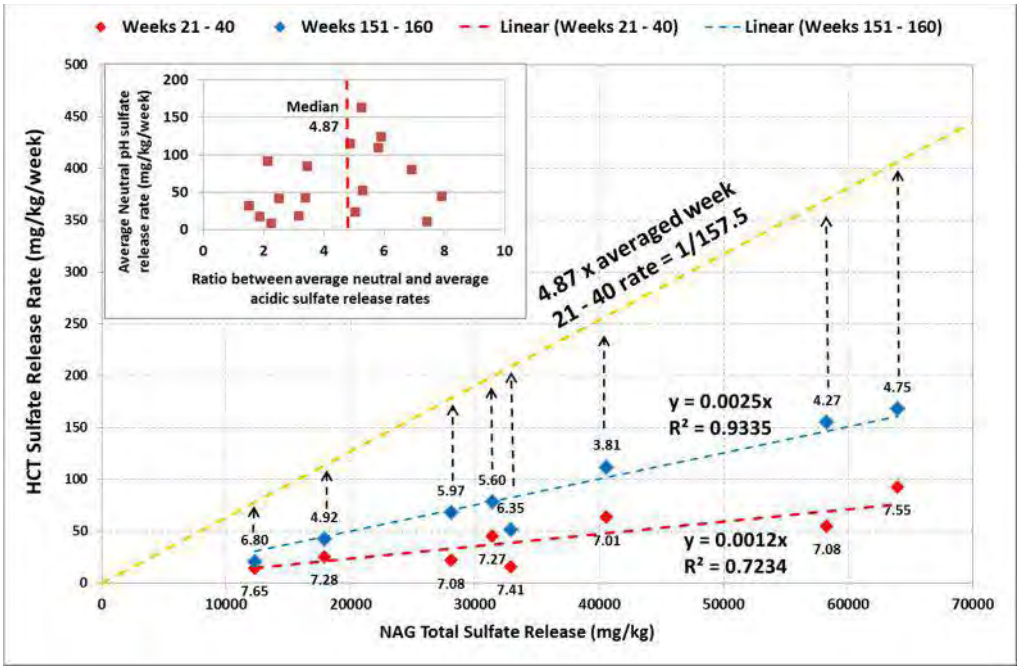

Figure 1 Variation between NAG release (mg/kg) and HCT sulfate release rate (mg/kg/week) for weeks 21 to 40 and weeks 151 to 160 HCT data respectively. Data point labels correspond to the average HCT pH for the period. The orange dashed line corresponds to 4.87 times multiplication of the weeks 21 to 40 slope rate resulting in a slope of 1/157.5. The inset graph shows the range of ratios between sulfate release rates under neutral and acidic conditions from previous HCT data.

Logically, for sulfide-bound metals, the rate at which sulfide is oxidizes and sulfate is released should correspond to the rate at which other sulfide-associated elements are released – except where solubility limits constraint this. The plots in **FIGURE 2** compare HCT release rates for Cu, Co, Ni and Zn with the corresponding calculated metals release rates using NAG test data divided by a factor of 157.5 (i.e. assuming that under acidic conditions within the HCT, that the total NAG metals are released linearly over 157.5 week period). Also shown is the line of unity between HCT and calculated NAG release rates. Measured HCT release rates are shown for both the average week 21 to 40 data and the 141 to 150 data.

It is clear that measured releases are significantly higher in the 141 to 150 period compared with the 21 to 40 period. In fact, during the early weeks of testing, both Cu and Co concentrations were consistently below the analytical detection limit (ADL) within the tests which accounts for the flat trend observed. Ni and Zn were both above ADL during the week 21 to 40 period with Ni showing a good linear correlation with calculated NAG Ni release rates.

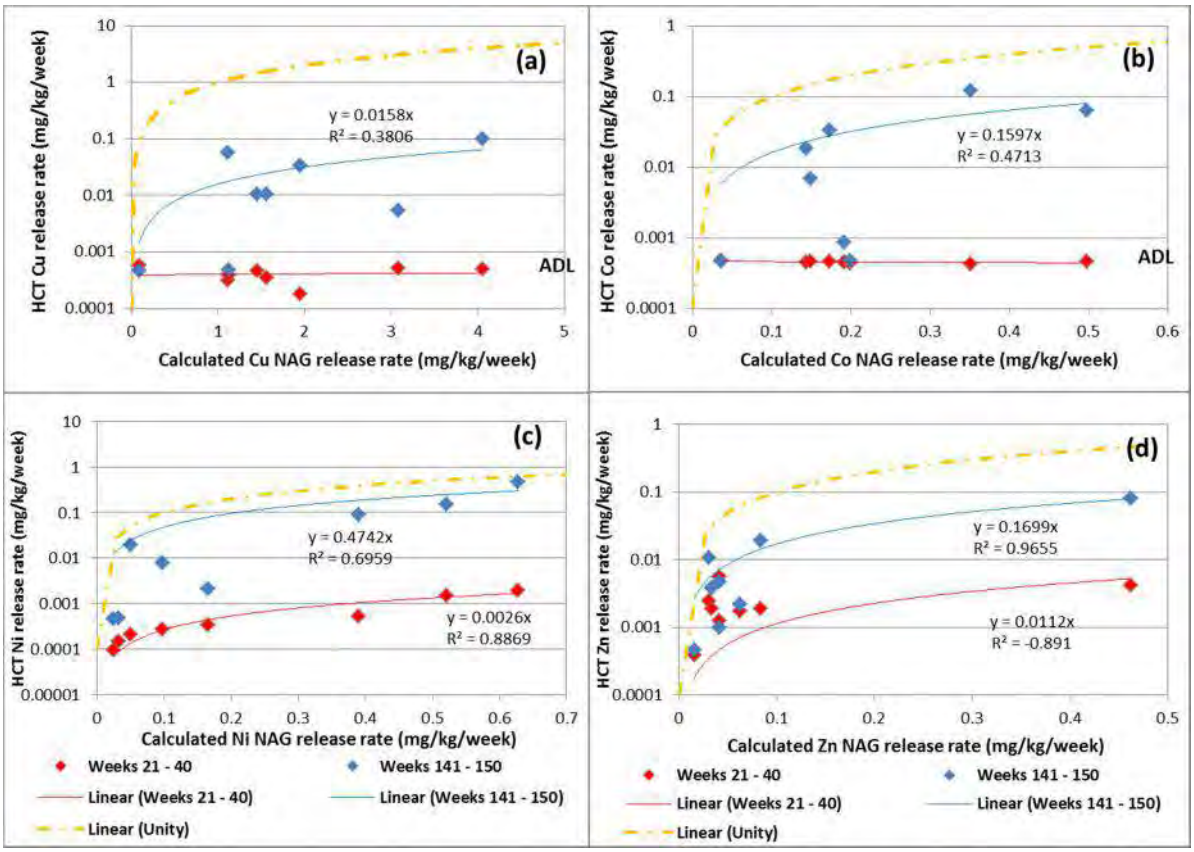

Figure 2 Comparison between measured HCT metals release rate (mg/kg/week) and calculated NAG release rate using the factor of 157.5 correction (as mg/kg/week equivalent) for a) Cu b) Co c) Ni and d) Zn. Comparison is made for HCT weeks 21 to 40 data and HCT weeks 141 to 150 data. The orange dashed shows 1:1 ratio between measured HCT release rates and calculated NAG release rates.

Metals release rates from the HCT increase significantly for Co, Cu, Ni and Zn, in most samples, between early stage and late stage leaching. However, it can be demonstrated that this increase in metals release is largely a result of the increasingly acidic pH as opposed to purely an increase in the rate of sulfide oxidation and primary release. For example, where the rate of sulfate release between early stage and late stage HCT weathering increases by a factor of about 2, in most cases, metals release increases by about 2 orders of magnitude for Co, Cu and Ni, and 1 order of magnitude for Zn. Therefore, the increasing sulfide oxidation rate cannot directly account for the increasing metals release. In order to further clarify this, a plot comparing metals release rate from the early stage and late stage HCT for Co, Cu, Ni and Zn against pH was produced (see **FIGURE 3**). This shows the clear log linear correlation between metals release rate and pH, behavior typical for transition metals cations due to retention through adsorption to iron oxides (Dzombak and Morel, 1999). The strong pH control of transition metal cations makes decoupling of the two processes of (i) primary release from sulfide minerals and (ii) actual release from the HCT column extremely difficult from HCT that have not reached acidic pH (pH << 4) due to the high proportion of metals being retained within the column. Due to the HCT metals release rate being compounded by sulfide oxidation rate and metals retention, it is difficult to use immature HCT release data to predict future release rates under acidic conditions without allowing the tests to run until such time as acidic pH conditions are reached. Because of the low final NAG pH, the calculated NAG metals

release rates are not anticipated to be significantly moderated by sorption (in this example) and therefore, use of the calculated NAG release rate allows a better indication of long term release rates than could be achieved through scaling of premature HCT test data alone. This is where NAG test data can prove highly beneficial, to demonstrate this, the calculated NAG metals release rate plotted against the NAG test solution pH has also been included in **FIGURE 3**.

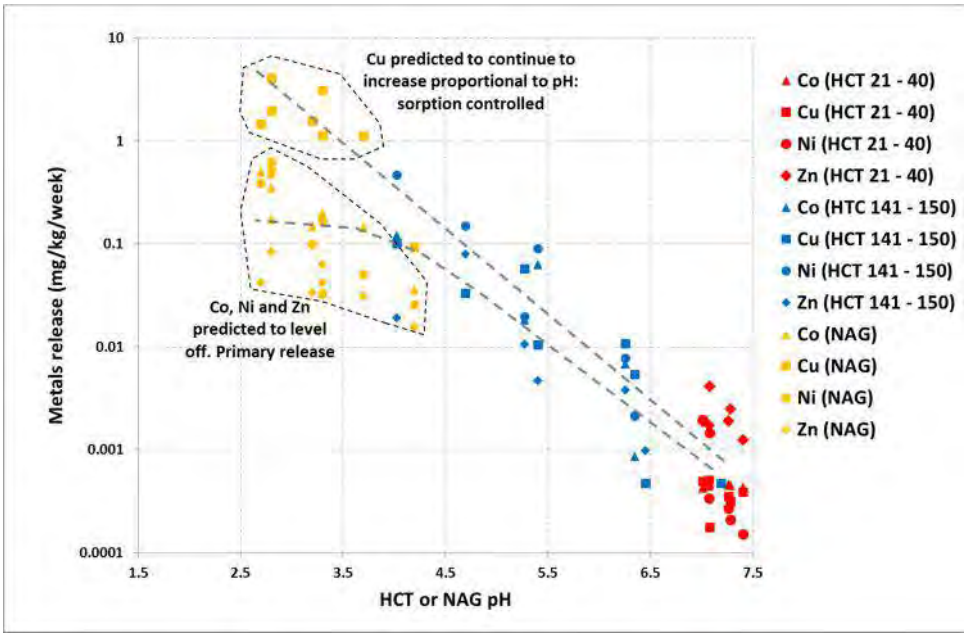

Figure 3 HCT metals release rates (mg/kg/week) verses pH for weeks 141 to 150 data. Also shown are predicted metals releases corresponding to NAG release rate (mg/kg) divided by a factor of 157.5.

The difference between measured and actual metals release rate are most apparent with the behavior of Cu. This is due to its high affinity for adsorption to iron oxides and the low adsorption edge relative to Co, Ni and Zn (Dzombak and Morel, 1999). The lower pH adsorption edge of Cu means that even at week 141 – 150, where most cells are generating mildly acidic pH solutions, a significant proportion of the Cu released through sulfide oxidation is likely to be retained within the cell through adsorption to iron oxides. It is only when the pH within the HCT drops significantly below 4 (assuming that this will occur) that the Cu release are predicted to increase to levels reflect by the proportion relationship with the NAG test data. Once the pH within the HCT solutions have declined below the adsorption edge of a particular metal, then the concentration of the metal within the solution should correlate with the sulfate release rate as the metal will no longer be retained within the cell. This can only be fully clarified by continuing the HCT tests until stable acidic pH are reached.

CONCLUSION

- For the particular samples and deposit type described in this paper, a good correlation was identified between HCT sulfate release rates and NAG test total sulfate release. This reflects the total available sulfur content within the sample which for these samples is correlated to the exposed sulfide mineral surface area.

- For samples that are expected to become acidic, the sulfide oxidation rate (in line with observations and literature) is expected to increase. It is possible that the initial sulfate release rate can be extrapolated to the final acidic pH release rate.
- The scaling of release rates under neutral condition to those under acidic conditions although logical for sulfate release, may not be applied to metals release so readily due to retention of metals by adsorption within the column. NAG test data shows promise for supplementing HCT prediction data by giving an indication of the maximum sulfide-associated metals release that can be expected under acidic conditions.

ABSTRACT

The lignite mining dump of Witznitz in Central Germany is characterized by iron concentrations in groundwater up to 4 g/L. Rising groundwater levels after the mine was closed in 1993 have resulted in the discharge of consistently high iron loads to the adjacent Pleiße river.

The quantity of groundwater discharge to the stream is described by a 3D groundwater flow model using the program PcGeofim. In order to predict the groundwater hydrogeochemistry, a batch model using the PHREEQC geochemical modeling package was firstly set up to reproduce the genesis of dump groundwater by considering the processes of iron disulfide weathering, solution of calcite and silicates as well as the formation of new minerals such as gypsum and siderite. The model was calibrated using a set of 350 groundwater analyses from 50 wells in the dump and investigations on the solid phase of the dump material. As a result, the mean iron disulfide degree of weathering was determined to be 18% of the total dump iron disulfide.

Based on this, both models were coupled using a Python script by implementing the hydrogeochemical batch model including mineral phases into each cell of the groundwater flow model. Thereby, the spatial variability of the degree of iron disulfide weathering was taken into account by Monte Carlo simulations. As a result, groundwater solute concentrations were predicted to decline in conjunction with the groundwater recharge and solution of the secondary mineral pool takes place, whereas the velocity of the process is determined by the rate of groundwater recharge as well as groundwater flow. Implementing the Pleiße river as a boundary condition in the model makes it possible to predict the quality and quantity of groundwater discharge into the river.

Keywords: reactive solute transport modeling; iron loads; dump aquifer; PcGeofim

INTRODUCTION

The surface water quality of the Pleiße river in the lignite mining area south of Leipzig, Germany, shows total iron concentrations of up to 6 mg/L during periods of low water. Besides the visual impact, the high iron concentration results in iron clogging of the river bottom as well as negative effects on the aquatic ecosystem. By this, the achievement of a good ecological potential in accordance to the European Water Framework Directive is hindered.

Iron originates from the lignite mining dumps alongside the river, whose groundwater exfiltrates into the river. Due to iron disulfide oxidation of tertiary sediments, the dumps are often rich in bivalent dissolved iron. During the transition from the anoxic groundwater to the aerated environment of the river, oxidation to trivalent iron takes place as well as further formation of iron(3)-hydroxides or -hydroxysulfates, respectively. The process is accompanied by the formation of acidity.

One major source of iron in the Pleiße river is the dump of the former surface mine Witznitz, which was operated between 1946 and 1993. Dump material mainly consists of quaternary flood sediments and tills as well as tertiary marine overburden and the adjacent sediments of the removed coal seams. After the devastation of the original river bed, the Pleiße river was relocated directly across the dump during the 1960s. Following the termination of operations, uplift of the groundwater table, which was formerly lowered by mining activities, began. This is connected with a direct discharge of dump groundwater into the river.

Recent mean total iron concentrations measured in dump groundwater are 1050 mg/L, whereas the mean pH is slightly acidic at 5.3. The ionic balance is decisively influenced by the concentrations of both calcium (480 mg/L) and sulfate (3700 mg/L). The spatial variability of iron concentrations is great, ranging from 26 to 4510 mg/L. This is due to a varying geochemical composition of the source material of the dump as well as a differing intensity of oxygen contact and iron disulfide weathering taking place during fore field drainage and dump formation as well as on active mining slopes and exposed dump surfaces.

In order to predict future dump-originated solute inputs to the Pleiße river, a reactive solute transport model was developed for the Witznitz dump, which allows a spatially differentiated calculation of groundwater discharge to the river both in quantity and quality.

METHODOLOGY

Reactive solute transport modeling was realized by coupling the groundwater flow and solute transport model PcGeofim (Blankenburg et al., 2013) with the hydrogeochemical simulator model PHREEQC (Parkhurst & Appelo, 1999). By coupling the two models, it is possible to take into account reactions within the liquid phase, interactions between liquid and solid phase, such as iron disulfide weathering, as well as gas exchange processes in combination with transport modeling.

Model coupling was taken out by a programming script using the language Python. For each time step in the model, groundwater flow and solute transport was calculated, taking into account 11 different migrating solutes. Using the solute concentrations resulting from this calculation, hydrogeochemical batch calculations were carried out between liquid, solid and gas phases for each cell. Thereby, the pH, which is a non-conservative parameter, is recalculated in every batch calculation based on the charge balance. The resulting solute concentrations are then used for the

groundwater flow and solute transport calculation of the next time step. Solid phase contents and cation exchange allocation are saved using internal storage.

Groundwater flow model

The 3D groundwater flow model of the Witznitz dump is part of a large-scale model which comprises the whole lignite mining area south of Leipzig. The surrounding consists of mining dumps as well as active mining areas with a still massive lowering of the groundwater table. PcGeofim calculations are based on the method of finite volumes.

The model grid of the Witznitz dump is 62.5 x 62.5 m. In vertical direction the dump is divided into six aquifer layers and coupled onto the adjacent natural aquifers. The hydraulic conductivity of the dump aquifer was calculated from the silt and clay content using an empirical relationship according to Kaubisch (1986). Kf-values of the upper dump are in the order of 10^{-6} m/s, whereas the lower dump is characterized by values in the order of 10^{-8} m/s. Groundwater flow therefore takes place primarily in the upper part of the dump aquifer. Surface waters such as the Pleiße river as well as mining lakes are implemented as boundary conditions. Groundwater recharge is derived from the catchment model ArcEGMO (Becker et al., 2002) and amounts to an average of 80 mm/yr considering the whole dump body.

The groundwater flow model was calibrated using measured hydraulic heads from 65 piezometers within the dump body. The standard deviation between measured and calculated hydraulic heads was 1.3 m.

Hydrogeochemical batch model of dump genesis

The batch model represents the genesis path of dump hydrogeochemistry originating from the initial unweathered substrates during dump formation to the recent monitored conditions. Similar modeling approaches were used *e.g.* by Wisotzky & Obermann (2001) for the Rhineland lignite mining area.

The primary minerals of the model are iron disulfide FeS_2, calcite $CaCO_3$, clay minerals (for the sake of simplicity represented by kaolinite $Al_2Si_2O_5(OH)_4$) as well as primary silicates such as feldspars or micas (fig. 1). The mineral contents were derived from the measured contents in the original geological layers that now form the dump body, taking into account the portions of the single layers in the dump structure.

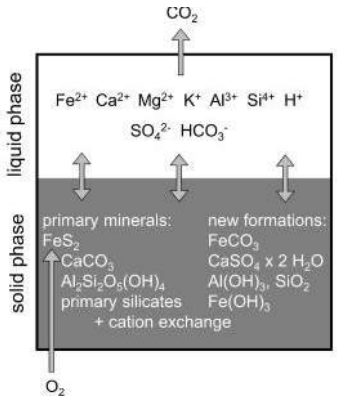

Figure 1 Hydrogeochemical process model

This results in an overall initial iron disulfide content of 2.1 mass-% and calcite content of 0.5 mass-% for the purpose of the model. Kaolinite is simplistically assumed to be abundant, whereas the weathering of primary silicates is coupled to the turnover of iron disulfide and fitted during calibration.

A stepwise addition of oxygen leads to an oxidation of iron disulfide and a release of iron, sulfate und acidity. Buffering is primarily provided by calcite and after depletion at lower pH values by clay mineral solution. Dissolution of primary silicates is a kinetically slow process which takes place in parallel with the processes mentioned before. As a result, the ionic strength of the liquid phase increases. On one hand, CO_2 originating from calcite weathering degasses in part; on the other hand, new mineral phases start to form. Siderite ($FeCO_3$) is a transient mineral formation of the released iron, which, however, gets resolved at lower pH values. A further new mineral formation is represented by gypsum ($CaSO_4x2H_2O$). Solution of silicates and clay minerals leads to the formation of aluminum hydroxide as well as silicon dioxide. Beyond that, precipitation of a mineral phase of trivalent iron is implemented in the model, as weathering of iron disulfides takes place mainly during unsaturated oxic conditions. At pH values > 3, iron hydroxides, oxyhydrates, or hydroxisulfates are formed. Exhibiting higher degrees of crystallization, part of these are irreversibly fixed within the dump substrate and are therefore stable against reductive dissolution during the uplift of the groundwater table. In the model this irreversible reaction was considered by an additional iron sink, which is coupled to the degree of iron disulfide weathering. Finally, the model takes into account the cation exchange of calcium, manganese, potassium, iron, and aluminum with an overall exchange capacity of 2.1 $cmol_c/kg$, which reflects the measured mean conditions in soil samples obtained from the dump body.

The model was calibrated using 350 chemical analyses from 50 monitoring wells and piezometers within the dump body as well as 87 soil samples, which were mainly analyzed for sulfur and carbon species as well as main cations and the cation exchange capacity. Based on the measurements, the process model was adjusted by varying solubility products of mineral phases, the portion of irreversibly bound trivalent iron minerals as well as the maximum partial pressure of CO_2. The computational realization was done by means of the simulator PHREEQC using the database wateq4f.dat.

Solute transport model of dump discharge

Model coupling of the groundwater flow and solute transport model with the hydrogeochemical batch model was realized alongside nine representative 2D vertical-plane cuts crossing the dump in groundwater flow direction to the Pleiße river. In principal, 3D modeling would also be possible. The advantage of the 2D cuts, however, is a clarity, which facilitates an understanding of the ongoing processes.

Discretization of the cuts was 50 m in the horizontal and 5 m in the vertical direction. Parameterization of hydraulic conductivity as well as hydraulic boundary conditions and groundwater recharge was taken from the 3D groundwater flow model of the Witznitz dump.

The hydrogeochemical batch model was implemented into every model cell using a Python script for model coupling. It considers primary iron disulfide oxidation taking place by fore field drainage and trapped oxygen during dump construction as well as on active mining slopes previous to the fill-up of the dump with groundwater. Spatial variability of the degree of iron disulfide oxidation as a percentage of the initial iron disulfide content was taken into consideration by Monte Carlo

simulations using a random generator based on a normal statistical distribution to calculate the turnover for every model cell.

Secondary iron disulfide oxidation takes place via the dump surface after the termination of the dump formation. It is accounted for by an additional oxygen input and corresponding iron disulfide turnover, which decreases successively with the age of the dump as growing vegetation reduces the oxygen input by soil respiration and iron disulfide minerals get less accessible to weathering due to passivation. In cases of oxic conditions close to the dump surface as a result of iron disulfide depletion, the formation of schwertmannite is allowed to take place according to the formula $Fe_{16}O_{16}(OH)_{9.2}(SO_4)_{3.4}x36H_2O$ (Bigham et al., 1996) in addition to the processes defined in the hydrogeochemical batch model.

The model was calibrated by using the same analytical data as for the calibration of the hydrogeochemical batch model, but also considering spatial patterns in total iron concentrations, particularly, variation with depth. Fitting parameters were given by the degree of primary iron disulfide oxidation including its standard deviation for Monte Carlo simulations to reproduce the measured variation of iron concentrations as well as by the quantity of secondary iron disulfide oxidation via the dump surface. The calculation was carried out beginning from the termination of dump formation, which is between 1951 and 1970 for the single cuts, for a time interval of 450 years.

RESULTS AND DISCUSSION

Grundwater flow regime

Groundwater dynamics within the Witznitz dump are essentially determined by surrounding surface waters (fig. 2). Due to comparably low hydraulic conductivities a groundwater cap is formed within the northern part of the dump at a level of +140 m above sea level (a.s.l.).

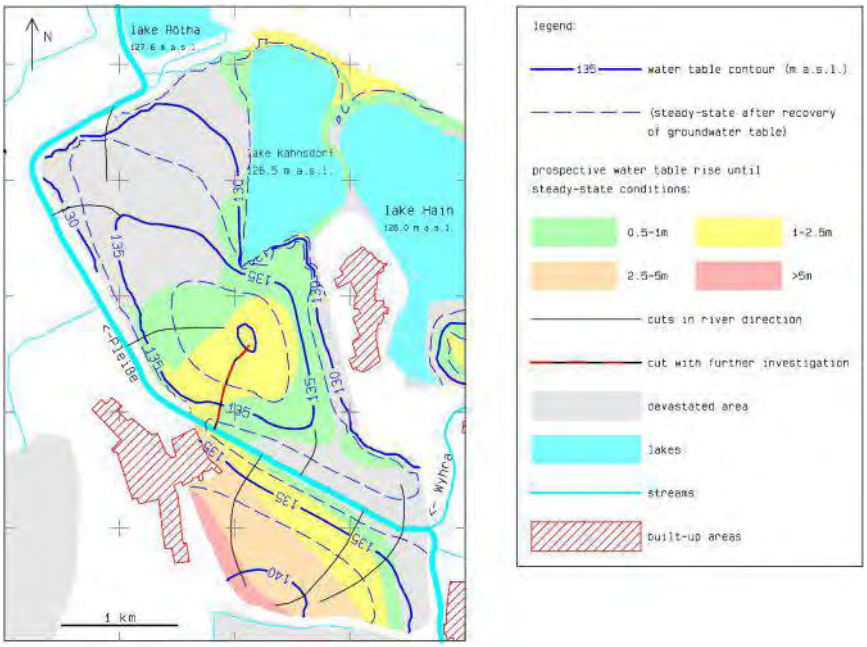

Figure 2 Steady-state water table contours, prospective rise and cuts in river direction for the transport model

Groundwater flow from the dump takes place to the Pleiße river, as well as to the mining lakes Kahnsdorf and Hain. The dump body south of the river is characterized by a groundwater flow to the river from southeastern direction at steady-state conditions after the completion of the groundwater table uplift.

In the northern part of the dump the groundwater table uplift is nearly complete. Future rises are below 2.5 m (fig. 2). By contrast, in the southern part of the dump there is a future rise of up to 6 m expected, which is caused by a further groundwater uplift in the dump surroundings. By means of the large-scale model, this could be considered in the groundwater flow calculation of the Witznitz dump.

The modeled groundwater inflow from the Witznitz dump to the Pleiße river amounts to 0.78 m^3/min for steady-state conditions.

Hydrogeochemistry of dump genesis

The model of dump genesis was realized by a stepwise increase of the degree of iron disulfide weathering releasing iron, sulfate, and acidity to the groundwater. Subsequently, several accompanying reactions take place, which are shown in the upper left plot of fig. 3 in relation to the sulfate concentration, which serves as an indicator of the degree of iron disulfide weathering.

The first buffering process is given by the solution of calcite and lasts up to sulfate concentrations of approximately 1800 mg/L.

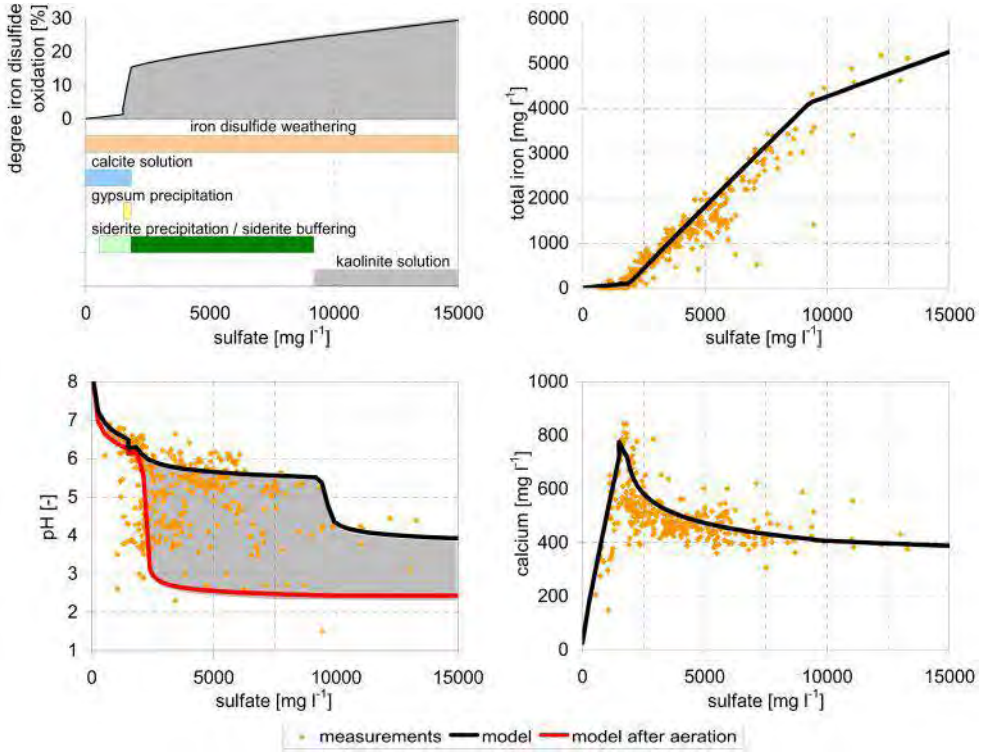

Figure 3 Mineral transformations during iron disulfide weathering and development of iron and calcium concentrations as well as pH as a function of the master variable sulfate; measurements and batch model

As a result of the rising calcium and sulfate concentrations in the solution, precipitation of gypsum starts at sulfate concentrations of about 1500 mg/L. It stops in parallel with the calcite solution as calcium is needed for the formation of gypsum. Siderite precipitation starts at sulfate concentrations of approximately 500 mg/L and similarly terminates with the end of calcite solution as carbonate for siderite formation is no longer available. At sulfate concentrations higher than 1800 mg/L resolution of siderite takes place connected with the release of hydrogen carbonate, which serves as a buffering mechanism up to sulfate concentrations of about 9200 mg/L. Afterwards solution of clay minerals represented by kaolinite begins.

Concentrations of total iron increase with rising sulfate concentrations (fig. 3, upper right plot). At sulfate concentrations of up to 1800 mg/L iron concentrations are low, which is due to siderite fixing. At higher sulfate concentrations, there is a clear rise in iron concentrations, as iron is firstly released by iron disulfide weathering and secondly by the resolution of siderite minerals. The slope of the curve decreases at sulfate concentrations above 9500 mg/L because of a depletion of siderite. The model results fit well with the measured data.

The pH decreases with an increasing degree of iron disulfide weathering (fig. 3, lower left plot, black line). During calcite buffering, the pH is above 6.3, within the siderite buffering interval it amounts to 5-6, whereas buffering by clay minerals (represented by kaolinite) results in a pH of about 4. Principally, iron appears in bivalent form in the dump groundwater. Trivalent iron occurs in traces only, as firstly the groundwater is anoxic due to prevalent iron disulfides and secondly trivalent iron is precipitated at pH values greater than 3. Nonetheless, partial aeration took place during groundwater sampling. Because of the low hydraulic conductivity of the dump material, part of the samples had to be taken from the standing water in the pipe after dry pumping on three consecutive days. This led to an iron oxidation and precipitation of hydroxides or hydroxysulfates respectively, which is connected with a release of acidity and a decrease of the pH. Measurements are mostly in between the black (no aeration) and the red line (full aeration) in the plot, indicating a partial aeration during the sample procedure.

Calcium firstly shows an increase (fig. 3, lower right plot), which is due to calcite dissolution. Concentrations decrease again with the beginning of gypsum precipitation to a level of 400 to 600 mg/L. Measurements fit well with the model.

The considered solubility product pK_{sp} of the mineral phase calcite is -8.48, which is in line with the value of the wateq4f.dat database. With respect to gypsum, pK_{sp} was selected as -4.53, which represents a very slight supersaturation of +0.05 for precipitation to occur compared to the considered database. Based on the measurements, pK_{sp} of siderite was determined to be -9.25, which implies a supersaturation of +1.2. This is in line with the findings of Lenk & Wisotzky (2007). This is possibly due to surface effects during the process of precipitation or the formation of mixed iron(2)-calcium-carbonates. Matching measured liquid and solid contents resulted in the assumption that one third of the iron released during iron disulfide weathering gets irreversibly bound by the formation of trivalent iron oxyhydrates. The maximum allowed partial pressure of CO_2 is 30%.

Resulting from the batch model, the great variability of measured groundwater quality data can be described by the variation of the degree of iron disulfide oxidation, which is a consequence of the varying exposure of the dump material connected with a differing contact to oxygen. The overall mean degree of iron disulfide weathering determined from the mean sulfate concentration of the dump groundwater, which is 3660 mg/L, amounts to 18%.

Future development of dump groundwater quality and solute discharge

The coupled groundwater flow and reactive solute transport model was realized for nine vertical-plane cuts in groundwater flow direction to the Pleiße river (fig. 2). In the following, one cut representing the groundwater flow from northern direction to the Pleiße river in the region of the river crossing the dump is investigated in detail (red-black dashed cut in fig. 2).

By implementing the hydrogeochemical batch model into every model cell, the model simulates the discharge of the solutes originating from iron disulfide oxidation with the groundwater flow. Considering a homogenous distribution of the iron disulfide oxidation rate, iron concentrations in the cut for the year 2010 are between 2000 and 4000 mg/L in the upper part and between 1000 and 2000 mg/L in the lower part of the dump (fig. 5). Concentrations are reproduced in the model by considering the iron disulfide turnover during the dump formation and shortly thereafter. Low hydraulic conductivities and slow groundwater flow lead to the preservation of high iron concentrations in the dump body for long time intervals. The vertical concentration gradient is due to the oxygen input via the dump surface leading to a secondary iron disulfide oxidation next to the primary one within the whole dump body. For the year 2100, the model predicts a clear reduction of iron concentrations in the upper aquifer because of diluting effects by groundwater recharge and the solute discharge to the river. This effect continues into the future. Correspondingly, modeled concentrations for the year 2300 are below 250 mg/L in the upper aquifer. In contrast, solute discharge from the lower aquifer is small, as the hydraulic conductivity is comparably low in this part of the dump.

Results considering a random distribution of the iron disulfide oxidation rate using Monte Carlo simulations show the same trend, though iron concentrations in the cut are additionally influenced by scattering.

Solute fluxes from the dump into the direction of the Pleiße river were calculated as weighted means per length of the respective river section combining the results of all nine cuts. From this, iron loads of approximately 1000 kg/d are calculated for a time interval of the next 100 years (fig. 4). Afterwards fluxes decline to 190 kg/d in 2400. Derived sulfate loads are in the order of 3500 kg/d during the next 100 years and decline to 2000 kg/d until 2400. Compared to iron the decrease of fluxes with time is less significant, as there is a great pool of gypsum bound in the dump, whose resolution takes place during a very long time interval. Monte Carlo simulations show similar solute fluxes compared to the homogenous distribution of iron disulfide oxidation, which indicates that spatial variability is averaged in the dump discharge.

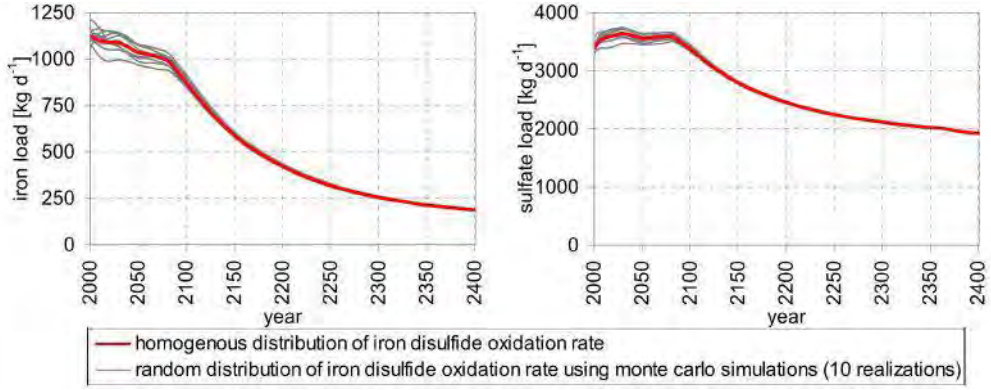

Figure 4 Modeled fluxes of iron and sulfate from the dump in direction of the Pleiße river

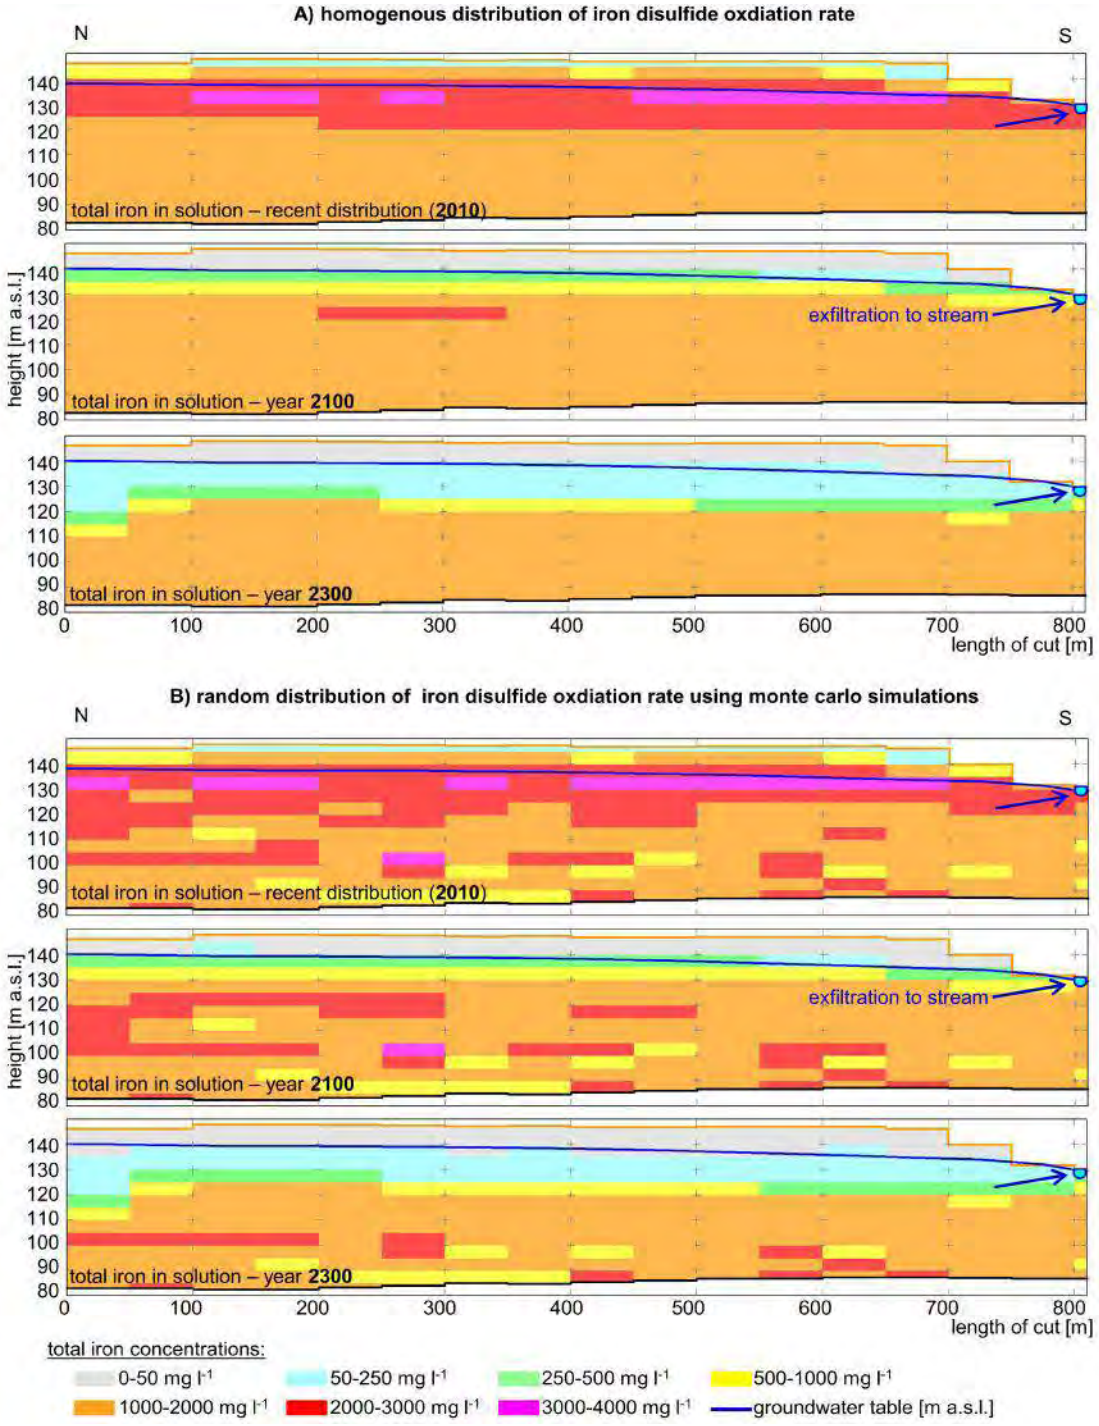

Figure 5 Modeled concentrations of total iron in den liquid phase along the red-black dashed cut (cf. Fig 2), time slices 2010, 2100 and 2300

CONCLUSION

The presented study is based on a large data pool of groundwater analyses and investigations on the solid phase of the dump material. This allows a detailed examination of the ongoing processes and the derivation of a process-oriented model. It was therefore possible to determine the relevance of single mineral phases during the genesis of the dump groundwater and to derive the solubility products of the participating mineral phases. This enables extrapolation to other areas with a less comprehensive pool of data.

The wide scattering of measured iron and sulfate concentrations is most likely due to the varying degree of iron disulfide oxidation. During solute transport modeling this was taken into consideration by a Monte Carlo simulation.

The newly developed model coupling allows a precise prediction of the future development of dump hydrogeochemistry and the expected solute fluxes into the Pleiße river, indicating that the process of solute discharge from lignite mining dumps exhibiting low hydraulic conductivities takes place on very long time intervals.

ACKNOWLEDGEMENTS

The study was funded by the Lusatia and Central German Mining Administration Company (LMBV), which also provided the immense data pool for investigation.

Simulating the Performance of a Dry Stack Tailings Design for Water Control Permitting

ABSTRACT

Dewatering tailings to below saturation prior to placement in a permanent storage facility, referred to as "dry stacking", offers significant advantages over conventional slurried tailings storage, especially in arid environments. These include significantly reduced water requirements, a much smaller environmental footprint, and reduced long-term water management costs. Even with these clear benefits, dewatered tailings have not previously been permitted in the state of Nevada. In order to demonstrate to the regulators that the proposed tailings design is feasible and to lay out a clear path for evaluating the performance of the facility design, a series of models and presentations were developed.

The modeling results provided clear evidence that the facility design and phased stacking plan would produce unsaturated tailings, limiting the potential flow of water into the subsurface and impacts to groundwater. A sensitivity analysis of the modeling was conducted to evaluate the parameters used and the possible facility performance under less than ideal conditions. The sensitivity modeling suggested that flux into the foundation layer is most affected by the water content of the placed tailings. Geochemical modeling was also conducted, incorporating results from the Meteoric Water Mobility Procedure results of site specific tailings samples. The geochemical modeling predicted that the geochemistry of the interstitial fluids in the tailings would be of generally good quality and below state standards.

The facility's Water Pollution Control Permit was issued in August 2013, conditionally approving the placement of dewatered, unsaturated tailings in the facility. The project has agreed to construct and monitor a field test cell over a minimum of a one-year period. Additional project work is currently underway to monitor water contents in the initial operating cells of the tailings storage facility. Both of these seek to validate the modeling results and demonstrate the efficacy of the tailings storage facility design.

Keywords: Modeling, dewatered tailings, geochemistry, permitting

INTRODUCTION

Dewatered tailings, also known as dry stack tailings (DST), are better suited for the arid southwest than traditional slurried tailings disposal due to the reduced water requirements, environmental footprint, long-term water management, and seepage. Additionally, concurrent reclamation can be completed on DST facilities because of the increased trafficability of the material compared to slurried tailings. Despite these clear benefits, as a DST facility had not previously been constructed or permitted in the state of Nevada, additional steps were necessary to permit such a facility with the Nevada Department of Environmental Protection (NDEP).

Prior to developing the predictive models to support the permitting of the DST facility, a presentation was provided for the regulators to help educate them on the operational design and function. This approach had previously been proven successful for permitting a DST facility in Arizona. The initial presentation was conducted in late 2011, and included the general concepts of dry stacking (including the water content of unsaturated "dry" tailings, the conveyance process, stacking plans, stability of DST, seepage mechanisms, and trafficability) and a path forward for additional site-specific field investigations, laboratory analyses, and modeling that could be used to verify the proposed design concept.

A second presentation was held in early 2012. The time between the presentations allowed the regulatory officials to digest the original information and develop specific follow-up questions about the project. The second presentation focused on the specific design proposed for the project and results of the predictive modeling. This second meeting also focused on presentation of a proposed alternative lining concept. For this project, an alternate liner system consisting of 0.45 meters (m) (18 inches [in]) of compacted tailings with a maximum permeability of $4x10^{-4}$ centimeters per second (cm/s) was proposed. These presentations and the predictive modeling laid the groundwork for open communication, which allowed for approval of the water pollution control permit application. The remainder of this paper focuses on the predictive modeling that was used to support these presentations and ultimately the permit application.

CONCEPTUAL MODEL

The predictive modeling was developed to supplement the engineering design report for the DST facility. Figure 1 shows the conceptual model of a DST facility. The conceptual model for a DST facility is similar to other mining facilities. The conceptual model shown in Figure 1 illustrates the system water balance components which consist of precipitation, evaporation, runoff, infiltration, and seepage. The tailings material will also contain some solution when it is placed in the facility (interstitial water), adding to the initial water balance of the facility. The gravimetric water content of the tailings at placement is expected to range from 15% to 17%, equivalent to a volumetric water content of 26%.

MODELING TECHNIQUE AND INPUTS

VADOSE/W (GEO-SLOPE, 2007a), a two-dimensional variably saturated flow model that is part of the Geo-Studio suite of programs, was used to simulate the flow of water through the tailings mass in the DST facility. To determine the quality of the water that could potentially seep from the base

of the facility into the foundation soils, fate and transport modeling was completed using a combination of particle tracking and geochemical modeling.

The objectives of the infiltration and seepage analyses were to assess:

- The performance of the proposed closure cover configuration;
- The rate of infiltration into the tailings mass;
- The rate of seepage to the drains; and
- The rate of seepage from the DST to the foundation soils.

The objective of the fate and transport analysis was to:

- Predict the geochemical quality of the seepage from the base of the DST facility;
- Evaluate the potential for seepage into the foundation soils; and
- Evaluate the potential for any seepage to impact the regional groundwater system.

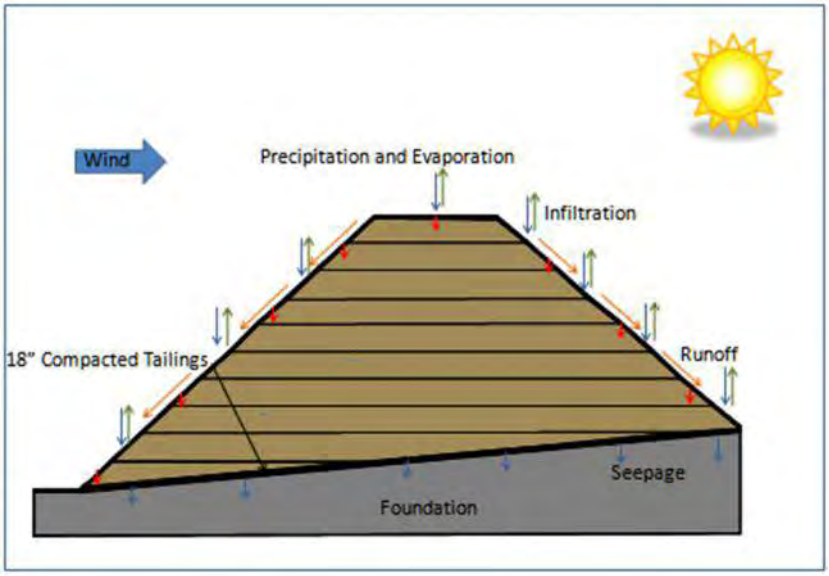

Figure 1 Conceptual Flow Model DST Facility

Climate

The Project is located in low barren hills above a dry alluvial valley. The climate is arid with hot summers and relatively mild winters, allowing nearby mining operations to work year round. Vegetation in the immediate project area is sparse low brush with local grasses suitable for limited cattle grazing. The alluvial Mason Valley to the west, hydrogeologically separate and different from the project area, contains numerous agricultural fields, primarily alfalfa, onions, vegetables, and pasture lands. These fields are watered by irrigation canals from the nearby Walker River and groundwater wells.

Daily climate data were used for the analyses. Actual daily precipitation and minimum and maximum temperatures were obtained from a meteorological station in Yerington, Nevada (WRCC Station 269229). The relative humidity and wind speed were obtained from Fallon Naval Air Station, Nevada (TuTiempo Station 724885[KNFL]). A data set spanning from 1914 through 2010 was assembled. The average annual precipitation is 12.2 cm (4.81 in) and the median precipitation is

11.7 cm (4.61 in) for the years included in the data set. A year matching the median precipitation, 1970, was chosen for use in the modeling to represent the typical conditions. The 75th percentile precipitation for the data set is 14.8 cm (5.83 in), occurring in 1918. This year was modeled to represent above average precipitation conditions. The daily measured precipitation for 1970 (median precipitation) and 1918 (above average precipitation) was applied over the models in 24-hour time periods distributed according to a sinusoidal function that peaks at noon (normal distribution).

Material Properties

Table 1 summarizes the material parameters used in the VADOSE/W (GEO-SLOPE, 2007a) models for the DST facility. The material properties used in the VADOSE/W (GEO-SLOPE, 2007a) models were based on the design properties of the facility, laboratory and field testing of actual Project materials, and literature values where no site specific data was available.

Table 1 Material Properties

Material Type	Porosity	Dry Density# (g/cm^3)	Saturated Hydraulic Conductivity (cm/s)	Initial Volumetric Water Content# (%)	Thermal Properties
Soil Cover	0.40*	1.92	5.0×10^{-4}*	10	silt
Capillary Break	0.34*	1.92	7.2×10^{-3}*	10	sand
Tailings	0.39^	1.60	3.1×10^{-3}^	26	sand

Facility Design

The configuration of the DST facility includes a 0.45 m (18 in) thick layer of compacted tailings placed directly on the foundation soils. The compacted layer of tailings will act as the liner unit to limit the flux of water into the underlying foundation soils. Over the compacted tailings layer, a network of gravel drains will be placed that will be used to collect and convey the solution draindown from the tailings into lined ditches and ponds. The gravel drains will be piped such that the draindown solution will be removed from the drainage network to an adjacent lined pond, where it will be managed. The DST will be placed over the compacted tailings and drainage network in 9 m (30 foot [ft]) lifts using mobile conveyors. Equipment traffic will be limited on the tailings surface as to avoid development of compacted zones, to minimize the changes to the material properties after stacking, and to limit the development of preferential flow paths. The stacking plan has been designed such that after the placement of each lift of tailings material, the tailings mass will be allowed to drain for an average duration of one year prior to the placement of the next lift. This will maximize the amount of solution that will be able to freely drain from the facility, and minimize the amount of solution remaining in the tailings material when future lifts are placed. The cover designs that were evaluated included both a single-layer and two-layer system incorporating a capillary break.

INFILTRATION AND SEEPAGE MODELING

The DST facility was modeled at three points in time (after placement of the first lift, mid-operations, and fully stacked facility). In order to assess the quantity of infiltration that is expected under ambient conditions and above average precipitation conditions, as well as the performance of the cover system, the model simulated typical climate conditions, a worst case runoff conditions, and a multi-day storm (worst case infiltration conditions)

RESULTS AND DISCUSSION

The first model simulated the placement of the first lift of the DST in the facility. The drainage of the first lift of the tailings material was considered to be the most likely to influence the water content of the foundation soils, thus the highest potential to impact the regional groundwater system. Additionally, the first lift model precipitation events have the shortest flow path to the foundation layer.

The volumetric water content of the tailings decreases steadily after placement, as illustrated in Figure 2. Figure 2 presents the simulated change in water content at individual points along a vertical profile through the central portion of the first lift of the DST facility. The locations near the surface of the lift decrease most rapidly because water is being removed by both downward flux and evaporation. The deeper portions of the lift have a slower decline in water content because this area is not subject to evaporation and this area is receiving water from the upper portions of the lift. The one point starting with a lower water content of approximately 17% by volume is representative of the compacted tailings layer at the base of the facility. It should be noted that based on the results of the sensitivity analysis, regardless of the starting volumetric water content, over the one year period after placement of the first lift, the tailings drain to a water content that is just above the residual water content of the material.

The second scenario simulated the flux through the DST facility after five lifts of tailings have been placed (approximately the mid-point of the mine life). The volumetric water content of the mid-operations scenario model one year after placement is presented in Figure 3. The flux into the drainage network at the base of the facility decreases with time and as additional lifts are stacked on top, because the water content of the tailings in the lower layers of the dry stack is smaller than the water content in the newly placed tailings material. The water in the newly placed tailings material has fewer connected pathways to travel through to the lower layers because the underlying layers have a lower water content causing the pore spaces to be physically disconnected from each other. At the beginning of the placement of the fifth lift, the water begins to migrate downward. However, there is sufficient storage capacity within the underlying tailings material that the water “spreads out” through the facility ensuring low water contents throughout the entire facility.

The final DST facility modeling scenario was the completely constructed facility. When the last lift of the DST facility is placed, the water within the tailings moves downward through the facility as observed from the mid-operations model. As with the mid-operations model, because the lower lifts have partially drained, there is sufficient storage capacity within the tailings material to dissipate the water content throughout the facility, resulting in only small zones of slightly increased water content.

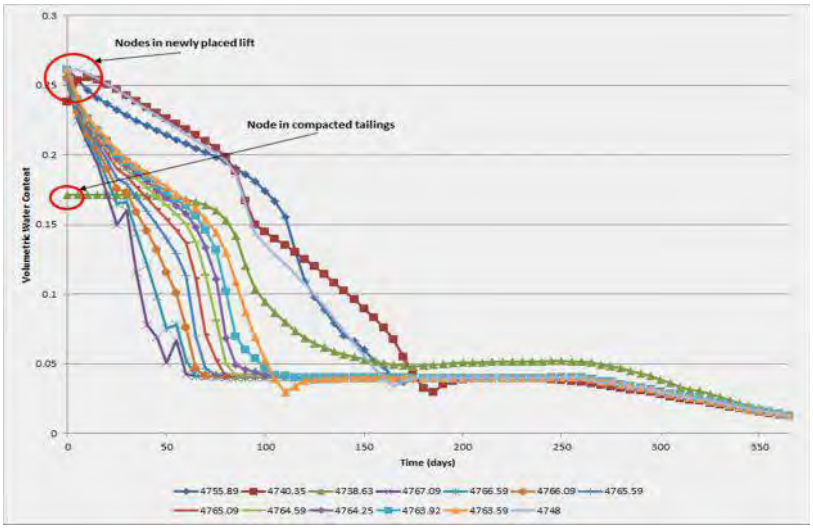

Figure 2 Volumetric Water Content with Depth – First Lift Model

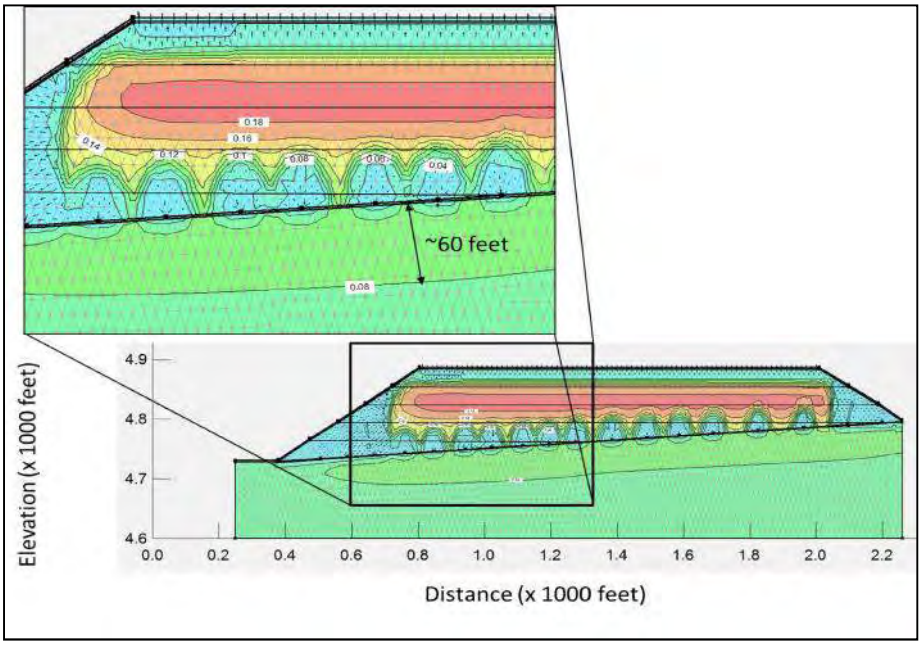

Figure 3 Volumetric Water Content DST Facility - Lift Five Model One Year After Tailings Placement

The net negative water balance of the site limits the amount of precipitation that infiltrates into the DST material. On average, only 29 days each year have measureable precipitation with approximately 18 cm (7 in) of snow. Based on the modeling, infiltration into the facility will be minimal under median and above average precipitation conditions. Figure 4 presents the daily flux of water into or out of the DST facility for the four climate scenarios modeled. The results suggest that only isolated storm events may result in infiltration into the upper surface of the tailings, and because of the high evaporation, this water is then later lost as it is drawn back out of the facility.

This behavior is typical of a store and release design, such as the evaluated cover systems. Annual evaporative water loss through the cover is calculated to be greater than annual precipitation for the Project. The placement of the cover improves the performance of the facility surface by reducing the flow of water, both into and out of the facility, by approximately 25%. These models only considered a one year period after placement of complete cover.

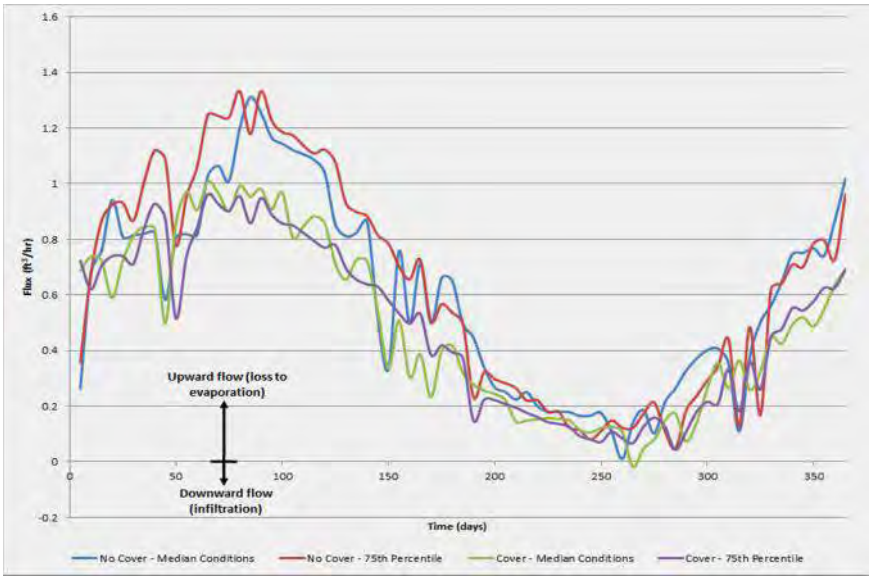

Figure 4 DST Water Flux at Tailings Surface – Completely Constructed Facility

FATE AND TRANSPORT MODELING

The flow modeling determined the quantity of water infiltrating into and seeping through the tailings in the DST facility, including the time of contact. To determine the quality of water that could potentially move downward from the base of the facility and seep into the foundation soil and possibly impact the underlying groundwater system, fate and transport modeling was completed.

Conceptual Fate and Transport Model

The fate and transport models were built from the same geometry and material properties as the infiltration and seepage models. As determined from the infiltration and seepage modeling, the general flow path through the DST is in the vertical direction. Therefore, the fate and transport modeling focused on the potential transport paths, both upward and downward within the DST.

Fate and transport modeling was completed in two separate steps. The first step involved particle tracking to determine the path of the water flow, including which materials the flow would come in contact with and the time required to reach the subsurface. The next step was a simple geochemical mixing model representing the water quality due to contact with the materials in the facility. The results of these two modeling steps were an estimation of where potential seepage would occur, including the water quality of the potential seepage. The following sections provide more detail of these two modeling steps.

Particle Tracking

Particle tracking modeling was performed using the program CTRAN/W (GEO-SLOPE, 2007b), another component of the GeoStudio software suite. The particle-tracking portion of the modeling estimated the flow paths of the water entering, traveling through, and exiting the DST facility. The particle tracking modeling also determined how long the water was in contact with each of the materials, and if seepage would be expected to travel into the foundation materials. The particle tracking model was run for a period of 10 years to allow sufficient time to determine water velocities, should it be determined that water is seeping into the foundation soil. This would allow for the calculation of travel times through the subsurface and the time required for water to reach the top of the regional groundwater system.

Geochemical Modeling

Geochemical modeling was conducted using the computer code PHREEQC (Parkhurst and Appelo, 1999), a reaction path chemical equilibrium model supplied by the U.S. Geological Survey (USGS). In addition to a computer code, geochemical modeling requires a database of thermodynamic and kinetic parameters associated with the chemical reactions. For this Project, the WATEQ4F database (Ball and Nordstrom, 1991) was chosen. However, this database did not include all of the metals of concern to the Project, so additional metals were added to the file. The information added was obtained from the PHREEQ database published with the computer code (Parkhurst and Appelo, 1999). The combination of the two databases provided the broad range of metals needed to predict water quality.

Model Construction

The particle tracking model used the same geometry and material properties as the infiltration and seepage model. The water content and flow conditions resulting from the flow modeling were also used as the starting conditions of the particle tracking models. The particles were placed near the top of the tailings surface, and throughout the facility. The model was run using a forward tracking solver, which calculates the path of the water flux within the facility and associated velocities.

The input solutions representing the leachable constituents in the geochemical modeling were based on the Meteoric Water Mobility Procedure data for three site specific tailings samples: Northwest Open Pit, Northwest Underground, and East/E2. All three samples are representative of tailings material to be placed within the DST facility. Solution concentration data from all three samples were mixed in equal proportions as the starting solution for fate and transport modeling. Each of the starting solutions was equilibrated with atmospheric concentrations of oxygen and carbon dioxide, which was also used to determine the relative pe (redox potential expressed as –log of electron activity). Starting solutions were also equilibrated with mineral phases commonly found within the DST to allow for precipitation or dissolution of minerals from solution.

Model Results

Based on the seepage and infiltration modeling, the water in the DST facility is expected to move downward through the tailings until drainage of the pore water is compete or the pore spaces become sufficiently disconnected to prevent further drainage. Therefore, fate and transport

modeling was completed to determine if water draining to the compacted base of the facility would be captured by the drainage network, or if the water would seep through the compacted base, enter the foundation soils, and potentially be transported into the groundwater system.

The model showed that there is minimal downward movement of water within the DST after the initial drainage of the interstitial water, as would be expected because the system is not saturated. Modeling that focused on the first lift of the DST facility showed that the particles primarily moved laterally towards the drains. None of the particles were shown to travel from the facility into the underlying foundation soils. This suggests that the slightly increased water content in the foundation soils observed in the seepage modeling is an equilibration condition instead of actual water movement. The results of the particle tracking of the full facility also show minimal movement of the particles. The greatest movement is only in the zone of highest water content, which does drain downward. Once those zones draindown, the remaining particles moved very little. The particles placed near the outer surface of the facility show the strong influence evaporation has on this facility. The particles in this area are moving upward toward the surface of the facility. The lower water contents and drying in the outer areas of the facility supports this movement.

Even though the flow and the particle tracking models suggests that no water will be transported to the regional groundwater system, the quality of the seepage from the facility was estimated using a geochemical mixing model to demonstrate it would meet regulatory standards. The results of the mixing model suggest that any potential seepage from the DST facility would still be of generally good quality and below NDEP Profile 1 Reference Values.

CONCLUSION

Based on the results of the infiltration and seepage modeling, the DST facility is not expected to impact the regional groundwater system. Under median and above average climate conditions, the water balance of the facility is negative, where draindown of entrained water into the network of drains and subsequent ponds and evaporation are the largest components of the system. Under these conditions potential seepage is limited to the entrained solution in the tailings material, and not precipitation. The flow of entrained solution into the foundation soils and increase in water content of the foundation soils is anticipated to be minimal throughout operations and into closure. The stacking plan includes periods of draining prior to the placement of subsequent tailings lifts, which maximizes the amount of solution that is allowed to drain into the drainage networks.

The compacted tailings layer placed under the main tailings mass is sufficiently impermeable to limit the seepage of water into the foundation soils, and to help move the drained solution to the drainage network. Regardless of the permeability of the compacted tailings layer, even with minor seepage into the foundation soils, there would only be a two percent increase in the volumetric water content. The depth of influence based on the modeling is less than 24 m (80 ft) below the base of the facility, indicating no anticipated impact to regional groundwater system, approximately 90 m (300 ft) below the facility. Based on particle tracking, there is no movement of water from the DST to the zone of influence suggesting equilibration of the system rather than transport.

NDEP reviewed the modeling and through discussions with the mining company, approved the facility's Water Pollution Control Permit in August 2013 including the DST facility. A field test cell was agreed upon to demonstrate over a minimum of a one-year period that the DST concept and the alternate lining approach would be fully protective of the environment, particularly the

underlying groundwater system. Initial tailings deposition cells will be constructed with an HDPE liner while the test cell is constructed and data analyzed. Additional project work is currently underway to develop, design, construct, instrument, and develop success criteria for the test cell to demonstrate its protectiveness of the environment.

Using PhreePlot to Calibrate Mining Related Geochemical Models: A User's Perspective

John Mahoney
Mahoney Geochemical Consulting, USA

ABSTRACT

With the release of the program PhreePlot, geochemists obtained a method to better understand and quantify geochemical processes. PhreePlot's ability to optimize a wide range of parameters in PHREEQC based models provides a simple and direct method to better calibrate geochemical models. In its fitting routines, PhreePlot calculates the weighted residual sum of squares [W(RSS)] between the measured (observed) and modeled data. The optimization routine minimizes this value by changing user defined variables in the attached PHREEQC model. The combination of several fitting options, plus flexibilities inherent in PHREEQC, allows for a range of approaches in quantitative geochemical data evaluation. The simplest applications permit straightforward fitting of experimental or field measurements for solubility product calculations. The fitting of surface complexation reactions over a large range of experimental conditions is another straightforward application. Many parameters in PHREEQC such as surface site densities, and rate constants are suitable for fitting and can be used to match measured data with modeled results. The quantitative understanding from these rigorous fits can produce stronger insights about the geochemical processes and potentially simplify regulatory reviews.

Keywords: PHREEQC, PhreePlot, Model optimization, Arsenic, Surface complexation

INTRODUCTION

The program PhreePlot (Kinniburgh and Cooper 2011) uses PHREEQC (Parkhurst and Appelo 2013) to prepare a wide variety of figures including species distribution plots, Eh-pH diagrams, and other types of activity - activity plots. To construct these figures, PhreePlot cycles through a range of user defined conditions such as pH, oxygen fugacities or pe, and component concentrations. Numerous options are available to make these figures and even animations can be prepared using the Hunt and Track method (Kinniburgh and Cooper 2004) to define the Eh-pH conditions, and a separate looping option to set a range of concentrations (see PhreePlot Website). Because it uses a large thermodynamic database the figures are more accurate than the simpler plots described in many textbooks and references.

The ability to change a "tagged" parameter(s) provides a means to optimize selected parameters through the fitting routine. There are several fitting options in PhreePlot, and it is this capability that is described below. In the current PhreePlot user's guide there are a limited number of fitting examples. The following describes a range of applications and efforts to learn how to prepare optimized geochemical models.

A comment about program installation is appropriate. Although installation of PhreePlot and its two supporting programs GPL Ghostscript and GSview appears daunting, it is straightforward. The key issue I have run into is to make sure that the path to the pdf maker is correctly listed in the pp.set file.

COMPARISON OF PhreePlot TO UCODE_2005

Before PhreePlot was released in 2011 one optimization method that was commonly employed was to couple a batch version of PHREEQC with UCODE_2005 (Poeter et al. 2005). Mahoney et al. (2009) used such an approach to fit four uranyl surface complexation constants onto the hydrous ferric oxide (HFO) surface. It was decided that these data sets and models would provide a reasonably straightforward test of PhreePlot capabilities. Both UCODE and PhreePlot use a similar method to "tag" the adjustable parameters and to tabulate observations. Consequently, the original batch PHREEQC input files and observation data files required little updating to accommodate the PhreePlot requirements. The same order of fitting the constants as described in Mahoney et al. (2009) was used. The K_1^{int} and K_2^{int} values were first fit using carbonate free experimental data, and then K_3^{int} was fit and finally the K_4^{int} value was fit. PhreePlot calculated the essentially same log K^{int} values (Table 1) reported in Mahoney et al. (2009).

Table 1 Comparison of batch PHREEQC/UCODE_2005 values of surface complexation constants to values estimated using PhreePlot, the NEA database for uranyl complexes was used in all calculations.

Uranyl Surface Complexation Species	Fitted K^{int}	Reaction	Method	Optimized Log K	Standard Deviation	No. of Observations/Data Sets
Strong Site Uranyl	K_1^{int}	Hfo_sOH + UO_2^{+2} = Hfo_sOUO_2^{+} + H^+	PHREEQC/ UCODE_2005	3.792	±7.97E-01	38/2 Strong and weak site complexes fit simultaneously
			PhreePlot	3.7897	±8.3788E-01	
Weak Site Uranyl	K_2^{int}	Hfo_wOH + UO_2^{+2} = Hfo_wOUO_2^{+} + H^+	PHREEQC/ UCODE_2005	2.507	±3.33E-01	
			PhreePlot	2.508	±3.4097E-01	
Uranyl Monocarbonate	K_3^{int}	Hfo_wOH +UO_2^{+2} + CO_3^{-2} = Hfo_w$OUO_2CO_3^{-}$ + H^+	PHREEQC/ UCODE_2005	9.150	±1.25E-01	81/10

			PhreePlot	15.2753	Not reported	

SCORODITE AND YUKONITE SOLUBILITY DATA

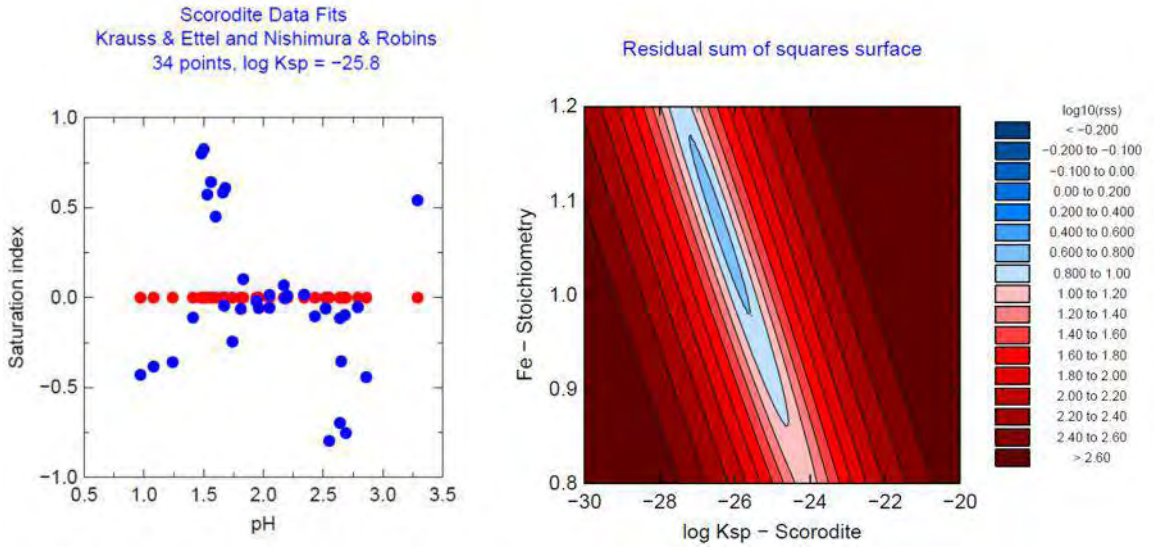
PhreePlot was used as part of an effort to calculate the solubility product constant (K_{sp}) and formula for yukonite, a calcium ferric arsenate, which may control arsenic concentrations under some conditions, has had various formulas reported in the literature. The first step was to determine if PhreePlot could provide a log K_{sp} value and a reasonable stoichiometry for a known phase. Scorodite ($FeAsO_4 \cdot 2H_2O$) was selected for several reasons. Its formula is well defined and I had worked with the data set presented in Langmuir et al. (2006), and like yukonite it is also a ferric arsenate. In the 2006 paper, we used a trial and error method with a simple sum of the squared residuals to confirm the fits. As an exercise, a data set was used to verify the previously reported solubility product (log K_{sp}) for crystalline scorodite. The data set contained 34 points. In the model, the log K_{sp} was adjusted to optimize the fit by minimizing the difference between the "observed" target saturation indices (SIs), which were set to zero, and having PhreePlot fit the SIs by adjusting the log K_{sp} value. These calculations can easily be conducted using just PHREEQC and averaging the saturation indices, but to accomplish further fittings using PhreePlot this step was required. PhreePlot uses tags, which are identified by less than and greater than symbols < > within the PHREEQC part of the file. For the initial setup only the <log_k1> value changed.

```
Scorodite_fitted        405

        FeAsO4:2H2O = Fe+3 + AsO4-3 + 2H2O

        log_k               <log_k1>
```

For crystalline scorodite, Langmuir et al. (2006) reported a log K_{sp} value of -25.83±0.07. For the PhreePlot calculations, the observation file defined the SIs for all samples at 0.00. This is different from calculations typically run using PhreePlot, where the measured data set shows the variance. In these calculations, the observed values (the SIs) were set to zero so there is no variance, but the experimental data do contain the variance, so the weighted residual sum of squares [W(RSS)] is still calculated. PhreePlot calculated log K_{sp} of -25.78±0.0724 for crystalline scorodite. For the 34 data points, an average log K_{sp} calculated with PHREEQC was -25.774 (Figure 1a).



Figures 1a,b PhreePlot prepared figure showing saturation indices as a function of pH. The "observed" values (red dots) are all set to zero. The blue dots represent the model calculated saturation indices after the program has adjusted the log K_{sp}. Figure (b) RHS, shows a contour plot showing the relationship between log K_{sp} and stoichiometric value for Fe

The next calculation was an effort to simultaneously calculate the log K_{sp} for scorodite and the stoichiometric coefficient for Fe^{+3}. This effort was a precursor to the yukonite calculations. To accomplish the second part of the fit the dissolution equation was redefined and the -no_check option was included:

Fe<stoic1>AsO4:2H2O = <stoic>Fe+3 + AsO4-3 + 2H2O

The relationship between <stoic1> and <stoic> was defined by the following numericTag:

numericTags <stoic1> = 1.00*<stoic>

The final estimates were close to the previous estimate with values of:

log_k1 = -26.40 ± 0.34799, stoic = 1.0739 ± 0.040576

For such a large dataset a fit closer to 1.0 for the Fe stoichiometry was expected; the fit is somewhat disappointing. The contour plot is a feature in PhreePlot that helps refine optimization search strategies. Figure 1b shows the RSS as a function of log K_{sp} and Fe stoichiometry. A blue lens (valley) shows the strong relationship between the two variables, and without other data it would be difficult to further refine the result.

The subsequent yukonite modeling required the simultaneous fitting of up to four parameters (calcium, iron, arsenic and the solubility product constant). Data were provided by Dr. George Demopoulos and his students from McGill University.

The general formula for yukonite is $Ca_xFe_y(AsC_4)_z(OH)_A$, where A balances the charge according to:

$$A = 2.0\,X + 3.0 \times Y - 3.0 \times Z$$

Due to convergence issues with the hydroxide term, most models were run using the Bound Optimization BY Quadratic Approximation (BOBYQA) method rather than the simpler Non-Linear Least Squares (NLLS). The BOBYQA method uses fitting parameter ranges. In one series of calculations, calcium was fixed at 2.0 and in the BOBYQA method the ferric and arsenate stoichiometries were allowed to vary within a small range. Both methods produced similar conclusions with a possible log K_{sp} near -111, and a formula of $Ca_2Fe_3(AsO_4)_{3.03}(OH)_{3.92}$ (Figure 2a), or - $Ca_2Fe_3(AsO_4)_3(OH)_4$. Waters of hydration were not estimated. The room temperature results remain suspect; X-ray diffraction did not confirm yukonite in most of these samples. Furthermore, activities of the Fe^{+3} component show a large variation, which influences the calculations. A simulation using data from 75°C and confirmed to contain Yukonite produced a log K_{sp} of -119 and a formula of $Ca_2Fe_3(AsO_4)_2(OH)_7$. The fit appears to be poorer than the room temperature fit. The discrepancy between the formulas and log K_{sp}'s and the visually poor fits for the data at 75°C (Figure 2b) raise questions about all the optimization results.

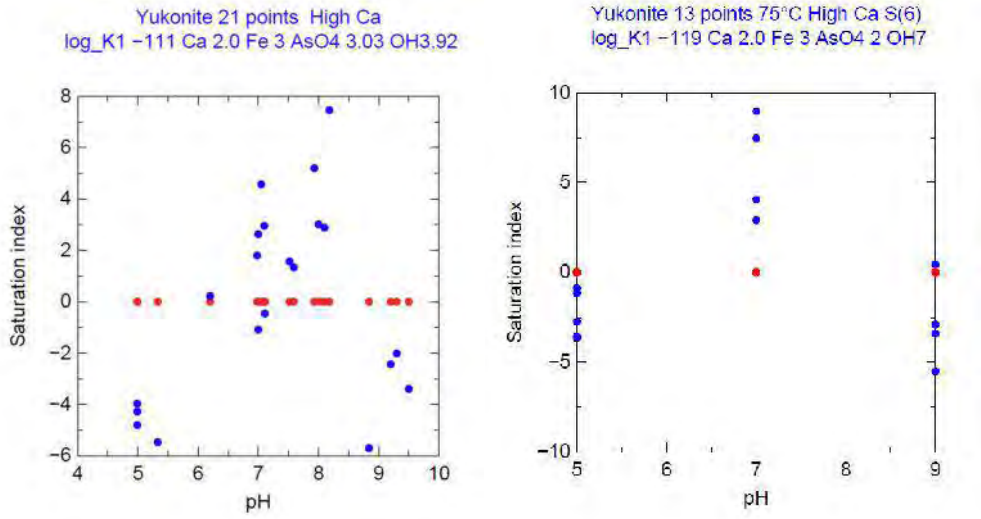


Figure 2a, 2b Example PhreePlot calculations to estimate Yukonite solubility. Figure 2a (left) shows the saturation indices for the 21 samples (blue dots) at room temperature after fitting, compared to "observed" values which were set to zero (red dots). Figure 2b (right) was for 13 samples run at 75°C.

Detailed contour plots based upon 52 data points were used to better define the relationship between the Fe and AsO_4 stoichiometric proportions. PhreePlot sweeps through a defined range of reaction coefficient values, and using the activities of the components in the solutions and the assigned stoichiometries the program calculates a log K_{sp} value. Using the measured concentrations, PhreePlot then calculates a W(RSS) and prepares contour plots of the $\log_{10}$(rss) values. Numerous data sets were evaluated. Figures 3a and 3b show some of these results. Unlike the deep narrow valley shown for scorodite (Figure 1b) the yukonite figures indicate that there are large "flat" zones where the iron stoichiometric values, in particular, show a large degree of uncertainty. For the $Ca_2Fe_y(AsO4)_z(OH)_a$ calculations for the oval that represents the minimum RSS (darkest blue), the

range for Fe is more than 2.0 units long, and even the As ranges from 1.65 to 2.65. To get a sense of how the Ion Activity Product (IAP) changes with changing stoichiometries, calculations were prepared using 1200 mg/L arsenic as arsenate, 1000 mg/L Ca, 2500 mg/L sulfate, the pH was fixed at 7.5 and ferrihydrite was present. These IAP values do not represent saturated conditions. "Yukonites" show a large spread in their log *IAP* values, for the upper point with Fe at 2.6 and AsO_4 at 2.4 (Figure 3a) the log *IAP* is -96.10. The smallest Fe value within the oval was Fe at 0.55 and AsO_4 at 1.65, and the log *IAP* value was -29.70. For the $Ca_3Fe_y(AsO4)_z(OH)_a$ formulas (Figure 3b) the upper and lower *IAP* values were -126.16 and -44.61. These ranges are too great to develop unique formulas and log K_{sp} values.

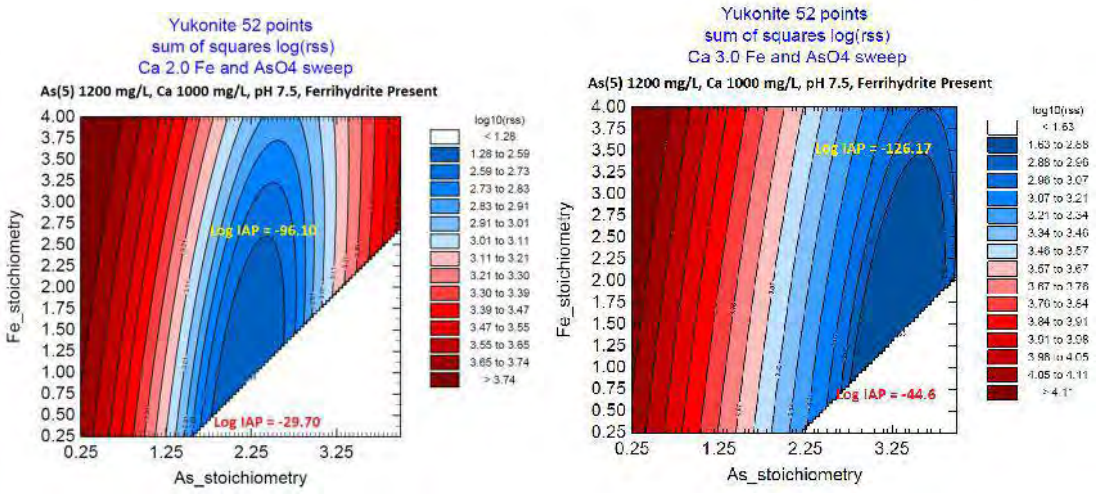

Figure 3a, 3b PhreePlot calculations used to evaluate stoichiometry factors for Fe and As for Yukonite. Figure 3a (left) used a Ca value of 2 and Figure 3b (right) used a Ca value of 3. White regions failed to converge in PHREEQC

Based upon the simpler scorodite calculation the approach appears to work, but it is highly sensitive to the quality of the data, and for yukonite the final parameter fit remains inconclusive at this time. It may be that ferric activities change as these samples age, further complicating the fitting calculations. This type of approach may be best for an iterative evaluation of laboratory data.

CALCULATION OF SURFACE SITE CONCENTRATIONS

The ability to vary any parameter in a PHREEQC model, provided one has sufficient data, means that better geochemical models can be developed, tested and refined using PhreePlot. In preparing a surface water discharge model for a uranium mill Mahoney and Frey (2014) used PhreePlot in several ways to produce a more rigorous model. One example is shown below.

The surface discharge model performed a series of mixing calculations for each year's discharge. The model is mainly a mixing model that uses site specific water balances to mix the various waters including surface waters and precipitation (rain and snow) at the discharge point. Additional surface water and precipitation dilute the composition in the two downstream lakes. The model was setup to allow for a wide range of options including evaporation, mineral precipitation and surface complexation. When appropriate, reactions in the receiving water bodies are included. Each model year was simulated independently. There was no year to year carry over in the models.

In the surface water discharge model, source waters are mixed at a discharge point (reservoir) and the waters flow through two additional bodies of water. By volume the two most important waters are from pit dewatering operations followed by the treated effluent from the mill. Chemical loads come from the treated mill water (Mill Discharge in Figure 4). For many major ions, simple mixing and dilution processes explain their concentrations in the downstream locations. However, arsenic concentrations are too low in the reservoir to be explained solely by mixing and dilution, so there must be an alternative geochemical process. Initial source term concentrations are too low for mineral solubility controls, so surface complexation becomes a means for arsenic attenuation. There is sufficient dissolved iron, particularly from the pit dewatering wells, that ferrihydrite appears to form and settle at the mixing/discharge point. Therefore, as part of the arsenic evaluation a surface complexation sub-model was included in the overall setup. Previous experience with arsenic surface complexation in pit lake models indicated that arsenic concentrations are unrealistically low when the standard site density parameter of 0.2 moles of weak HFO sites per mole of ferrihdyrite precipitated is used. Therefore, it was decided to prepare a model that tracked the amount of HFO that formed as the waters were mixed at the discharge point, and then fit the surface site density to obtain the best fit for the arsenic in the three lakes. Twelve data points, each representing annual averages for the various source terms and the concentrations in the three lakes for a total of 36 points were used. Surface complexation constants reported in Gustafsson and Bhattacharya (2007) for arsenic were used instead of the values in Dzombak and Morel (1990), speciation reactions defined in Langmuir et al. (2006) and Marini and Accornero (2010) were included. Based upon other observations, it was decided to estimate two different site concentration values. The first one was for the first six years, followed by another estimate for the final six years. The calculations adjusted the <sitedens> value. For years 1 through 6 the PHREEQC input follows:

```
SURFACE 1012000
 Hfo_wOH Ferrihydrite    equilibrium_phase <sitedens>    53400
 Hfo_sOH Ferrihydrite    equilibrium_phase <Strong>
```

The lines of input shown above tell PHREEQC to define the weak site surface concentration Hfo_wOH based upon the moles of ferrihydrite present as an equilibrium_phase times the value of sitedens. The surface area is assumed to be 600 m^2/g or 53400 m^2/mole of Ferrihydrite present as the equilibrium_phase. The strong site concentration Hfo_sOH is defined in a similar manner, but the strong site value is related to the weak site concentration through the following numericTag, <Strong>="<sitedens>/40". A similar setup was used for years 7 through 12, but the terms were <sitedens2> and <Strong2>. As ferrihydrite only forms in the first lake it is also the only location where surface complexation takes place. The lowering of concentrations in lakes 2 and 3 is caused by dilution from surface waters and rainfall/snowfall.
The PhreePlot estimated site density values were:

sitedens = 9.0497E-02 ± 1.7243E-02

sitedens2 = 1.2961E-01 ± 1.4404E-02

The site density values for the Hfo_wOH sites are about half of the value originally defined in Dzombak and Morel (1990), they defined a value of 0.2 sites per mole of HFO precipitated for weak sites. The fitted model uses smaller values and is considered to be more conservative (i.e., protective of the environment). Figure 4 compares different model setups for arsenic. The figure

shows a mixing/dilution only scenario (purple circles) which clearly overestimates estimates arsenic concentrations. The red lines are the optimized arsenic modeled concentrations based upon the fitted site densities. Surface complexation also appears to influence uranium concentrations, but a problem was noted, the site density values when fitted to the arsenic data produced models that underestimate uranium surface complexation and overestimate uranium concentrations in the lakes. The differences between the arsenic and uranyl fits suggest a disconnect in the surface complexation databases. It was decided to retain these lower site density values because higher surface site concentrations would lower dissolved arsenic concentrations producing a less conservative model. Also, the values tend to predict somewhat high uranium concentrations, which are considered to produce a more conservative model.

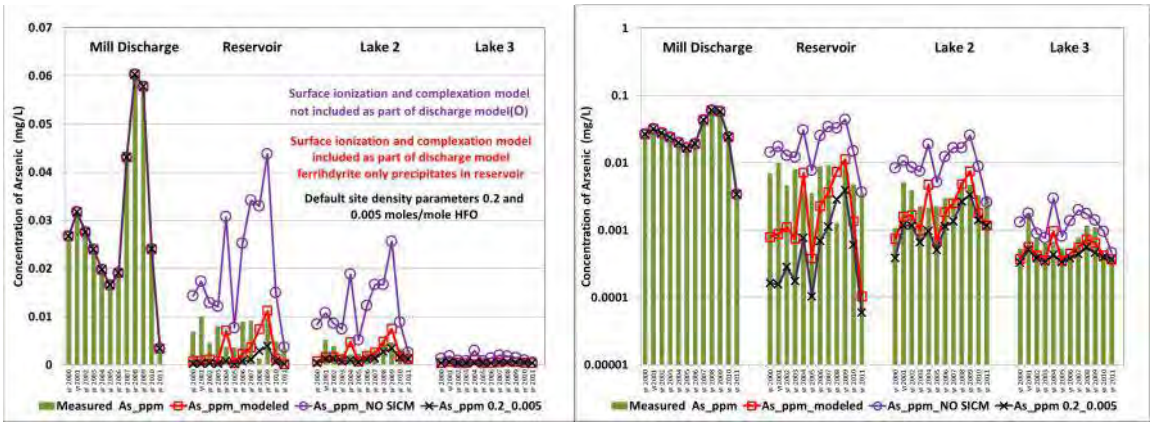

Figure 4a, 4b Surface water discharge model for arsenic, linear (a) and log concentrations (b). The figures shows observed values as green lines, the open circles did not include surface complexation reactions, red squares represent PhreePlot fitted model with surface complexation reactions on precipitated HFO. Black X's used the default site densities defined in Dzombak and Morel (1990)

ESTIMATION OF RATE LAW CONSTANTS

The following example shows how laboratory leach tests can be used to optimize a parameter in a geochemical model. Rate constants for kinetic models can also be fit using PhreePlot. Leach amenability studies (also called bottle roll tests) were used to determine rate constants for uraninite (UO_2) dissolution for a proposed in-situ uranium recovery operation in the Powder River Basin (Wyoming). The rates and rate law were subsequently included in a PHAST (Parkhurst et al. 2012) model to understand the nature of the leaching process in a three dimensional reactive transport system. The tests are used to demonstrate that the uranium mineralization is capable of being leached using conventional in-situ leach (ISL) methodologies. The leaching solution consisted of sodium bicarbonate (1 g/L $NaHCO_3$) as the carbonate complexation agent. Hydrogen peroxide at 0.5 g/L H_2O_2 (equivalent to 235 mg/L of dissolved oxygen) was used as the uranium-oxidizing agent. These tests were conducted at ambient pressure.

The bottle roll tests used 300 grams of solid and 1500 ml of leachate, the subsequent PHREEQC models maintained these proportions and used 200 grams of solid for 1 L of solution. The bottles were rolled for 16 hours (5.76e4 seconds), with eight hours available to collect samples and set up the next cycle, each sample under went six cycles. Ten tests were run and the ten samples covered a range of concentrations.

A kinetic model was developed to obtain a rate constant (k) for the dissolution of uraninite. A modified version of the rate law developed by Posey-Dowty et al. (1987) was used. The original rate law was:

$$dU/dt = k\left({}^{SA}/_{V}\right)(O_2)^{0.5}((U_s - [U])/U_s)$$

Where: k is the rate constant at 4.9(±2.2)e-5 (mole)(1)(m)$^{-1}$(atm)$^{-1/2}$(min^{-1}) reported by Posey-Dowty et al., (1987). Converting to seconds the value is 8.166 e-7(mole)(1)(m)$^{-1}$(atm)$^{-1/2}$(sec^{-1}), and

- SA is surface area in m^2,
- V is volume of water in liters,
- O_2 is the partial pressure of oxygen in solution in atmospheres,
- U_s is the uranium concentration at saturation, and [U] is the concentration of uranium at that point in time (units are moles) in the model.

The original paper was vague in defining the *(Us-[U])/Us)* term. They did not define the mineral that was to attain saturation or provide a limiting value for U_s, so the rate law was changed to:

$$dU/dt = k\,(SA/V)(O_2)^{0.5}((1\text{-}SR(\text{“}Schoepite\text{”}))^{*}(m/m0)^{power}$$

SR is the saturation ratio (IAP/K_{eq}), and the term *((1-SR(“Schoepite”)* slows the overall dissolution rate as the solution approaches saturation with schoepite. This type of limiting term is commonly used in many PHREEQC rate laws. At equilibrium, the SR = 1.0 and the dissolution process halts. For these models, uraninite was originally considered as the limiting mineral, but leaching conditions were so far from saturation with uraninite, that the SR term is exceedingly small, and would not have any impact as dissolution proceeded. The m0 value represents the moles of uraninite at time 0.0, and m represents the number of moles as the dissolution process proceeds. The *(m0/m)* term provides a means to adjust the rate as the uraninite particles get smaller and the surface area decreases. For theoretical reasons, the term is usually raised to the 0.67 power, but better fits were noted in the models where the power was 1.0.

The preferred RATES keyword for uraninite dissolution written in BASIC is:

```
RATES; Uraninite; -start
10 if(si("Uraninite")>=0) then goto 50
15 if (m <= 0) then goto 50
20 rate=<Rate_constant>*parm(1)*((10^SI("O2(g)"))^0.5)*(1-
SR("Schoepite"))*((m/m0))
30 moles = rate * time
40 if (moles > m) then moles = m
50 save moles
-end
```

The model also required a surface area (SA/V) value and uraninite concentrations, i.e., the m0 terms for each sample. Laboratory data provided the uraninite concentrations and QEMSCAM data indicated that the average diameter of the uraninite particles was 20 microns. The particles were assumed to be spherical, the areas were calculated. These surface areas are the parm(1) term in each model.

The 2012 models were prepared using PHREEQC and the rate constant was estimated using a trial and error method. The fit was based upon the Test 8 results, which had the largest concentration of uranium. Each bottle roll test was modeled using a one cell six shift TRANSPORT model. Essentially, the “beaker” (or cell in PHREEQC syntax) contained 0.2 kilograms of solid sample and

contacted 1 liter of fresh leaching solution six times. The time for each contact was assumed to be 16 hours or 5.76e4 seconds. For the trial and error approach this provided the needed concentrations as a function of time. The rate constant was used to prepare models of the other nine tests and the observations were compared to the modeled values. The trial and error fits were acceptable. To get the sequence of data in the SELECTED_OUTPUT file for the PhreePlot calculations, rather than use six shifts, an initial non-transport step was used, followed by five shifts in the TRANSPORT step, and the PRINT keyword turned writing to the SELECTED_OUTPUT file off and on, as needed (D. Parkhurst, personal communication).

The earlier trial and error method produced a rate constant of 2.8e-7(mole)(1)$(m)^{-1}(atm)^{-1/2}(sec^{-1})$, the value was subsequently used in a PhreePlot calculation to estimate the W(RSS) and for the sixty data points, the W(RSS) was 1.5754e04. Two different models were run using PhreePlot. The first model used the $(m/m0)^{0.67}$ function (Figure 5) and the second model used a 1.0 power. A smaller W(RSS) was produced for the $(m/m0)^{1.0}$ model. This is probably because the uraninite particles are not all 20 micron spheres. The best fit value is 2.433e-7 ±1.011e-8 (mole)(1)$(m)^{-1}(atm)^{-1/2}(sec^{-1})$. This value is close to the trial and error value estimates in 2012. Both rate constants are less than the value reported by Posey-Dowty et al. (1987). But differences are relatively small and could be related to differences in sample storage and handling, particle size estimates and subsequent estimation of surface areas, or differences between the two ore deposits.

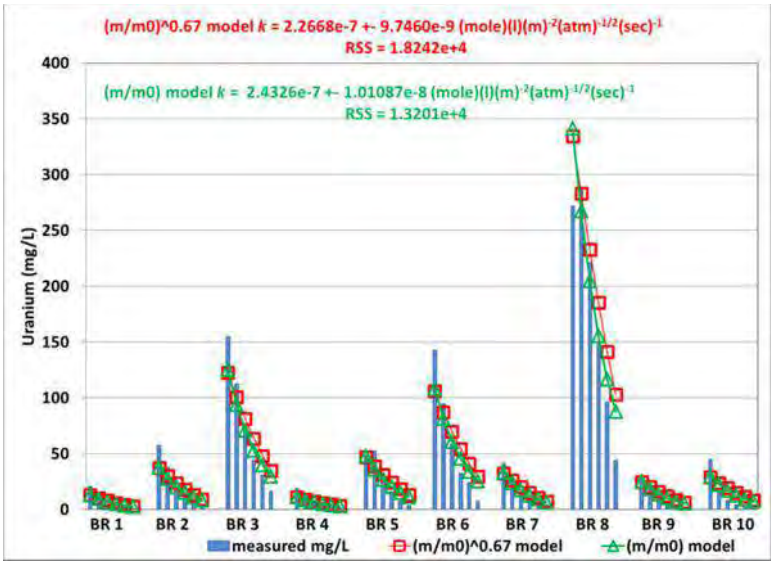

Figure 5 Bottle roll test data (blue lines) and PhreePlot Model fits. Red squares used an $(m0/m)^{0.67}$ term, green triangles used an $(m0/m)^{1.0}$ term

CONCLUSIONS

Nearly any parameter in a PHREEQC model can be fit using PhreePlot to better match observational data and produce a better model. Potential future applications might include: adjusting mixing parameters in a pit lake model to match early recovery time concentration data in the nascent lake to further refine the water balance, or for a 1 dimensional transport model, the length of time for shifts in a series of cells can be fit to calibrate transport velocities by matching the concentrations observed over time in a down gradient well with the modelled estimates. Such

calibrations even with limited early data produce better long term predictive models. The surface water discharge model described previously demonstrates this process. An improved understanding of the role of different processes also provides further insights about the whole discharge operation, which further strengthens the "what if" scenarios that are typically considered in predictive models.

This paper has shown just a few applications of the fitting capabilities in PhreePlot. It is hoped that other users will continue to apply PhreePlot to their specific studies.

ABSTRACT

Aroeira dam received for the last 10 years, zinc silicate tailing material (willemite $Zn_2(SiO_4)$ from the mill plant (USICON) of Vazante Mine. Votorantim Metals is nowadays developing a Feasibility Project of Zinc-Ambrosia oxidized sulphide zinc deposit, located in the nearby municipality of Paracatu / MG. This new ore deposit is subdivided into two parts (North and South Cava), and the North Cava has 800,000 tons of oxidized sulphide zinc ore. The financial feasibility of the ore exploitation of this new deposit requires the disposal of the new tailings into Aroeira dam. Work recently carried out by Votorantim Metals technicians using acetic acid leaching test in several samples of tailings had values for lead and cadmium relatively high. However, test results from the same samples using water leaching test (using distilled water) had values of the same parameters (Pb and Cd) below the detection limit of the analytical methods for most of the samples. Considering the above issues presented here in terms of the solid waste metal leaching, Ambrosia tailing characteristics should be considered in the final tailing disposal. In addition, the actual tailings are low in sulfide and have large neutralizing capacities, so decreasing in pH conditions are not expected. The work presented here aims to demonstrate through a hydrogeochemical model, using geochemical waste material characterization data and the software PHREEQC the environmental impact of disposal of Ambrosia mining waste into Aroeira tailings dam. The study developed here required the water sampling and tailing geochemical characterization according to MABA, NAG, water leaching test, and SPLP and the use of these results together with the dam physical characterization for the development of a future water quality model for this reservoir. Results obtained from this work allow someone to state that the disposal of Ambrosia tailings will not impact the local water resources.

Keywords: Water quality prediction, Hydrogeochemical modeling.

INTRODUCTION

Aroeira dam received for the last 10 years, zinc silicate tailing material (willemite $Zn_2(SiO_4)$ from the mill plant (USICON) of Vazante Mine. Votorantim Metals is nowadays developing a Feasibility Project of Zinc-Ambrosia oxidized sulphide zinc ore deposit, located in the nearby municipality of Paracatu / MG. This new ore deposit is subdivided into two parts (North and South Cava), and the North Cava has 800,000 tons of oxidized sulphide zinc ore. The disposal of the new tailings into Aroeira dam is fundamentally important for the financial viability of this new project. Considering the above issue presented here in terms of the solid waste management, Ambrosia tailing characteristics should be considered in the final tailing disposal. So, Aroeira tailing dam will receive new solid waste coming from Ambrosia ore deposit and also coming from other zinc mine (Extremo Norte mine). The first one is an oxidized sulphide lead and zinc ore deposit and the last one is a zinc silicate ore deposit hosted in a geological carbonate formation. The aim of this work is to demonstrate, using a PHREEQC model, that the current tailing dam can receive this new tailing material (Ambrosia deposit and Extremo Norte mine) without significant changes in the water quality of the current conditions of this reservoir.

METHODOLOGY

The water sampling of the tailing pond was carried out on July/2014 by the technicians of HidroGeo & Amplo consulting companies with the help and support of an employee from Votorantim Metals who was the boat operator for the water sampling collection. The water sampling was based on the Brazilian technical standards ABNT NBR 9897 - Planning sampling of liquid effluents and receiving bodies and ABNT NBR 9898 - Conservation and sampling techniques of liquid effluents and receiving water. This technical norm presents the fundamental aspects that should be followed during any water sampling campaign. All the technical aspects related to water sampling were strictly executed by field technicians.
The methods of analysis of water samples were those recommended by the Standard Methods for the Examination of Water and Wastewater, in its 21st edition of 2005. Some methodologies of the Environmental Protection Agency (EPA) were also adopted regarding the collection and analysis of industrial effluents and receiving waters.

Water and tailing sampling

Eight water samples were collected at four points inside the Aroeira tailing dam at two depths as shown in Table 1 below. To collect these samples field technicians used the Van Dorn bottle. Table 1 presents the identification and characteristics of the sampling points, and the depth of the collection. Tailing samples of the future waste material that will be discharged into the Aroeira reservoir were obtained from metallurgical plant, provided by Votorantim Metals for geochemical characterization.

Tailing samples from the Aroeira reservoir were collected at the same time that water samples were collected (Table 1).

Table 1 List of water and tailing sampling points at Aroeira reservoir

Point	ID	Date	Hour	Location: coordinate UTM SAD 69 Zone 23		Sample Depth (m)
1	ARO 01	07/02/2014	12:31	307906	8012222,	0.5
	ARO 02		13:30	307906	8012222	2.0
2	ARO 03	07/02/2014	14:27	307597	8012347	0.5
	ARO 04		15:00	307597	8012347	2.5
3	ARO 05	07/02/2014	15:27	307689	8012245	0.5
	ARO 06		15:50	307689	8012245	6.5

	ARO 08		16:50	307746	8012169	8.5

The parameters temperature, pH, dissolved oxygen (DO), electrical conductivity (EC) and redox potential (Eh) were measured in situ with a multiparameter equipment Hanna HI9828. The equipment was calibrated daily as part of the protocol (QA / QC) for data collection in the field.

The samples were filtered and preserved in the field with membrane of 0.45 μm to determine the dissolved metals (Figure 1).

Figure 1 Photo of the water sampling and filtering procedure in the Aroeira tailing dam.

Tailing Geochemical characterization (Mill plant, Vazante tailing, Extremo Norte tailing, Ambrosia tailing)

Geochemical characterization for acid generation (static tests) and metal leaching potential were performed in all tailing samples. For acid generation it was used modified acid base account (MABA) and net acid generation (NAG) and for metal leaching it was used synthetic precipitation leaching procedure (SPLP) and a Brazilian version of TCLP test that uses diluted strong acids and acetic acid at pH 5 (ABNT NBR 10,005) and another Brazilian test that uses water leaching procedure for characterization of solid waste (ABNT NBR 10,006). All these metal leaching tests were used to better understand the potential metal leaching capacity of sample at normal and extreme condition of water pH. Results and comments are presented in the next section.

Underneath there is a schematic profile representing the sampling points along the main axis of the tailing dam (Figure 2).

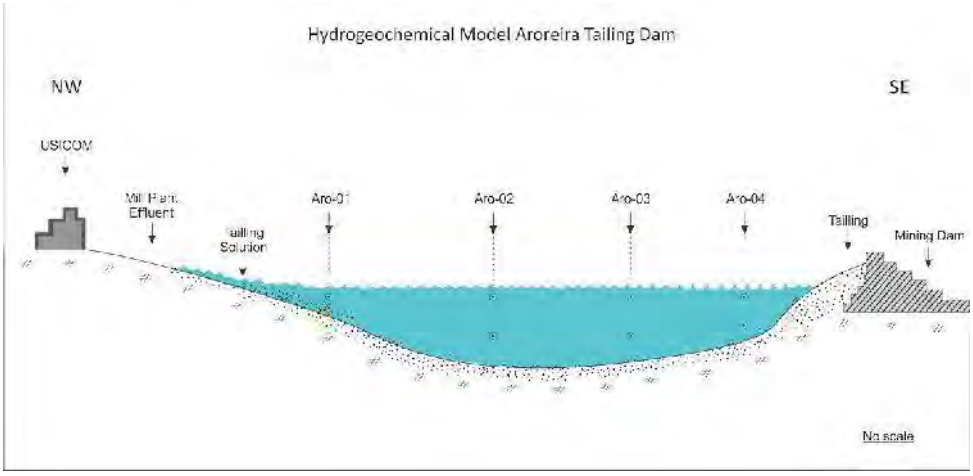

Figure 2 Schematic representation of the sampling points of water and tailings from Aroeira dam.

Conceptual Site Model (CSM)

To be able to develop a hydrogeochemical model using PHREEQC it is necessary to develop a conceptual site model (CSM) based on the tailing's water balance and solutions chemical composition. Five solutions were considered in this model and they are the following: Solution 1- Underground mine effluent; Solution 2- Mill plant effluent; Solution 3- Rainfall precipitation; Solution 4- Tailing water; and Solution 5- Tailing spillway. These solutions are represented in the following CSM figure (Figure 3). Groundwater contribution was not relevant for this case; therefore, it was not considered in the CSM presented here.

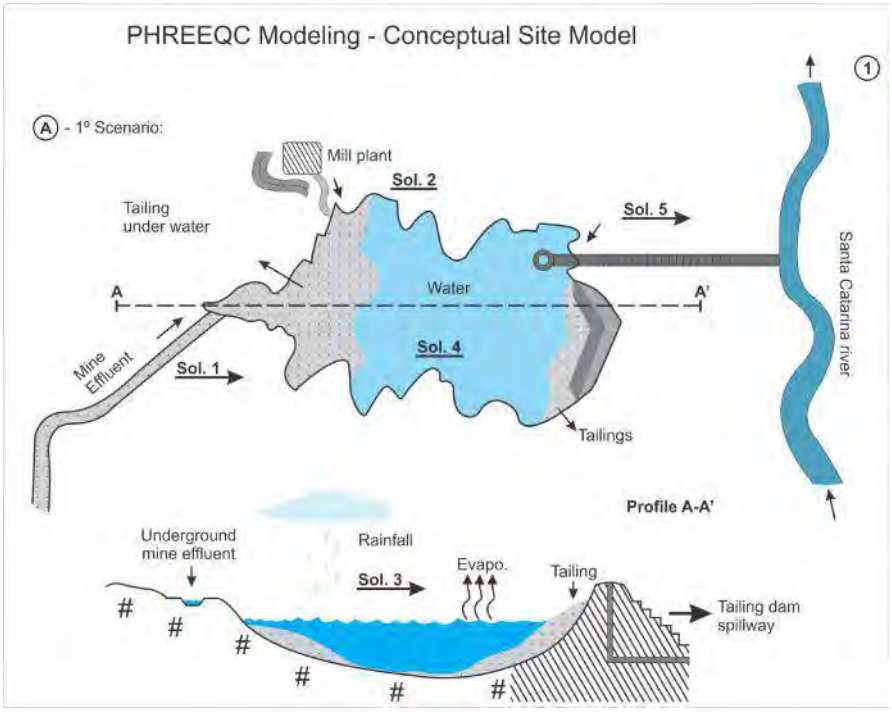

Figure 3 Conceptual site model (CSM) representing a map and a profile of the site, and no scale.

PHREEQC input data

The PHREEQC used in this paper took MINTEQ database to run the model and the input data is basically the water quality of each solution that compound the system to be modelled and the percent volume of each solution, then three scenarios were simulated. The first one was the current tailing scenario where the underground mine effluent mix with the mill plant effluent to make the tailing water composition. The other two scenarios are derivatives of the first one, where just the second solution (solution 2), coming from the mill plant effluent would change considering the new type of ore material that will be processed there.

Hydrogeochemistry model calibration

To be able to calibrate the model the following approach was used. Based on the CSM tailing water chemical composition (solution 4) is derived from the mix of solution 1 (underground mine effluent) and solution 2 (mill plant effluent). Therefore, in this work, solution 4 was used to calibrate the mix of solution 1 and 2. Once, the results obtained from the model come out very similar to the results obtained from solution 4 the model was considered calibrated and it was run for the other two scenarios where solution 2 would change in function of the new ore material or mix of ore that would be processed in the mill plant. So, the only solution that will change from scenario 1 to 2 and 3 is solution 2 (Table 2).

Table 2 Hydrogeochemical calibration of PHREEQC using current scenario of the tailing dam

Solutions	*Solution ID*
Solution 1	Underground Mine Effluent (sampling point ARO 09)
Solution 2*	Current mill plant tailing; Ambrosia; Mix of tailings (Ambrosia, Vazante and Extremo Norte)
Solution 3	Annual precipitation water quality
Solution 4	Tailing dam water quality (Average of sampling points)
Solution 5	Spillway of the dam (sampling point ARO 10)

* Solution 2 will change in function of the 3 scenarios.

RESULTS AND DISCUSSION

Geochemical characterization of the tailing samples

The potential to generate acidity conducted from static tests can be interpreted by various types of graphical forms. In this study, it was chosen one type of interpretation often used for this purpose (INAP, 2009; MEND, 2009) (Figure 4).

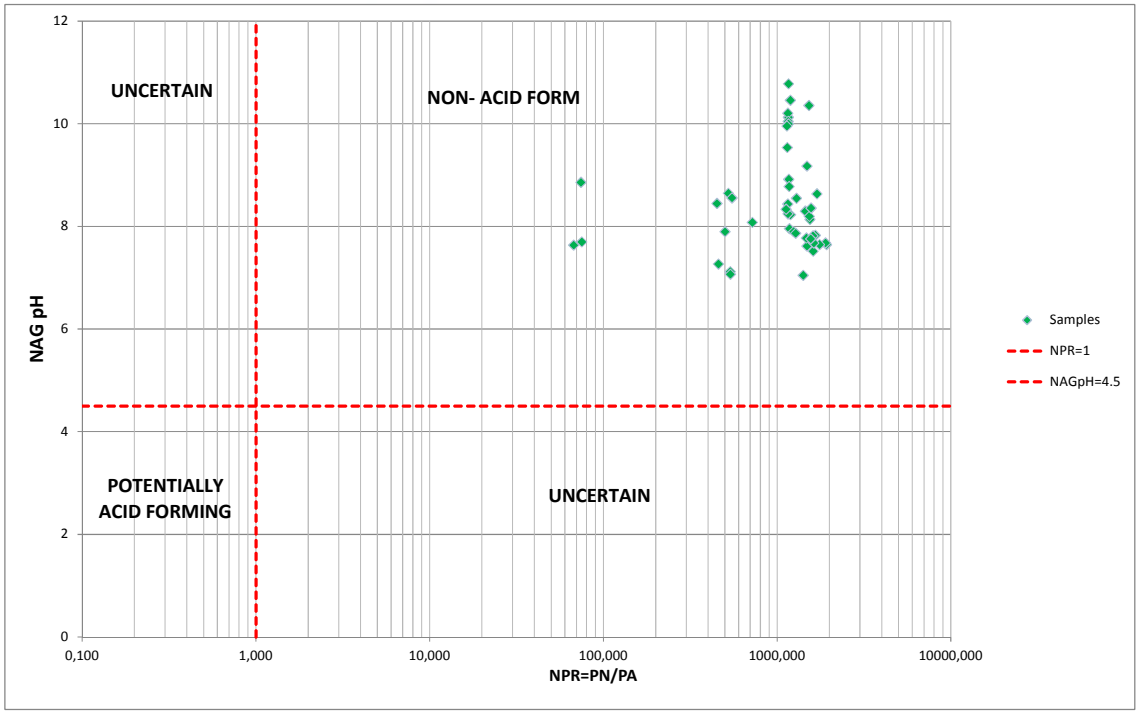

Figure 4

From the results obtained in the MABA and NAG tests presented above it can be concluded that it is very low and unlikely that these tailing samples already displaced or that will be disposed into the Aroeira reservoir will generate acidity. These results are consistent with the mineralogical composition of the rocks that generated Vazante tailing samples that are metamorphosed carbonate sediments, as marls and dolomites, intercalated with phyllites. The geological formation of this zinc deposit is a classical karst environment. In addition, underground water flow in the underground mine is super critic with a water flow rate of 10,315 m^3/hr.

Results of metal leaching test according to the North American standard SPLP, using diluted strong acid at pH 5, (US EPA 1312) presented very similar numbers and the only parameter that showed the greatest potential for leaching was just lead (values varied from 3.74 mg/L to 10.43 mg/L). For modeling purpose neither SPLP test nor the Brazilian acetic acid leaching test results (ABNT NBR 10,005) were used because they do not accurately represent tailing physical chemical conditions. Water leaching results from a mix of tailings at the following proportion 10% (Ambrosia Mine); 40% (Extreme North); 50% (Vazante Mine), used for modeling purposes, is presented in the underneath table (Table 3).

Table 3 Water leaching test in mixed tailings.

Cu	mg Cu/L	<0.003	<0.003	0.006	<0.003	<0.003
Cr	mg Cr/L	<0.01	<0.01	<0.01	<0.01	<0.01
Fe	mg Fe/L	<0.05	<0.05	<0.05	<0.05	<0.05
Mn	mg Mn/L	<0.03	<0.03	<0.03	<0.03	<0.03
NO_3	mg N_NO_3/L	<0.05	<0.05	<0.05	<0.05	<0.05
pH solution (ratio 2:1)	-	9.04	9.08	9.17	9.1	9.18
Ag	mg Ag/L	<0.003	<0.003	<0.003	<0.003	<0.003
Se	mg Se/L	<0.01	<0.01	<0.01	<0.01	<0.01
Na	mg Na/L	8.08	8.23	7.54	7.67	7.57
SO_4	mg SO4/L	24.1	23.7	27.1	27.8	23.7
Zn	mg Zn/L	0.006	<0.005	0.013	0.011	0.006

The only trace metal with significant water leaching values was lead (Pb = 0.03 and 0.02 mg/L). However, this order of magnitude of values obtained for lead (i.e., decimals ppm) is not considered high because of the dilution factor that should be also counted for in this analysis.
Water quality of each solution is presented in the table underneath (Table 4). The water percent volume is presented right after (Table 5). It is noticeable that the solution 1 coming from the underground mine effluent is the biggest percent volume and probably will play major role in the final tailing water composition (solution 4) considering its volume.

Table 4 Water quality input data for PHREEQC model for Aroeira tailing dam at different scenarios.

Considering that there is no gain or loss of water from or to the groundwater in the tailing dam area, the tailing reservoir (Solution 4) is made out of approximately 92% of water coming from the underground mine effluent and 8% of water coming from the mill plant (Table 5). The percent of water coming from rainfall precipitation is not significant therefore it was neglected in this study in particularly.

Table 5 Percent volume of each type of solution used in the hydrogeochemical model.

Solutions	*Volume (m^3/year)*	*Solution ID*	*Percent Volume (%)*
Solution 1	90,436,000.00	Underground mine	91.87
Solution 2	168,340.87	Mill plant	8.10
Solution 3	70,927.57	Rainfall	0.03
Solution 4	2,080,297.39	Tailing water	-
Solution 5	85,759,000.00	Spillway	-

PHREEQC output data

The current tailing pond is basically composed of water from the underground mine (sol. 1 = 91.87%) and solution waste from the beneficiation plant (USICON) (sol. 2 = 8,10%). The mixture of these two solutions must generate another solution very similar in composition to the water dam (sol. 4). The PHREEQC output data for the three modeled scenarios are shown at Tables 5, 6 and 7 below. Scenario 1 is considered in this exercise the calibration operation. It is remarkable that pH from the underground mine effluent raised com 7.3 to 8.4 after being displaced in the tailing dam (sol. 4). This fact means that solution alkalinity coming from the inlet increases in more than 10 times. PHREEQC model was able to consistently represent the field data. For most of the other parameters the different in concentration were not higher than 35%, so this represents a fair agreement between field data and model results , only trace metal such as: Fe, Mn, Zn and Cu that had very low concentration presented relative difference higher than 35% (Table 6).

Table 6 PHREEQC Output data for scenario 1 (model calibration)

Elements	*MIX of Sol. 1 and Sol. 2 (mg/L)*	*Water tailing Sol. 4 (mg/L)*	*Relative difference (%)*
Al	0.033	0.0211	36.6
Ca	33.37	28.79	13.7
Cd	0.0005	0.0005	0.0
Cl	1.00	1.00	0.0
Cu	0.002	0.003	50

Mg	20.60	20.25	24.6
Mn	0.015	0.030	6,2
Ni	0.005	0.010	100
Pb	0.005	0.005	0.0
Zn	0.040	0.023	42.5
pH	7.3	8.40	1.8

Once we got the model calibrated in relation to the tailing water (solution 4), the next step was to run the same model framework in terms of solution volume but now solution 2 would change accordantly to the water leaching from the tailing material generated by the mill plant. Result obtained demonstrates that the addition of tailing from Ambrosia ore deposit to the reservoir will not change significantly water quality of Aroeira tailing dam (Table 6). Sensitivity analysis was done further on to demonstrate that even when someone double the metal leaching results obtained from the geochemical test, simulating a more conservative scenario, final modeling results in the tailing dam still similar to the one obtained here (results not presented). Aluminum and zinc concentration was lower in the current tailing solution and it is probably due to some sorption of this metal with ferryhydrite or another form of iron oxyhydroxides.

For the other scenarios the same procedure as the previous one was used. The system framework was kept the same, except the water composition of solution 2. Now this solution was obtained from a mix of tailing water leaching composition (Table 6). Again the difference between the mix of solution 1 and 2 was close to the standard solution 4 that we use to evaluate the model results. In this particular case sodium and sulfur different was even higher than before and this must be related to field tailing water composition tailing characterization procedure. The mix of sample definitely was not processed with sodium sulphide and sodium carbonate.

Zn	0.076	0.076	0.023
pH	8.25	8.25	8.40

CONCLUSION

All tailings evaluated (current mill plant tailing; Ambrosia tailing; Mix of tailings, Vazante and Extremo Norten tailings) did not show potential to generate acid drainage and have low potential for metal water leaching. They also have very similar geochemical behavior comparing to the waste currently disposed at the bottom of the Aroeira tailing dam. The hydrogeochemical modeling performed in this study using a computational tool PHREEQC, was used to demonstrate this behavior and it reflected the boundary conditions presented above. The solution 1 from the underground mine, due to its large volume (92% of the total water volume), will dominate the water quality of the Aroeira tailing dam and other tailings solutions from the processing plant, solution 2, (i.e., mix of Ambrosia and mix waste) will not be able to change the current quality of the reservoir. Therefore, water quality in the Aroeira dam will not turn into acid and no significant metal solubility from tailing displaced in the dam to the water will occur. So, it is possible to conclude that this new disposal of tailings will not cause any harm to the local environment.

ACKNOWLEDGEMENT

ABSTRACT

Reaction modeling can be a valuable tool in predicting the long-term behavior of waste material if representative rate constants can be derived from long-term leaching tests or other approaches. Reaction modeling using the REACT program of the Geochemist's Workbench was conducted to evaluate long-term drainage quality affected by disseminated Cu-Ni-(Co-)-PGM sulfide mineralization in the basal zone of the Duluth Complex where significant resources have been identified. Disseminated sulfide minerals, mostly pyrrhotite and Cu-Fe sulfides, are hosted by clinopyroxene-bearing troctolites. Carbonate minerals are scarce to non-existent. Long-term simulations of up to 20 years of weathering of tailings used two different sets of rate constants: one based on published laboratory single-mineral dissolution experiments, and one based on leaching experiments using bulk material from the Duluth Complex conducted by the Minnesota Department of Natural Resources (MNDNR). The simulations included only plagioclase, olivine, clinopyroxene, pyrrhotite, and water as starting phases. Dissolved oxygen concentrations were assumed to be in equilibrium with atmospheric oxygen. The simulations based on the published single-mineral rate constants predicted that pyrrhotite would be effectively exhausted in less than two years and pH would rise accordingly. In contrast, only 20 percent of the pyrrhotite was depleted after two years using the MNDNR rate constants. Predicted pyrrhotite depletion by the simulation based on the MNDNR rate constant matched well with published results of laboratory tests on tailings. Modeling long-term weathering of mine wastes also can provide important insights into secondary reactions that may influence the permeability of tailings and thereby affect weathering behavior. Both models predicted the precipitation of a variety of secondary phases including goethite, gibbsite, and clay (nontronite).

Keywords: acid mine drainage, mineral dissolution, mine tailings, water quality prediction, REACT

INTRODUCTION

Predicting long-term weathering behavior of mine waste, though a formidable challenge, holds great importance for the mining industry. Traditional static tests, such as acid-base accounting, provide information about maximum potential acidity, but offer no insight about how that acidity may evolve over time. Results from static tests have great value as screening tools, which form the basis for more costly and labor-intensive studies, such as kinetic tests. Kinetic tests, such as humidity-cell experiments, provide empirical information about the time-dependent weathering of mine waste, but are generally limited by the experimental duration. The longest duration leaching experiments are probably those conducted by the Minnesota Department of Natural Resources (MNDNR), which have been ongoing for more than 24 years, on waste rock from the Duluth Complex, northern Minnesota (Kellogg et al., 2014). The MNDNR also has weathering test results from ongoing 10-year experiments on tailings derived from pilot metallurgical tests on Duluth Complex low-sulfide ores hosted by troctolitic rocks (Lapakko, Olson & Antonson, 2013a). For permitting purposes, time scales of these lengths are challenging as is scaling laboratory tests up to a mine scale. Barrel tests and instrumented tests on waste-rock and tailings piles are being used once mine development has begun to help address this challenge (Smith et al., 2013; Lindsay et al., 2009).

Uncertainty about the long-term behavior of mine waste clouds the decision-making process for many mine-permit applications. Extrapolating laboratory results significantly into the future has significant uncertainty, particularly for experiments in which the acid-generating potential has not been exhausted. This report explores the possibility of using geochemical reaction modeling to predict the long-term weathering behavior of mill tailings from low-sulfide Duluth Complex Cu-Ni-(Co)-PGM ores (Fig. 1). Acid-generating potential is the initial focus of this ongoing study. Major and trace element behavior will be a future emphasis.

The Duluth Complex of northern Minnesota has high potential for future mining of large tonnage, low grade Cu-Ni-(Co)-PGM resources (Ripley, 2014). Collectively, estimated reserves exceed 4.4 billion tons with approximately 0.66 percent Cu, 0.2 percent Ni, and total PGMs ranging between 0.3 and 0.6 mg/kg (Pd > Pt) (Listerud and Meineke (1977). The ores are found in troctolites and gabbros in the lower 100 to 300 m of the Partridge River and South Kawishiwi intrusions (Fig. 1) (Ripley, 2014). The host rocks comprise plagioclase, clinopyroxene, and olivine, with minor amounts of orthopyroxene, biotite, potassium feldspar, and ilmenite; the rocks are essentially devoid of carbonate minerals (Lapakko, Olson & Antonson, 2013a; Ripley, 2014). The principal sulfide minerals are pyrrhotite, chalcopyrite, cubanite, and pentlandite.

METHODOLOGY

Conceptual framework

The goal of this study is to explore the feasibility of using geochemical reaction computer software to model the long-term weathering behavior of tailings generated from the disseminated, low-sulfide ores at the base of the Duluth Complex for time periods spanning decades. The 10-year weathering test results for pilot-test tailings from the Duluth Complex low-sulfide ores are used as a basis to validate various simulation parameters (Lapakko et al., 2013a). The disseminated sulfide ores at the base of the complex are characterized by a low sulfide content (generally < 1 wt. % S)

and virtually no carbonate minerals (Lapakko and Antonson, 2012; Lapakko, Olson & Antonson, 2013a; Ripley, 2014). Thus, the acid-neutralizing potential of the mine waste is supplied by silicate minerals such as plagioclase, olivine, and pyroxene.

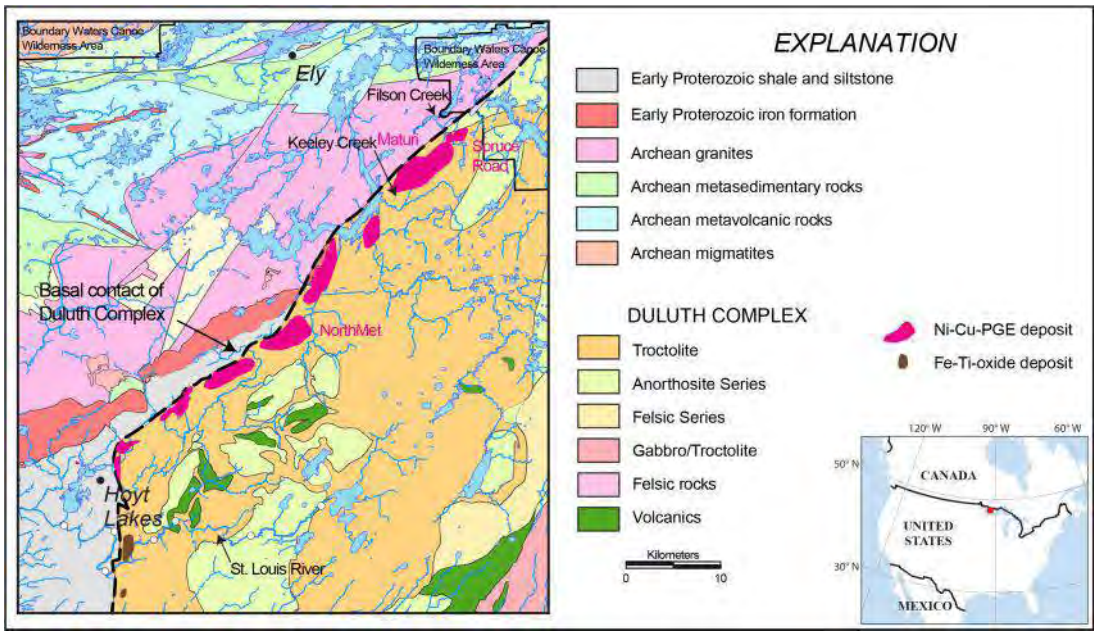

Figure 1 Geologic map of the Duluth Complex and older rocks in the vicinity of the disseminated Cu-Ni-(Co)-PGM deposits.

Software

The software package used in this study is the suite of programs included in the Geochemist's Workbench, primarily the program REACT (Bethke, 2008; Bethke and Yeakel, 2014). REACT simulates the reaction of a specified mass of solid with 1 kg of solution. Equilibrium modeling titrates increments of the solid into the solution, following a specified number of steps, allowing reaction progress to be followed. Kinetic modeling, using user-defined rate constants for solids, reacts a specified amount of solids with 1 kg of solution for a specified amount of time.

Thermodynamic and Kinetic Data

This study used the Lawrence Livermore National Laboratory (LLNL) thermodynamic database supplied with the Geochemist's Workbench for these simulations, because it contained data applicable to the silicate, sulfide, and sulfate phases included in the study. Two sets of kinetic data were used. The first set is the compilation of published single-mineral rate constants from Palandri & Kharaka (2004). The second set, from Kellogg et al. (2014), is based on normative-style calculations from weathering tests on waste rock from the Duluth Complex.

The initial system

The model system used in this study is based on the 10-year laboratory weathering tests by Lapakko, Olson & Antonson (2013a) performed in small reactors on mill tailings derived from metallurgical testing. The sample comprised plagioclase (An_{57}; 57 %), clinopyroxene (X_{Mg} 0.77; 11 %), olivine (X_{Mg} 0.55; 9.8 %), quartz (9.8 %, assumed to be contamination of the sample from the country rock), and biotite (X_{Mg} 0.65; 5.7 %) with trace amounts of ilmenite, potassium feldspar, and orthopyroxene. The sample contained 0.2 wt. % sulfur, assumed for the purposes of modeling to be present as pyrrhotite, which is known to be the most common sulfide mineral in the Duluth Complex (Ripley, 2014). Lapakko, Olson & Antonson (2013a) were only able to identify chalcopyrite in their mineralogical characterization of their tailings sample, but they assumed the presence of both pyrrhotite and pentlandite.

For this exercise, the mineralogy of the starting model system was simplified to consist of plagioclase, clinopyroxene, olivine, and pyrrhotite. To account for solid-solution effects, the two end members of binary solid-solution series were included in proportion to the average composition for these minerals as described by Lapakko, Olson & Antonson (2013a). Thus, the simulations included plagioclase as both albite and anorthite, clinopyroxene as diopside and hedenbergite, and olivine as forsterite and fayalite. Pyrrhotite was assumed to be stoichiometric troilite (FeS). The masses of these phases, normalized to 100 percent, are presented in Table 1.

Table 1 Mineralogical composition of model system and dissolution rate constants.

Mineral	Component	Abundance	Surface Area	Rate Constant (k)	Rate Constant (k)
Units		mass %	$cm^2\ g^{-1}$	mol $cm^{-2}\ sec^{-1}$	mol $cm^{-2}\ sec^{-1}$
Source		Lapakko, Olson & Antonson (2013a)	Estimated This Study	Palandri & Kharaka (2004)	Kellogg et al. (2014)
Plagioclase	Albite	31.1	330.0	2.75E-17	6.2E-17
	Anorthite	41.2	330.0	1.6E-15	6.2E-17
Clinopyroxene	Diopside	10.7	330.0	1.1E-16	8.8E-16
	Hedenbergite	3.2	330.0	1.1E-16	8.8E-16
Olivine	Forsterite	7.1	330.0	1.0E-14	1.4E-16
	Fayalite	5.7	330.0	2.0E-15	1.4E-16
Pyrrhotite	Pyrrhotite	1.0	330.0	2.0E-12	2.2E-14

The grain size and surface area of reacting phases were estimated on the basis of the particle-size distribution data of Lapakko, Olson & Antonson (2013a). All minerals were assumed to have the same particle size (Table 1).

A dilute surface-water solution was chosen from Filson Creek, upstream of the mineralized basal zone of the Duluth Complex (Piatak et al., 2015; Table 2). At an active mine, waters percolating through tailings piles will likely be a combination of process water and local precipitation. The solution was assumed to be saturated with respect to atmospheric oxygen and buffered by the atmosphere.

Table 2 Starting solution composition for modeling simulations

Parameter	Units	Concentration
pH	S.U.	6.7
Na	mg L^{-1}	1.3
K	mg L^{-1}	0.2
Ca	mg L^{-1}	3.7
Mg	mg L^{-1}	2.8
Al	mg L^{-1}	0.1
Fe	mg L^{-1}	0.1
SiO_2	mg L^{-1}	1.0
SO_4^{2-}	mg L^{-1}	1.6
HCO_3^-	mg L^{-1} as $CaCO_3$	12.2
Cl	mg L^{-1}	1.0

Modeling Approach

This modeling exercise attempts to reproduce the laboratory weathering results of Lapakko, Olson & Antonson (2013a), focusing on acid generation and neutralization, and sulfur geochemistry. The tailings examined by Lapakko, Olson & Antonson (2013a) had an acid-generating potential (AP) of 6.2 kg $CaCO_3$/t and an acid-neutralizing potential (NP) of 19 kg $CaCO_3$/t, which results in a neutralizing potential ratio (NPR) of 3.1, and a classification of "not potentially acidic drainage generating". Their study was designed to investigate mineral dissolution rates under air saturated conditions rather than to simulate field conditions. Additional information that is useful for validation purposes can be found in Lapakko, Olson & Antonson (2013b), Lapakko et al. (2013), and Wenz et al. (2013). For the weathering tests on tailings (Lapakko, Olson & Antonson, 2013a), pH dropped from a starting value of approximately 7.5 to a minimum value of approximately 6.4 over the course of the 10-year experiment. The pH drop was most rapid in the first year of the experiments, and showed generally gradual decreases for the remainder of the experiments. Sulfate was released at the greatest rates in the first two years of the experiment and then leveled off. At the end of 10 years, the amount of remaining sulfur in the solids was between 45 and 49 percent of the starting concentration (0.2 wt. %). In contrast, Kellogg et al. (2014) conducted similar tests on waste rock (75 g; particle size 50 – 150 μm diameter) of varying starting sulfide sulfur contents ranging from 0.18 to 1.64 wt. %. In these experiments, pH started at near-neutral values (7 – 8), but reached minimum values of approximately 3 in the most sulfur-rich samples. The pH profiles were more complex with the high sulfur samples exhibiting increased pH values after reaching their minima. Sulfate release was similarly complex, with significant release early and a decrease over time, followed by maxima that correlated with pH minima in the high sulfur samples. In these experiments, the amount of sulfur remaining in the solids ranged between 0 and 55 percent of the starting concentration.

Using the starting conditions described above, the interaction of the solution with tailings was simulated by allowing fixed amounts of solids to react with 1 kg of solution for either 10 or 20 years. Under these scenarios, the sensitivity of the simulations was evaluated by using the different sets of rate constants described above, by varying the water/rock ratio, changing the starting concentration of sulfide-sulfur, and by changing the pyrrhotite dissolution rate constant relative to silicate rate constants. The pH of the model simulations is the primary screening tool to assess the success of the modeling at this stage, followed by the sulfur geochemistry.

RESULTS AND DISCUSSION

Rate Constants

Two sets of rate constants for the dissolution of silicate minerals and pyrrhotite were used in this study (Table 1): (1) Those based on single-mineral laboratory experiments compiled from the literature (Palandri & Kharaka, 2004); and (2) Those based on weathering tests on waste rock from the Duluth Complex (Kellogg et al., 2014). The variation of pH over the course of a 10-year simulation shows distinct differences between the two sets of rate constants (Fig. 2a). The simulations based on the MNDNR (Kellogg et al., 2013) values show a steady decrease from the starting value (6.7) to a value of 6.3 at 10 years, which is similar to pH evolution observed in the weathering tests of Lapakko, Olson & Antonson (2013a). In contrast, the rate constants based on single-mineral laboratory experiments have a distinctly different pattern. This simulation has a more rapid drop in pH, reaching a mínimum of approximately 5.8 between Years 1 and 2, followed by an increase in pH to approximately 8.4 in Year 9. Therefore, the rate constants based on single-mineral experiments predict the exhaustion of acid-generating potential from pyrrhotite and acid-neutralization by silicates that are significantly faster than the empirical observations in the tailings weathering tests (Lapakko, Olson & Antonson, 2013a). However, the rate constants based on the weathering tests on Duluth Complex waste rocks provide a better description of the pH evolution in the tailings weathering tests. Kellogg et al. (2014) summarized their pyrrhotite dissolution rate constants in terms of minimum, maximum, and average values. A comparison of these values, and that of Palandri & Kharaka (2004) relative to the MNDNR silicate rate constants shows that the MNDNR maximum value best describes the tailings weathering test (Fig. 2b). The MNDNR silicate rates were used for the remainder of the simulations. Because of the limited pH range shown by the experiments of Lapakko, Olson & Antonson (2013a), the silicate dissolution rates were assumed to be constant.

Water/Rock Ratio

The water/rock ratio of the experiment has a profound effect on the resulting pH of the simulation. Weathering tests using 1 kg of solid, which is leached with 0.5 kg of water on a weekly basis, would be exposed to a water/rock ratio of 26/1 per year or 260/1 over the course of 10 years. Simulations were made using water/rock ratios of 1/1, 10/1, 100/1, 260/1, and 1000/1 (Fig. 3). Based on these results, the water-dominated simulations appear to describe the tailings weathering experiments better than that the rock-dominated simulations. The water/rock ratio corresponding to 10 years of weathering tests (260/1) results is a lower pH than observed, which suggests that: (1) the effective reactive (i.e., exposed) mass of pyrrhotite may be significantly less than the total present; (2) the pyrrhotite dissolution rate constant used is too fast; (3) that the silicate dissolution rate constants are too slow; or (4) a combination of these factors.

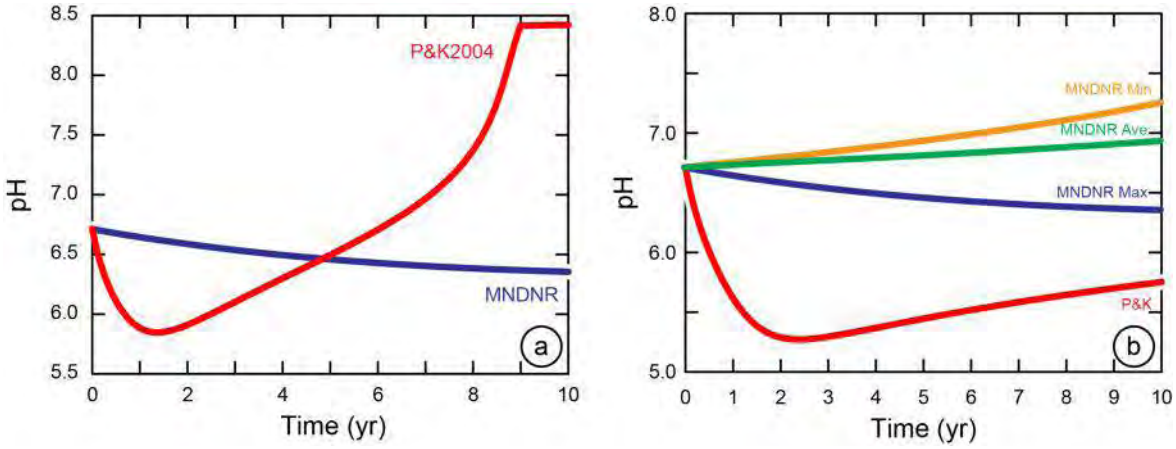

Figure 2 Comparison of rate constants for the dissolution of minerals in tailings. a. Comparison of single-mineral constants (P&K2004, Palandri & Kharaka, 2004) and empirical constants (MNDNR, Kellogg et al., 2014); b. Comparison of pyrrhotite dissolution constants from Kellogg et al. (2014) for their maximum (MNDNR Max) average (MNDNR Ave) and minimum (MNDNR Min) observed rates and from Palandri & Kharaka (2004; P&K).

Effect of Sulfide Content

The sulfide content of mine waste determines its acid-generating potential. To assess the sensitivity of the model simulations to sulfide content, simulations were run at various sulfide contents that span the range that has been observed in the ores in the basal zone of the Duluth Complex: 0.2, 0.5, 1.0, and 2.0 wt. % S (Kellogg et al., 2014; Lapakko, Olson & Antonson, 2013a, b; Fig. 4a). The simulations show the influence of sulfide content on pH. The simulations with the highest sulfide content produced the lowest pH values, reaching a low of 3 in the simulation with 2 wt. % S. These relationships of sulfide content to pH variations are similar to those observed by Kellogg et al. (2014) for weathering tests on waste rock from the Duluth Complex. They divided their samples into three groups on the basis of sulfide content and origin of sample material. Their Group I (0.18 – 0.22 wt. % S) produced pH values above 6, Group II (0.4 – 0.58 wt. % S) reached a low of approximately pH 3.5, and Group III (0.71 – 1.64 wt. % S) reached a low of pH 3.

The effectiveness of this modeling approach can also be evaluated by comparing the predicted depletion of sulfide-sulfur in the tailings with observed depletion in the weathering tests (Lapakko, Olson & Antonson, 2013a). Figure 4b shows both the measured depletion of pyrrhotite (red dots) and the predicted depletion of pyrrhotite (blue line) with time. The measured depletion reflects a greater initial loss of pyrrhotite in the first year, perhaps due to oxidation of very fine sulfide grains, but the rate slows in subsequent years compared to the predicted loss of pyrrhotite. However, the general agreement between the observed and predicted depletion of pyrrhotite indicates that the model provides a reasonable description of pyrrhotite weathering.

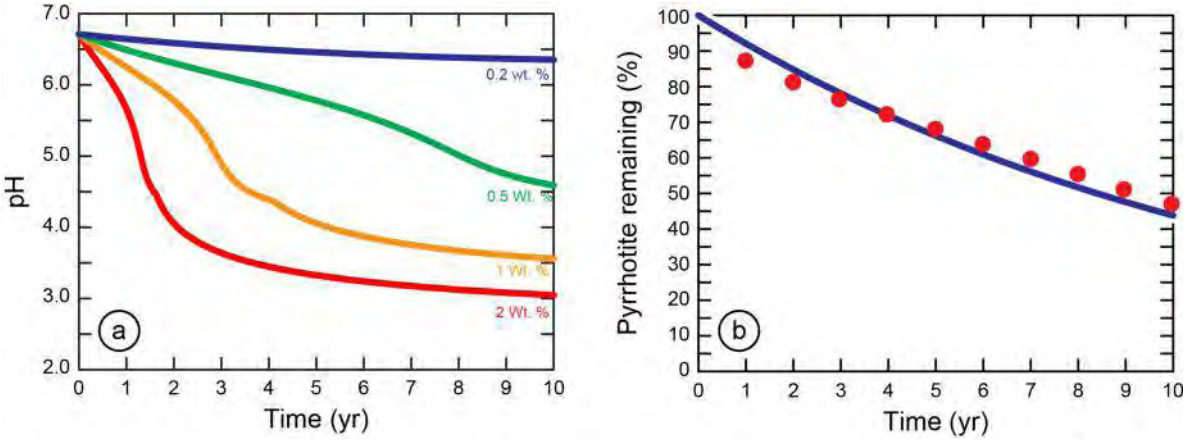

Figure 4 Influence of sulfur geochemistry. a. The effects of different total sulfide contents on pH. b. Comparison of predicted (blue line) with observed depletion of sulfide-sulfur (red dots).

Long-Term Implications

The effectiveness of REACT to describe the general aspects of tailings weathering for the low-sulfide ores of the Duluth Complex suggests that useful insights can be gained from reaction modeling. The pH reaches a minimum around Year 13 (Fig. 5a), indicating that the amount of pyrrhotite has been exhausted to the point where the rate of acid neutralization exceeds the rate of acid generation. The pyrrhotite content at the end of year 20 is predicted to be 20 percent of the starting concentration.

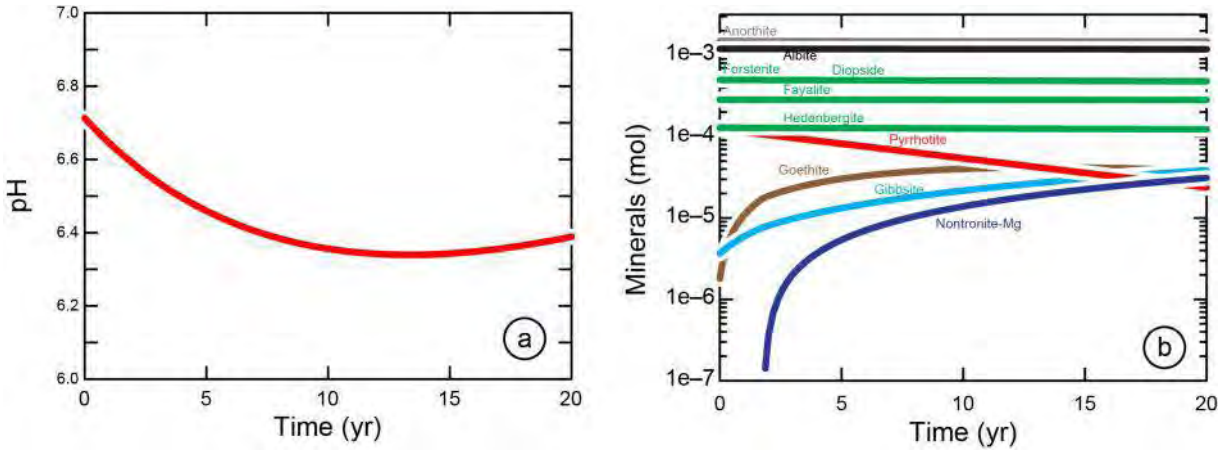

Figure 5 Twenty-year simulation of the weathering of low-sulfide tailings from the Duluth Complex. a. Variation of pH with time. b. Variation of primary and secondary minerals

The simulation indicates that pyrrhotite dissolution occurs at a much greater rate than plagioclase, olivine, and clinopyroxene dissolution (Fig. 5b). The simulation predicts the secondary phases, including aluminum and ferric hydroxides, and clay (nontronite), should form (Fig. 5b). In a tailings pile, these secondary phases could decrease permeability and limit weathering rates. The sulfate salts gypsum and epsomite are predicted to be significantly undersaturated throughout at the simulation at high water/rock ratios. However, at low water/rock ratios, gypsum becomes saturated. Thus, gypsum may be an important secondary phase that could limit the infiltration of water in the vadose zone of tailings storage facilities.

CONCLUSION

In concert with established methods, computer-based reaction modeling represents another promising tool to assess the long-term behavior of tailings. One of the greatest limitations for applying this approach is the lack of appropriate rate constants for mineral dissolution. Rate constants derived from single-mineral laboratory experiments appear to be unrealistically fast to describe weathering tests. Rate constants based on weathering tests are more realistic, but their derivation is more problematic because multiple minerals are dissolving simultaneously in these experiments. Long-term simulations can identify potential secondary phases that can influence the permeability of tailings and affect their weathering behavior, and thus permit a more insightful interpretation of other types of mine-waste weathering data.

Modelling Humidity Cell Experimental Data by Making Use of the PHREEQC Code

Nicolaus Van Zweel, Rainier Dennis and Ingrid Dennis
Centre for Water Sciences and Management, North West University, South Africa

ABSTRACT

Most of South Africa' energy is generated by coal fired power stations. South Africa has rich coal deposits concentrated in the north-east of the country and as the demands for electricity are growing so are the associated mining activates, a large number of which are shallow opencast mines. The mining method results in post-closure back filled pits and above ground disposal facilities. Leachate emanating from these disposal sites is saline and in most cases highly acidic. Currently the standard testing procedure to quantify expected leachate qualities include Acid Base Accounting (ABA) with static and kinetic leaching.

The aim of this study is to model standard humidity cell leach tests performed in these studies using the PHREEQC code. This model can then be scaled up to field conditions to model 1D reactive mass transport. It is commonly accepted that the rate of pyrite oxidation in backfilled pits and waste storage facilities is governed by the rate of oxygen ingress and that no pyrite oxidation takes place in the saturated zone. This is not the case for humidity cells, as sufficient oxygen is available for reaction. Pyrite reaction rates in humidity cells are expected to be governed by a combination of available reaction surface and ash layer resistance. This is modelled in PHREEQC (Parkhurst & Appelo, 1999) using the KINETIC block. Leachate composition is then modelled in the column, making use of the TRANSPORT block. The experimental data is fitted by means of the reactive surface and ash layer diffusion coefficient.

This model can then be used to estimate long term water qualities beyond the twenty week norm. The model can then be scaled up to field conditions by compensating for the oxygen ingress component.

INTRODUCTION

Most of South Africa's energy is generated by coal fired power stations. South Africa has rich coal deposits concentrated in the north-east of the country and as the demands for electricity are growing so are the associated mining activates, a large number of which are shallow opencast mines. The mining method results in post-closure back filled pits and above ground disposal facilities comprising of mined out rock and discard from the beneficiation process respectively. Leachate emanating from these disposal sites may range from acidic to alkaline, with commonly observed elevated levels of sulfate, iron, manganese and aluminium (Usher et al., 2002). In order to implement a successful mitigation strategy, sources of pollution must be identified and there must be a good understanding of the related source term governing the pollution. According to Nordstrom (2000) several points must be considered when looking at geochemical modelling. Firstly when referring to a model, it is not necessarily implied that the model is a computer code or a mathematical approach. It can consist of a well constrained logical proposition with the goal to improve or refine a conceptual model of the problem. A geochemical model can provide invaluable insight in this this regard and can assist in the interpretation of field data (Linklater et al., 2005). In order to develop such a model Usher et al. (2002) suggested the Acid-Base: Accounting, Technique and Evaluation (ABATE) strategy to develop a model of the geochemical problem at hand.

Field data/Experimental data

Acid Base Accounting (ABA) is generally used as a first order classification procedure in acid rock drainage (ARD) prediction methodologies (Usher et al., 2002) and results provide information about the potential of a sample to generate ARD (Price, 1997). Net Acid Generating (NAG) tests are also performed to aid in improving the interpretation of the ABA results (Miller et al., 1997). Usher et al., (2002) recommends a kinetic leach test methodology adapted from the D5744-96 Standard Test Method (ASTM, 2001). The minimum suggested duration of this leach test is twenty weeks and this is in some cases insufficient for sulphate production to stabilize. Static methods do not address the transient behaviour of ARD formation; humidity leach test supplements statics test in this regard and can assist in obtaining rates of reaction and a generalized indication of the potential mineral leaching behaviour of rock samples (Price, 1997). In the ABATE strategy mineralogy is required before the kinetic leach test is performed. In most cases mineralogy in the form of XRF is performed with the kinetic leach test.

Numerical geochemical modelling

Numerical geochemical modelling is the last step in the ABATE strategy. The need for numerical modelling will depend on the objectives of the study. Kinetic modelling of a spoils heap becomes complex as the concentrations of chemical components in the effluent is a function of both space and time. In turn the concentrations depend on the sulfide mineral oxidation rate, water infiltration rate and chemical oxidation rates (Pantelis et al., 2001). Several mathematical models that describe the leaching process in spoils heaps, has been developed over the last couple of years (Davis & Ritchie, 1986; Molson et al., 2005; Linklater et al., 2005; Pantelis et al., 2001).

Sulfide mineral oxidation

The dominant sulfide mineral in mine waste is pyrite (FeS_2). The oxidation of pyrite is a multi-step complex reaction consisting of both the oxidation of disulphide (S_2^{2-}) and of ferrous iron (Fe^{2+}) (Appelo & Postma, 2005). The following balanced reaction is generally accepted to represent the overall oxidation of pyrite at atmospheric conditions (Appelo & Postma, 2005; Lefebvre et al., 2001):

$$FeS_2 + \frac{15}{4}O_2 + \frac{7}{2}H_2O \rightarrow Fe(OH)_3 + 2SO_4^{2-} + 4H^+ \quad (1)$$

Oxidation of pyrite by oxygen has been shown to be slow and does not account for the rapid decrease in pH commonly observed from field conditions. This may be explained by the influence of pyrite oxidation by ferric iron (Fe^{3+}) (Lefebvre et al., 2001) and bacterial catalization of the reaction (Andre, 2009). Kinetics reported by Williams and Rimstidt, and also referenced by Appelo & Postma (2005) for the oxidation rate of pyrite by O_2 is as follows:

$$r = 10^{-8.19} m_{O_2}^{0.5} m_{H^+}^{-0.11} \quad (2)$$

where r is the rate with the units (mol/m²/s) and m_x denotes the molar concentration of x. It can be seen that the rate has a square root dependency on the concentration of O_2. This results in a significant effect on the rate if the oxygen concentration is low and a small effect at high oxygen concentrations. This effect is explained by Appelo & Postma (2005) by referring to the work conducted by Nicolson et al., (1988) as the pyrite surface becomes saturated with oxygen. A general rate law describing the dissolution/precipitation of minerals can be written as follows (Appelo & Postma, 2005):

$$r = k\frac{A_0}{V}\left(\frac{m}{m_0}\right)^n g(C) \quad (3)$$

where r is the overall reaction rate with the units (mol/L/s) and k is the specific rate with the units (mol/m²/s). The initial area and solution volume is denoted by A_0 and V respectively. The factor $(\frac{m}{m_0})^n$ accounts for the change in surface area where m_0 is the initial moles of the solid and m is the moles at a given time. The function $g(C)$ accounts for the effect of the solution composition on the rate e.g. the pH of the solution or the distance from equilibrium.

Sulphate mineral oxidation in tailing facilities

In the well-known work of Davis & Ritchie (1986) and also later Molson et al. (2005) the shrinking core model is used to describe the reaction kinetics of pyrite oxidation in a waste dump. In this approach it is assumed that the rate of oxygen diffusion to the reaction area is the rate limiting step. This is also discussed as an important factor in the oxidation of pyrite soils (Appelo & Postma, 2005). It is noted that oxygen transport is only important in the unsaturated zone. In the saturated

zone the approximate amount of oxygen available for pyrite oxidation is 0.33 mM O_2, suggesting that the unsaturated zone is the most reactive and the greatest source of sulfide oxidation.

Davis & Ritchie (1986) further assumes that the rate of unreacted core shrinkage is much slower than the oxygen diffusion rate within the particle (Levenspiel, 1962). It is assumed that the reaction at the surface of the particle is instantaneous and that ash layer diffusion is the rate determining step.

In the model developed by Davis & Ritchie (1986), it is assumed that diffusion is the only means of oxygen transport. Fick's second law with a consumption term is used to describe the diffusion process mathematically:

$$\frac{\partial U_A}{\partial t} = D_1 \frac{\partial^2 U_A}{\partial z^2} - q(z,t) \tag{4}$$

The model describes a two-stage diffusion process to the reaction sites. The first stage consists of oxygen diffusion through the air filled pores. D_1 is the diffusion coefficient for this stage. The consumption term $q(z,t)$ in Equation 4 represents the change in volume due to the oxidation of pyrite, and can be expressed as follows (Molson et al., 2005):

$$q(z,t) = D_2 \frac{3(1-\theta)}{R^2}\left(\frac{r_c}{R-r_c}\right)\frac{[O_2]_a}{H} \tag{5}$$

where D_2 is the diffusion coefficient, R is the particle radius, r_c is the unreacted core radius, θ is the porosity, $[O_2]_a$ the concentration of oxygen dissolving into the water film surrounding the particle and H is Henry's constant for a given temperature. The diffusion coefficient D_2 represents the forming ash layer that is shielding the shrinking particle. The schematic representation of an oxidizing particle is shown in Figure 1.

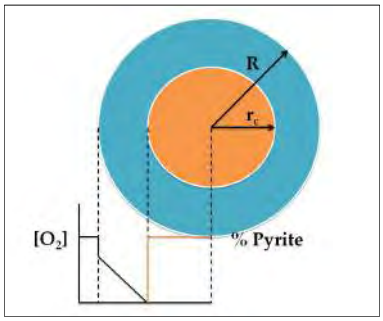

Figure 1 Schematic representation of an oxidizing particle (Davis, 1983)

From Equation 5 and Figure 1 it is clear that the change in oxygen due to pyrite oxidation can be related to the change in unreacted core radius (r_c):

$$\frac{dr_c}{dt} = \frac{D_2(1-\theta)}{\epsilon \rho_s} \frac{R}{r_c(R-r_c)} \frac{[O_2]_a}{H} \tag{6}$$

where ϵ represents the ratio of oxygen to sulphur consumed on the basis of reaction stoichiometry (Equation 1). The density ρ_s is calculated from the bulk density and the weight fraction of pyrite present.

METHODOLOGY

Actual humidity cell leach test (HCT) data were modelled using the PHREEQC code. Only the main principles are discussed here. PHREEQC has the ability to model dynamic processes using such as reaction kinetics, 1D reactive transport using the RATES block and TRANSPORT block respectively.

HCT approximated as a continues stirred tank reactor

The HCT is approximated as a continuous stirred tank reactor (CSTR) as shown in Figure 2. This may be an over simplification of the system as it do not account for preferential flow paths in the HCT It is assumed that the leachate has come into contact with all the particles before exiting the cell or reactor.

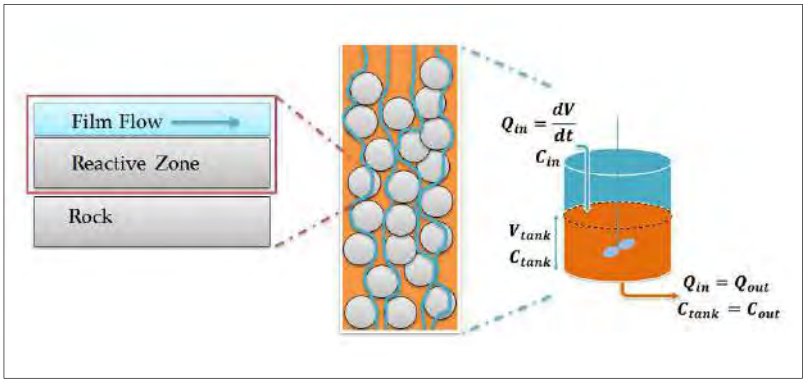

Figure 2 Schematic representation of the CSTR approximation (Andre, 2009)

The CSTR can be described by the following equation:

$$\tau = \frac{V_{tank}}{dV/_{dt}} \tag{7}$$

where τ is the residence time and V represents the volume of the tank. In work conducted by Tiruta-Barna (2008), a CSTR is modelled by solving the differential equation in the RATES block of PHREEQC. The reactor can also be modelled by making use of the TRANSPORT block in

PHREEQC. In the TRANSPORT block stagnant cells can be defined to interact with 'active' transport cells using the MIX block. Reaction kinetics and solution composition can then be defined for individual cells.

Input parameters

The mineral composition of the sample was calculated from the XRD data of the sample (Table 1). The reaction kinetics of pyrite oxidation was defined substituting Equation 2 in Equation 3 and compensating for the influence of the saturation state, rendering the following rate expression:

$$r = \left(\frac{A_0}{V}\right)\left(\frac{m}{m_0}\right)^n \left(10^{-6.07} m_{O_2}^{0.5} m_{H^+}^{-0.11}\right)(1 - SR(Pyrite)) \quad (8)$$

The unit of the rate expression is (mol/L/s) and *SR (Pyrite)* represents the saturation state. The exponent n is a function of the particle geometry and for cubical dissolving particles a value of n = 2/3 can be assumed (Appelo & Postma, 2005).

It was assumed that oxygen is present in excess. This was defined in the EQUILIBRIUM block of PHREEQC. The PHREEQC TRANSPORT block was used to describe the flow characteristics of the system approximated as a CSTR.

Table 1 XRD data of sample used in the humidity cell leach test

Mineral	Weight %
Anatase	3.43
Dolomite	1.83
Kaolinite	51.69
Muscovite	5.45
Pyrite	6.98
Quartz	30.28
Siderite	0.33

Shrinking core model

The shrinking core model can also be applied in PHREEQC by making use of the RATES block. The rate of pyrite oxidation (mole/litre bulk/s) is defined as follows (Mayer, 1999):

$$r = -10^3 S_i \frac{D_2}{3.5} \frac{R}{(R - r_c) r_c} [O_2]_a \quad (9)$$

where S_i is the reaction surface at time t_i and is defined as:

$$S_i = 10^{-3} \frac{3\varphi_i}{r_c} \quad (10)$$

where φ_i is the volume fraction of minerals defined in units (m^3 mineral/m^3 bulk). The concentration of oxygen dissolved in the liquid film can be calculated using Henry's law. Usually the Henry's law constants are reported at a reference temperature of 25°C and 1 atm. The following two equations can be used for temperature (Koretsky, 2003):

$$\left(\frac{\partial lnH_i}{\partial P}\right) = \frac{H_i^{\infty} - h_i^{v}}{R} \tag{11}$$

where R is the gas constant, H_i^{∞} is the partial molar enthalpy and h_i^{v} is the pure species enthalpy. A similar equation describes the correction for pressure, but it is beyond the scope of this study due to the fact that the pressure will always be at 1 atm. Assuming the mole fraction of oxygen in ambient conditions is $y_{O_2} = 0.21$, the partial pressure of O_2 is then formulated as follows:

$$P_{O_2} = (0.21)P \tag{12}$$

where P is the atmospheric pressure. The concentration of oxygen in solution is the calculated using the Henry's coefficient for oxygen in water ($H_{O2} = 44252.9$ Bar @ 25°C and 1 atm):

$$x_{O_2} = \frac{y_{O_2}P}{H_{O_2}} = \frac{0.21(bar)}{44253.9(bar)} = 4.75 \times 10^{-6} \tag{13}$$

The concentration of oxygen, $[O_2]$ in molality, is expressed as:

$$[O_2] = \frac{n_{O_2}}{V} \tag{14}$$

Where V is 1 litre of water and n_{O_2} is the molar amount of dissolved oxygen. The concentration of dissolved oxygen is then calculated as:

$$[O_2] = x_{O_2}\frac{n_{O_2}}{V} = 2.63 \times 10^{-4} M \tag{15}$$

By defining the partial pressure of oxygen as $\log(P_{O_2}) = -0.67$ in the EQUILIBRIUM_PHASES block and defining a set oxygen concentration in the liquid film surrounding the particles, the above described kinetics were used to model the oxidation of pyrite. The PHREEQC result together with the validation from the equivalent mathematical model in MATLAB is presented in Figure 3.

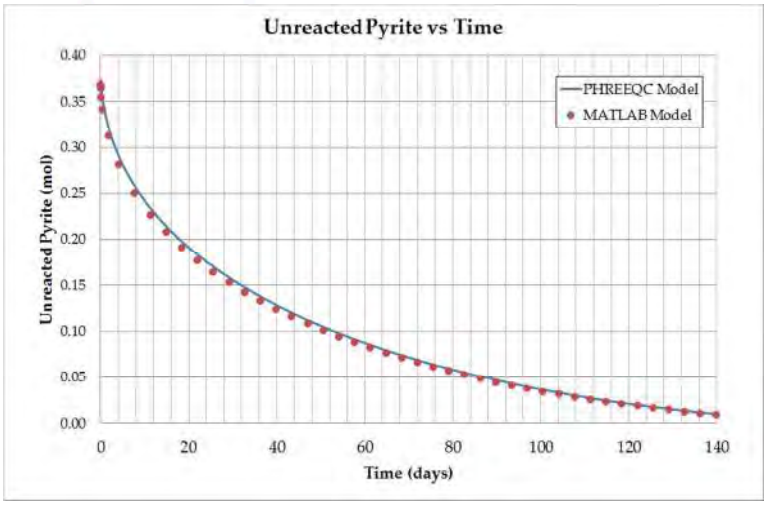

Figure 3 Model results of PHREEQC shrinking core model validated with MATLAB

PHREEQC does not have functionality for gas transport to describe the change in pore gas phase composition over time (Equation 4). This makes the use of this rate expression problematic as the gas phase composition will have to be changed for every time step outside the PHREEQC environment.

Analytical Approximate Solution

Due to the complexity of implementing Equation 4 in PHREEQC it is suggested to use the Analytical Approximate Solution (AAS) proposed by Davis & Ritchie (1986). By using this approach the rate of sulphate production already accounts for the rate limiting effect of oxygen diffusion.

In order to use the AAS model to describe a HTC, it must be assumed that oxygen is in fact rate limiting for sufficiently small particles (tailing samples) with a high moisture content. This assumption can be tested by making use of Fick's second law, and assuming an infinite homogeneous slab. The oxygen concentration profile can be described by the following equation:

$$U_a(x,t) = U_{a0}\left[1 - erf\left(\frac{x}{2\sqrt{D_1 t}}\right)\right] \tag{16}$$

where U_{a0} is the surface concentration of oxygen. The value of D_1 can be calculated from the following equation:

$$D_1 = 3.98 \times 10^{-9}\left[\frac{\theta_A - 0.05}{0.95}\right]T^{1.5} \tag{17}$$

where θ_A is the effective porosity and T is the temperature (K). From Equation 16 and Equation 17 it is clear that the oxygen concentration decreases linearly for a standard leach cell and that the percentage of saturation will only influence the oxygen profile at high levels of water saturation.

RESULTS AND DISCUSSION

The data obtained from an HCT was modelled using both the AAS model (Davis & Richie, 1986) and the Surface Kinetic (SK) model as shown in Figure 4. The SK model shows a better fit for the leach data. Although gypsum was not detected in the mineralogy, it is apparent from the leachate analysis that gypsum might be present as a minor component material and may not necessarily be picked up by the XRD analysis. In both models, gypsum was defined to dissolve kinetically to account for initial high sulfate leach values. The AAS method shows a moderately good fit to the data. It can clearly be seen that the shrinking core model does not describe the kinetic behavior of the oxidation of pyrite accurately under the conditions observed in the HCT. In the AAS model it is assumed that ash layer diffusion is the rate controlling step; this may be an over simplification of the system. The shrinking core model can be expressed to account for both ash layer controlled and chemical reaction controlled rates (Levenspiel, 1962). Although this approach may yield a better fit, it introduces more variables to the model and either the diffusion coefficient D_2 or the rate constant of the chemical reaction rate must be determined experimentally to define the system in such a manner so that a reasonable model can be constructed.

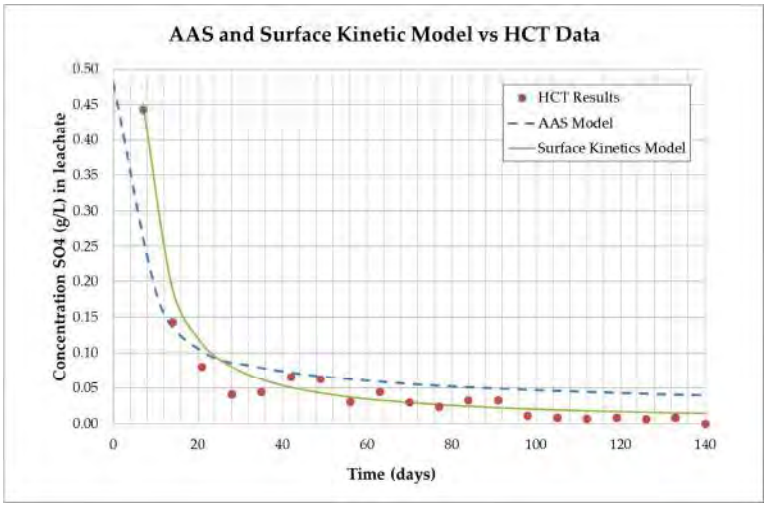

Figure 4 Comparison of AAS Model and SK Model fitted to HCT data

CONCLUSION

Both the AAS model and the SK model showed a reasonable fit to the HCT data. The SK model does however describe the data better. It was found that assuming the ash layer diffusion as the only rate controlling factor is a gross over simplification of the system. This results in compensating for the influence of chemical reaction controls to obtain a more accurate model. The standard HCT setup will not provide this data and further experimental data will be required to obtain either the kinetic rate constant for the chemical reaction controlled step or the diffusion coefficient.

ABSTRACT

The Diavik Waste Rock Project consists of laboratory scale and field scale experiments with one of its primary goals being the development of scale-up techniques for the prediction of impacts from mine wastes on groundwater and surface water. As part of the Diavik project, humidity cell experiments have been conducted to assess the long term geochemical evolution of the low sulfide content waste rock. Reactive transport modelling has been used to assess the significant geochemical processes controlling oxidation of sulfide minerals and subsequent sulfate and metals release from the humidity cell experiments. The geochemical evolution of effluent from waste rock with sulfide content of 0.16 wt. % (primarily pyrrhotite) in a subset of the humidity cells was simulated with the reactive transport model MIN3P under the conceptual model of constant water flow and that sulfide oxidation is controlled by the availability of ferric iron. Elevated metal concentrations in the humidity cell effluent were released through sulfide oxidation, which is controlled by diffusion of ferric iron to the unreacted particle surface and aerobic oxidation of the released ferrous iron. Elevated sulfate concentrations in solution are influenced by the production of intermediary sulfur compounds (represented in the model by S^0). Comparison of humidity cell experiments containing rock of varying sulfide content and temperature indicate available surface area and temperature also play important roles in rates of sulfide oxidation and subsequent sulfate production. The simulations also indicate that secondary mineral formation affects solute release. The humidity cell simulations are intended to provide a baseline for future reactive transport simulations of the larger scale field experiments at the Diavik site.

Keywords: sulfide oxidation, shrinking core model, reactive transport

INTRODUCTION

An important component of the planning of a mining project is the prediction of waste-rock effluent quality. The potential for mine waste rock to generate acid and elevated solute concentrations in effluent and the associated long term effects to the surrounding environment are often characterized using laboratory scale humidity cell experiments (Lapakko, 2003; Ardau, Blowes & Ptacek, 2009; Sapsford et al., 2009). The subsequent prediction process commonly involves the extrapolation of contaminant leaching rates derived from humidity cell experiments using empirical scale factors. The resulting scaled leaching rates are used to assess the potential for poor quality effluent from full scale waste-rock piles (commonly referred to as scale-up). Scale factors often include parameters understood to influence effluent quality such as pH, grain size, moisture content, temperature, oxygen availability and mineral surface area and volume (Kempton, 2012). The empirical scale factor method is often rendered incapable of accurate effluent quality prediction since site specific heterogeneities that arise during scale-up such as variability in flow mechanisms and geochemical reaction mechanisms are difficult to model given the simplified parameters. Reactive transport modelling has the potential to address some of the complexities associated with scale-up by providing a detailed, mechanistic, and quantitative approach to assessing effluent quality that encompasses the capability to take site specific processes into consideration.

The reactive transport model MIN3P (Mayer, Frind & Blowes, 2002) is used to simulate the weathering of waste rock to allow assessment of the primary geochemical processes involved. This article presents a conceptual model of pyrrhotite weathering in low S waste rock using the results of humidity cell effluent quality sampling and the resulting estimated weathering rate, and mineralogical and hydraulic properties from the humidity cell experiments and field scale experiments. The simulations are intended to provide a comprehensive geochemical conceptual model that will later be included in modelling of larger scale field experiments.

HUMIDITY CELL METHODOLOGY

As part of the Diavik Waste Rock Project (DWRP), 36 humidity cell experiments were conducted at the University of Waterloo over a period of approximately six years using representative run of mine waste rock collected at Diavik Diamond Mine (Diavik). The experiments were designed to assess the primary geochemical mechanisms controlling effluent quality from waste rock piles at the mine site. The primary sulfide mineral present in the waste rock is pyrrhotite wherein minor substitution of Ni and Cu for Fe has occurred in the following approximate ratio: [$Fe_{0.852}Ni_{0.004}Co_{0.001}S$] (Jambor, 1997). Given the relatively low sulfide content of the waste rock, the humidity cell experiments were used to assess the potential for acid generation as well as increased concentrations of solutes such as sulfate [SO_4], Fe, Ni, Cu, and Zn.

The Diavik waste rock used in the humidity cell experiments was collected in 2004 and 2005 and includes approximately 75 % granite (primarily quartz [SiO_2], k-feldspar [$KAlSi_3O_8$], and albite [$NaAlSi_3O_8$]), 14 % pegmatitic granite, 10 % biotite schist, and 1 % diabase (Blowes & Logsdon, 1998; Langman et al., 2014). The biotite schist is composed primarily of albite (35–55 %), quartz (20–50 %), and biotite [$KMg_2FeAlSi_3O_{10}(OH)_2$] (10–25 %) and contains a mean sulfide content of 0.24 wt. % S (Langman et al., 2014). Static testing was conducted on each of the humidity cell samples to determine S and C content (Langman et al., 2014). Other sulfide minerals present in the waste rock include minor amounts of chalcopyrite [$CuFeS_2$], sphalerite [ZnS], and pentlandite [$(Ni,Fe)_9S_8$]. The

waste rock is sorted into three types according to sulfur content (Type I < 0.04 wt. %, Type II 0.04 to 0.08 wt. %, and Type III > 0.08 wt. % S) (Smith et al., 2013).

Each humidity cell contained 1 kg of Type I, Type II, or Type III waste rock, through which deionized water was flushed at a rate of 500 mL·wk^{-1}. Once per week water was added to the cells and held for approximately one hour then allowed to drain from the cells. Draining of the cells typically lasted four to six hours and was followed by periods of dry air flow (three days at < 10 % relative humidity) and humid air flow (three days at > 95 % relative humidity) lasting the remainder of the week (Langman et al., 2014). The experiments followed the American Society for Testing and Materials (ASTM) method for humidity cell testing (ASTM, 1996) with increased flooding in the early stages according to the ASTM method modification described by Lapakko and White (2000). Duplicate sets of humidity cell experiments were conducted at two control temperatures (one set at approximately 22 °C and one set at approximately 5 °C).

CONCEPTUAL MODEL

The conceptual model presented here was based on the Type III (sulfide content of 0.16 wt. %), room temperature humidity cell experiments conducted as part of the DWRP and described by Langman et al., 2014. Because of the abundance of oxygen and moisture in the system, sulfide oxidation has been posited to be the significant geochemical process contributing to elevated concentrations of sulfate, Ni, and Co in the humidity cell effluent. Water flow through the model domain is described as continuous infiltration at a rate of 500 mL·wk^{-1}. Although the addition of water to the cells was conducted as flooding events (i.e. 500 mL over the period of a few hours), continuous infiltration was assumed to be a reasonable approximation because weekly flooding and limited evaporation during the dry air influx period did not likely result in significant moisture content reduction.

The oxidation of pyrrhotite was represented by a series of three primary reactions designed to simulate the reaction pathways for sulfide mineral oxidation outlined by Schippers & Sand (1999) and Rohwerder et al. (2003). Following the reaction mechanism for sulfide oxidation, ferric iron was considered as the dominant sulfide oxidizer according to the following overall reaction (Nicholson & Scharer, 1998; Janzen, Nicholson & Scharer, 2000; Belzile et al., 2004):

$$Fe_{(1-x)}S + (8-2x)Fe^{3+} + 4H_2O \rightarrow (9-3x)Fe^{2+} + SO_4^{2-} + 8H^+ \quad (1)$$

The reaction mechanism presented by Schippers & Sand (1999) and Rohwerder et al. (2003) includes the polysulfide pathway wherein several partially oxidized S species (primarily S^0 in the absence of sulfur oxidizing bacteria) can be produced as the reaction sequence progresses towards the fully oxidized product SO_4. The polysulfide pathway is appropriate for the oxidation of monosulfides such as pyrrhotite (Schippers & Sand, 1999; Rohwerder et al., 2003). Elemental S was selected as a proxy for the intermediary components in the MIN3P simulations. Introducing S^0 as an intermediary component results in the following reaction sequence (Nicholson & Scharer, 1998) where equation 2 represents an oxidation process and equation 3 represents an oxidation and dissolution process:

$$Fe_{(1-x)}S + (2-2x)Fe^{3+} \rightarrow (3-3x)Fe^{2+} + S^0 \quad (2)$$

$$S^0 + 1.5O_{2(aq)} + H_2O \rightarrow SO_4^{2-} + 2H^+ \quad (3)$$

Equations 2 and 3 were ultimately driven in the simulations by the oxidation of Fe^{2+}, facilitating the replenishment of Fe^{3+} represented by the following reaction (Singer & Stumm, 1970; Schippers & Sand, 1999; Rohwerder et al., 2003):

$$Fe^{2+} + 0.25O_{2(aq)} + H^{+} \leftrightarrow Fe^{3+} + 0.5H_2O \quad (4)$$

The rate of sulfide oxidation (equation 2) was simulated using the shrinking core model (Levenspiel, 1972; Wunderly et al., 1996; Mayer, Frind & Blowes, 2002) and was represented in the model using the following rate expression (after Mayer, Frind & Blowes, 2002):

$$R_{Po\ ox} = -10^3 S_{Fe_{0.852}Ni_{0.004}Co_{0.001}} \left[\frac{r^p}{(r^p - r^r)r^r}\right] D_{Fe^{3+}} \left[\frac{Fe^{3+}}{1.714}\right] \quad (5)$$

where $R_{Po\ ox}$ represents the rate of pyrrhotite oxidation using the shrinking core model [mol·L^{-1}·d^{-1}] and $S_{Fe_{0.852}Ni_{0.004}Co_{0.001}}$, r^p, r^r, and $D_{Fe^{3+}}$represent the reactive surface area [m^2 mineral·dm^{-3} porous medium], average particle radius [m], unreacted particle radius [m], and effective diffusion coefficient [m^2·s^{-1}] of Fe^{3+} to the unreacted surface, respectively.

In addition to chemical oxidation processes, microbial populations play an important role in the oxidation of sulfide minerals (Nordstrom & Southam, 1997; Blowes et al., 2003). Most probable number bacteria count data from the DWRP humidity cell experiments (Langman et al., 2014) indicates that neutrophilic sulfur oxidizing bacteria (nSOB) were the dominant microbiological catalyst in the system. As a result, biotic oxidation was represented in the rate expressions associated with equations 3 and 4 by simulating the increase in reaction rate with increasing substrate (in this case Fe^{2+} and S^0) concentration to represent the increase in microbial activity.

The rate of ferric iron production (equation 4) was simulated using the rate expression (after Singer & Stumm, 1970; Mayer, Frind & Blowes, 2002; Roden, 2008):

$$R_{Fe^{2+}-Fe^{3+}} = -S\left[k^1_{Fe^{2+}-Fe^{3+}}[Fe^{2+}][O_{2(aq)}] + k^2_{Fe^{2+}-Fe^{3+}}[Fe^{2+}][O_{2(aq)}][OH^-]^2\right]$$
$$-k^3_{Fe^{2+}-Fe^{3+}}\left[\frac{[Fe^{2+}]}{K_s+[Fe^{2+}]}\right] \quad (6)$$

The first two terms in equation 6 represent the chemical oxidation of Fe^{2+} by aqueous oxygen where $R_{Fe^{2+}-Fe^{3+}}$ represents the rate of Fe^{2+} oxidation [mol·L^{-1}·d^{-1}] and S, $k^1_{Fe^{2+}-Fe^{3+}}$, and $k^2_{Fe^{2+}-Fe^{3+}}$ represent a scaling factor [-], the reaction rate constant for pH < ~ 3.5 [L·mol^{-1}·d^{-1}] (Singer & Stumm, 1970), the reaction rate constant for pH > ~ 4.5 [mol·L^{-1}·d^{-1}] (Singer & Stumm, 1970), respectively. The third term in equation 6 represents the biotic oxidation of Fe^{2+} by microbes where $k^3_{Fe^{2+}-Fe^{3+}}$ and K_s represent the reaction rate constant [mol·L^{-1}·d^{-1}] and half-saturating constant [mol·L^{-1}], respectively.

Sulfate concentrations in humidity cell effluent were simulated by the bioitic oxidation of S^0 to SO_4 according to the reaction stoichiometry in equation 3. The rate of S^0 oxidation is dependent on the presence of both oxygen and the S^0 however, due to the abundance of oxygen in the system only S^0 is represented in the following rate expression (after Roden, 2008):

$$R_{S^0-SO_4} = -k_{S^0-SO_4}\left[\frac{[S^0]}{K_s+[S^0]}\right] \quad (7)$$

where $R_{S^0-SO_4}$represents the rate of biotic S^0 oxidation by [mol·L^{-1}·d^{-1}] and $k_{S^0-SO_4}$and K_s represent

the reaction rate constant [mol·L^{-1}·d^{-1}] and half-saturating constant [mol·L^{-1}] respectively.

Minor constituent sulfide minerals chalcopyrite, sphalerite, and pentlandite, were also included in the simulations undergoing oxidation by Fe^{3+} according to the shrinking core model (equation 5, Table 1). Additional primary minerals were simulated to dissolve as surface controlled reactions (Table 1) according to pH dependent (calcite, biotite, muscovite, and albite) or transition state rate expression (k-feldspar and quartz).

Secondary minerals (primarily iron-bearing oxides and hydroxysulfates) are expected to precipitate in association with the oxidation of sulfide minerals (Blowes et al., 2003; Jambor, 2003). Several secondary minerals were added to the system based on saturation index analysis conducted using Type III, room temperature humidity cell effluent chemistry data in conjunction with the geochemical speciation software PHREEQC (Parkhurst & Appelo, 1999). The saturation index analysis indicated that minerals ferrihydrite [$Fe(OH)_3$], jarosite [$KFe_3(SO_4)_2(OH)_6$], and gibbsite [$Al(OH)_3$] were supersaturated in the humidity cell effluent at various points of the experiments. These minerals were allowed to precipitate or dissolve during the simulations according to equilibrium controlled rate expressions. Amorphous silica [$SiO_{2(am)}$] was also allowed to precipitate according to an equilibrium controlled rate expression to prevent excess Si build up.

Table 1 Reaction stoichiometry used in sulfide weathering simulations

Mineral	Primary Minerals	log K
(1) pyrrhotite	$Fe_{0.852}Ni_{0.004}Co_{0.001}S + 1.714Fe^{3+} \rightarrow 2.566Fe^{2+} + 0.004Ni^{2+} + 0.001Co^{2+} + S^0$	--
(2) sphalerite	$ZnS + 2Fe^{3+} \rightarrow 2Fe^{2+} + Zn^{2+} + S^0$	--
(3) chalcopyrite	$FeCuS_2 + 4Fe^{3+} \rightarrow 5Fe^{2+} + Cu^{2+} + 2S^0$	--
(4) pentlandite	$Fe_{4.5}Ni_{3.6}Co_{0.9}S_8 + 18Fe^{3+} \rightarrow 22.5Fe^{2+} + 3.6Ni^{2+} + 0.9Co^{2+} + 8S^0$	--
(5) calcite	$CaCO_3 \rightarrow Ca^{2+} + CO_3^{2-}$	-8.48
(6) biotite	$KMg_2Fe(AlSi_3O_{10})(OH)_2 + 10H^+ \rightarrow K^+ + 2Mg^{2+} + Fe^{2+} + Al^{3+} + 3H_4SiO_4$	--

MODEL PARAMETERS

The humidity cell experiments were conducted in cylinders with diameter of approximately 0.1 m resulting in an average height of waste rock of 0.1 m. Flow through the humidity cells was simulated as a 1-D column with the vertical domain set at 0.1 m, discretized into 100 1 mm control volumes. The simulations were run for a 2240 d period corresponding approximately to the data set available as of September 2014. Because atmospheric air (humidity adjusted) was used for the air flow portions of the experiment and the infiltrating deionized water was not isolated from atmospheric conditions, the cells were assumed to be in equilibrium with atmospheric oxygen and carbon dioxide at all times. The temperature of the simulations was set at 22 °C to be consistent with the conditions of the experiments. Flow parameters (Table 3) including porosity, hydraulic conductivity, and soil hydraulic function parameters were based on the work of Neuner et al., 2013 or by analysis of humidity cell data; dispersivity along the 0.1 m flow path was ignored. Mineral weight percent (Table 4) for pyrrhotite, calcite, biotite, muscovite, k-feldspar, albite, and quartz were calculated based on the general waste rock content documented by Jambor (1997), with values for chalcopyrite and sphalerite estimated from the molar ratios of Cu^{+2} and Zn^{+2} to Ni^{+2} in humidity cell effluent. The resulting estimates for the weight percent of chalcopyrite and sphalerite were consistent with values estimated by Bailey (2013). The weight percent for pentlandite was calibrated as part of the simulations. The initial volume fractions of secondary minerals expected to precipitate were set to an arbitrary low value (i.e. 1 x 10^{-10}).

Table 3 Physical parameters used in simulations

Parameter		Value
hydraulic conductivity ($m \cdot s^{-1}$)		2.5 x 10^{-4}
van Genuchten soil hydraulic parameters	α (m^{-1})	8.8
	n	1.7
flow rate ($m \cdot s^{-1}$)		1.0 x 10^{-9}
Porosity		0.26

Table 4 Composition of waste rock

Mineral	wt. %
pyrrhotite	0.17[1]
chalcopyrite	0.01[1]
sphalerite	0.01[1]
pentlandite	0.01[1]
calcite	0.07[1]
biotite	7.0[2]
muscovite	2.3[2]
k-feldspar	38.0[2]
albite	20.3[2]
quartz	30.4[2]

[1]Based on results of static testing with adjustment during calibration phase of model.

[2]Based on results of Jambor 1997

Dissolution and precipitation reactions involving primary minerals were kinetically controlled and irreversible (with the exception of calcite, which was simulated as a reversible reaction). Secondary mineral precipitation and dissolution reactions were kinetically controlled and reversible.

RESULTS AND DISCUSSION

To evaluate the conceptual model and assess the resulting simulations, the output of the MIN3P simulations were optimized for best fit to measured effluent concentrations of selected solute parameters from the Type III, room temperature humidity cells. All hydraulic parameters were fixed during the optimization process. Initial elevated concentrations of SO_4 and cations were not considered since they were likely a result of the initial blasting process (Bailey et al., 2013). Subsequent to the initial flush of blasting residuals, measured solute concentrations increased from relatively low concentrations to peak concentrations over a period of ten to approximately 24 weeks depending on the parameter (SO_4 concentrations peaked at approximately ten weeks whereas Ni^{2+} and Co^{2+} concentrations peaked at approximately 24 weeks).

To assess the general applicability of the simulations to other humidity cells and field scale experiments, the simulated rate of sulfide oxidation was compared to the rate of sulfide oxidation for the Type III waste rock calculated using the concentrations of SO_4 in the Type III, room temperature humidity cell effluent by Langman et al. (2014) (Figure 1). The good fit over most of the simulated period indicates that the model captures the general rate of oxidation suggesting a reasonable approximation of the overall sulfide oxidation process at the laboratory scale.

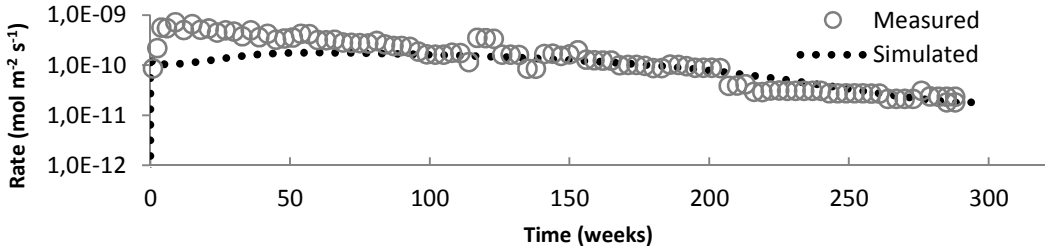

Figure 1 Rate of sulfide oxidation [mol·m^{-2}·s^{-1}] versus time [weeks] as estimated from measured SO_4 concentrations in humidity cell effluent compared to MIN3P sulfide oxidation simulation results

To assess specific processes, the measured effluent concentrations of SO_4,Ni^{2+}, and Co^{2+} from the Type III humidity cells are compared to the simulation results (Figure 2). The effective rate constants for non-sulfide minerals were used to calibrate the simulations to allow best fit to the measured effluent chemistry data. For sulfide minerals, the reactive surface area was used to calibrate the simulations.

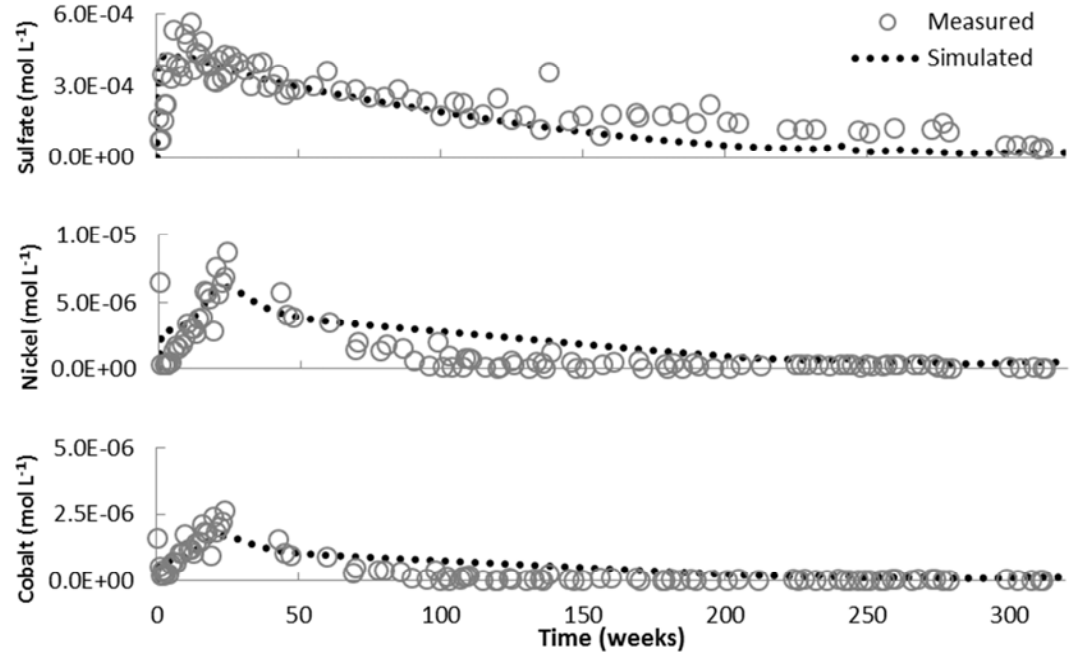

Figure 2 Concentrations of sulfide oxidation products SO_4, Ni^{2+}, and Co^{2+} [mol·L^{-1}] versus time [weeks] measured in humidity cell effluent compared to aqueous concentrations exiting the simulation domain

Simulated sulfate concentrations show a good fit to the measured data throughout the modelled period indicating an initial increase to peak concentrations at approximately ten weeks followed by a monotonic decrease. These trends are simulated through changes in the rates of microbially mediated oxidation reactions and available reactive surface area, as described by the shrinking core model.

Simulated Ni^{2+} and Co^{2+} concentrations followed a pattern generally similar to SO_4, with peak concentrations occurring slightly later than the sulfate concentration peak (Ni^{2+} and Co^{2+} concentrations peaked at about 24 weeks). The later peak concentrations of cations are attributed to slower oxidation rates for pentlandite when compared to the oxidation rate of pyrrhotite.

CONCLUSIONS

The general agreement between the simulated solute concentrations and the measured humidity cell concentrations indicates a reasonable conceptual geochemical model has been put forward for the oxidation of sulfides contained in Diavik waste rock. The major components controlling oxidation of the sulfide minerals were identified by the modelling study to be the biotic influence on the rate of S^0 oxidation and the available reactive surface area of sulfide minerals. Further work is required to identify the major controls on iron concentrations and biotite dissolution rates, which will facilitate use of the geochemical conceptual model for the field scale experiments that are part of the DWRP.

ACKNOWLEDGEMENTS

Funding for this research was provided by a Collaborative Research and Development Grant from the Natural Sciences and Engineering Research Council of Canada (NSERC) awarded to D.W. Blowes, Principal Investigator; Diavik Diamond Mines, Inc.; the International Network for Acid Prevention; and the Mine Environment Neutral Drainage Program.

NOMENCLATURE

$\boldsymbol{R_{Po\ ox}}$	rate of pyrrhotite oxidation
$S_{Fe_{0.852}Ni_{0.004}Co_{0.001}}$	reactive surface area
r^p	average particle radius
r^r	unreacted particle radius
$D_{Fe^{3+}}$	effective diffusion coefficient of Fe^{+3} to the unreacted surface
$\boldsymbol{R_{Fe^{2+}-Fe^{3+}}}$	rate of Fe^{+2} oxidation
$k^1_{Fe^{2+}-Fe^{3+}}$	reaction rate constant for pH < ~ 3.5
$k^2_{Fe^{2+}-Fe^{3+}}$	reaction rate constant for pH > ~ 4.5
S	scaling factor
$k^3_{Fe^{2+}-Fe^{3+}}$	reaction rate constant
K_S	half saturating constant
$\boldsymbol{R_{S^0-SO_4}}$	rate of S^0 oxidation
$\boldsymbol{k}_{S^0-SO_4}$	reaction rate constant

ABSTRACT

Predicting water chemistry resulting from mining activities is arguably one of the most important aspects of environmental management at mines. The water quality within waste storage facilities presents an especially important consideration in mine planning and the ability to accurately simulate the chemical evolution within such facilities is a major goal for environmental planning.

To illustrate the concepts in development of a predictive model, a water quality model for the tailings storage facility (TSF) at the Antamina mine in Peru is presented. The model is based on fundamental mineralogical and thermodynamic controls and monitoring data from the mine's regular monitoring and field research programs.

The model has developed as a collaborative effort between KCB and Antamina. The geochemical controls and water balance mechanisms simulate the interaction in the TSF and these are continually calibrated against observed data. This iterative process has resulted in the construction of a robust model that can predict, with confidence, water quality originating from the facility for the life of mine and after closure.

Here we outline the main control mechanisms built into the model and compare these to the observations of the tailings storage facility at Antamina. By introducing 'stresses', such as erroneous water flows or large inputs of sulfate, we can demonstrate that the model is robust and able to handle a variety of alternative scenarios. We also use established geochemical modelling software, such as PHREEQC and GWB, to cross-check predicted mineral and geochemical controls and compare the equilibria predicted in these models to those that have been constructed in the Antamina water quality model. The results show that that model's mechanisms and simulation algorithms are robust and versatile and may be utilised successfully at this mine site but also in a variety of mining waste rock dumps, tailings storage facilities and water catchments.

Keywords: GoldSim, modeling, geochemistry

INTRODUCTION

The Antamina mine is a polymetalic skarn deposit situated in the Peruvian Andes, approximately 270 km northeast of Lima. The mine produces copper, zinc and molybdenum concentrates. Waste material generated by the mining process is deposited in two waste rock dumps (WRD) and a tailings storage facility (TSF).

Due to the distinct wet and dry season climate (Harrison *et al.*, 2012), Compañía Minera Antamina (Antamina) manages water using infrastructure such as: diversion channels; passive treatment wetlands; capture and pump-back and operational controls such as flocculation and neutralization. Antamina conducts regular monitoring of water quality and flows across the mine site and compliments this information with a comprehensive geochemical testing program. The program includes static testing (acid-base accounting, whole rock analysis, mineralogy and leachate testing) and kinetic testing through laboratory and field testing methods (*e.g.* field cells and instrumented waste rock piles).

KCB uses the geochemical testing data, site water quality and flows to understand site interactions, construct feasible conceptual models for each of the major mine site components, calibrate and test the operation of the model. This collaborative effort has resulted in a mine site-wide integrated water balance and water quality model (IWBWQM).

The IWBWQM has been built using the GoldSim Pro software developed initially in partnership with Golder Associates and the United States Department of Energy for water balance purposes. The Antamina IWBWQM is a coupled water balance and water quality model built to simulate a variety of different scenarios including: predicting water levels, flows, seepage, pumping needs, and water quality as a solution of up to 42 water quality parameters at a variety of locations throughout the system. GoldSim was considered an appropriate choice for Antamina due to its capacity for complex modelling in terms of handling of data arrays, measurement unit continuity, error checking and user interface. GoldSim simulation software is capable of deterministic and probabilistic modelling as well as providing sensitivity analyses. Specific to this project, multiple realizations of the water balance can be achieved and the sensitivity of different input parameters or processes can be determined. The GoldSim model construction means the model is flexible enough to make impact assessments even given a broad range of potential future water management scenarios.

The Antamina IWBWQM encompasses the entire project area. Here, we focus on the construction and development of the modelled TSF facility. In this paper we demonstrate the fundamental concepts that form the underlying infrastructure of the TSF model, the integration of this framework with data provided by Antamina and comparisons between the predicted evolution of the TSF with historical data. Finally, we demonstrate that the principles in the TSF model construction can be applied to other components of the mine site and that the Antamina mine provides the ideal setting to test this.

METHODOLOGY

The conceptual design and construction of the IWBWQM have been detailed by Strand *et al.* (2010). This study focuses on the design, construction and subsequent testing of the TSF.

The TSF is the most interconnected facility to simulate in the model, with contributions from over 20 inflows and 10 outflows, geometric calculations and area balances. TSF inputs and outputs are based on processes and controls operating at Antamina. The transport of reaction products is taken into account primarily from the dissolved flows and tailings reactivity. Geochemical systems are simulated in both the pond and the tailings pore space as separate systems, with mass transfers between the pond and the tailings as a function of flows and diffusion. Use was made of PHREEQC (Parkhurst and Appelo, 1999) and Geochemist's Workbench (Bethke, 2008) in both the pond and pore space. Mine infrastructure plans, waste schedules and static geochemical test results are used to define the mass of reactants available. Field kinetic cells are used to define the expected reaction sequence and kinetic loading rates under oxidizing (beach surface) and reducing (beach pores and base pores) conditions. The site's water quality monitoring record is used to define the expected behaviour, provide reasons for observations and deviations from expected flows or concentrations. The approach is summarised schematically in Figure 1.

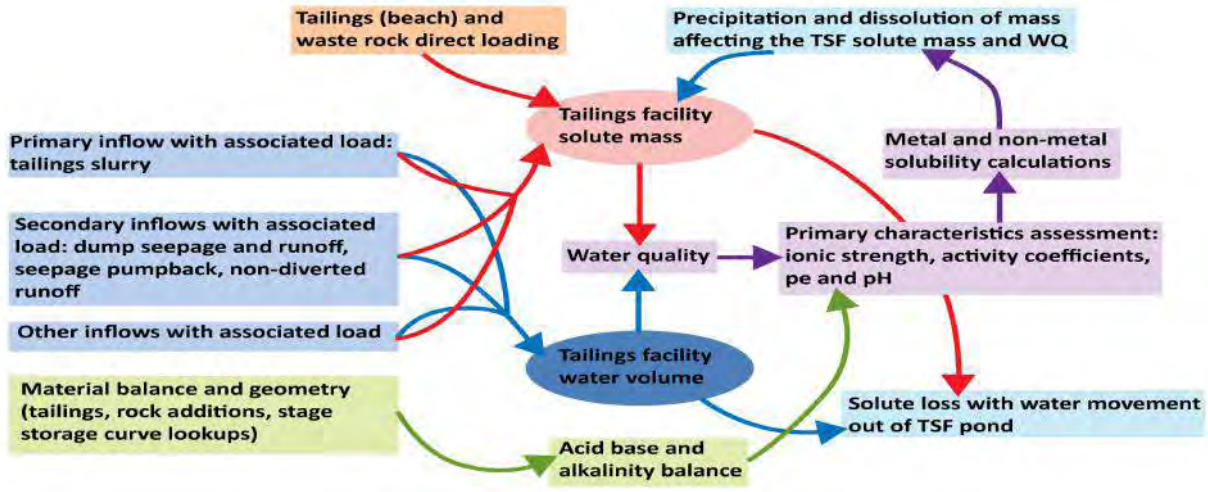

Figure 1 TSF model conceptual components

The TSF pond is the central reservoir and is affected by all of the water inflows and outflows of this section of the model. The most significant inflow to the system is the tailings slurry, which regulates the chemistry in the TSF pond by constant addition of dissolved load and high pH water. Secondary inflows from the waste dumps are the greatest contributors of dissolved metals. These flows include direct precipitation, runoff and contact flows from the waste rock dump or water inflows from non-contact sources. Direct loading from the tailings beach and waste rock also provides a significant contribution. Solute loss is controlled through the precipitation of minerals within the pond, or loss associated with water movement out of the TSF via dam seepage to the seepage pumpback system.

Time and mass dependent loading rates are calculated by multiplying the effluent concentrations by the effluent volume and dividing by the sample mass and the sample interval to produce a mg/kg/week value, Equation 1.

$$Loading\ Rate = \frac{[X]v}{\frac{m}{t}} \quad (1)$$

where X is the concentration in the effluent, v is the effluent volume, m is the mass of the source term used (rock mass) and t is the time interval between measurements.

Subaqueous deposition is associated with considerably slower kinetic rates than aerated deposition. Reaction rates are derived from the kinetic geochemical testing program. The kinetic rates are obtained from the humidity cell data and subsequent field cells operated by Antamina; there are cells currently in operation which continue to provide data for model population.

The model uses a mass balance approach combined with an acid-base accounting and alkalinity balance system and subsequent pH modelling to assess the net load of acid or alkalinity entering the TSF pond via loading at each time step. The TSF load, (the result of water concentration and flow) entering the TSF is a function of all sources considered. Therefore, because those sources vary rapidly, it is assumed that incoming acidic loads only neutralise according to the total concentration of alkalinity present in aqueous solution; thereafter neutralisation is due to the tailings material itself.

The total mass of dissolved solute present in the pond is simulated. All dissolved solute is added to this "reservoir", and all precipitation or physical removal via outflow is removed directly from this element. Dissolved loads that are associated with inflows and dissolution of secondary precipitates also contribute. The solute mass is a primary input for the tailings pond free water quality.

Since the TSF is a mixing pond of several different water flows, preliminary acid base accounting is undertaken through a series of algorithms prior to depleting neutralizing potential (NP) in the TSF. If a water flow is assumed to be acid, then the acidity from that inflow is allowed to deplete the dissolved alkalinity load reporting to the TSF. The net addition of alkalinity and acidity to the pond is the difference between the various alkalinity and acidity contributors. Excess acidity is simulated to then consume the available NP in the tailings, which is present as calcite and small amounts of dolomite in the tailings solids. This differs from other facilities, which consider pyrite oxidation (based on conservative estimates) as the primary driver for the source term systems with acidity generation through sulfide oxidation and subsequent neutralization of acidity by carbonate minerals. From this point, however, acidity as a driver is handled much the same as in source term facilities. Excess acidity consumes minerals contributing to neutralization potential of the tailings.

The TSF pond is modelled using the established carbonate-bicarbonate-CO_2 equilibrium detailed in Strand *et al.* (2010). In the model, the 'central pillar' is considered to be the alkalinity within the TSF pond, which can be estimated as the molar concentration of bicarbonate (HCO_3^-). A certain amount of alkalinity is present in the pond; this is based on measurements provided by Antamina. When the model is operated, any acidity added to the pond (e.g., from the mill) consumes alkalinity. This in turn shifts the equilibrium so that the net effect is to dissolve calcite ($CaCO_3$) to produce more bicarbonate (Strand *et al.*, 2010). The shift in equilibrium results in the dissolution of CO_2, which is assumed to be in equilibrium with the atmosphere (Strand *et al.*, 2010). The model thus combines calcite dissolution/precipitation and CO_2 dissolution/degassing to buffer acidity additions to the TSF pond, provided solid calcite remains in the system (atmospheric CO_2 is considered to be constantly replenished). Alkalinity is also added to the pond from the various additions (e.g., from the mill slurry), which are simulated in the model based on data provided by Antamina.

Calcite provides the major buffering mechanism in the TSF, but bicarbonate is stable within a pH range of ~ 6 – 9. At lower pH levels, other mineral buffering systems are more appropriate and

these have been built into the model. Minerals and secondary precipitates that neutralize acid and buffer pH, using similar principles to the calcite system, have been assigned the pH ranges in the model as follows, after Blowes & Ptacek (1994):

1. Calcite and /or dolomite (6.3 pH – 9 pH)
2. Siderite (4.8 pH – 6.3 pH)
3. Alumosilicates and gibbsite (pH 4.0 – 4.5)
4. Iron Oxides Ferrihydrite and/or Goethite (2.5 pH – 3.5 pH)
5. Jarosite (1.8 pH – 2.0 pH)

Geochemical processes controlling water quality at Antamina

TSF concentrations are governed by kinetic reaction rates, equilibrium controls on saturation and associated water volumes. The major mineral assemblages are dominated by calcium containing carbonates (Strand *et al.*, 2010). Water quality variation appears to be most strongly affected by the oxidation of sulfide minerals, which drives the increase in salinity, sulfate and the acidity. Neutralization of the acidity may occur through the water's natural alkalinity, but occurs principally through the dissolution of Ca-containing carbonates. Sulfide oxidation and concurrent buffering increases salinity and releases the associated metal in the sulfide (*e.g.*, Fe, Cu, Zn or Pb). The resultant increased sulfate and calcium culminates in gypsum ($CaSO_4$) precipitation (Fig. 2). The continued presence of carbonates maintains neutral to alkaline conditions, which limits mobilization of many of the metals, apart from neutral drainage species, such as As and Mo.

Using the sulfate generation rate allows an estimation of the amount of acidity and the amount of carbonate needed to buffer this acidity (i.e. depletion of calcite/dolomite as a result of sulfide oxidation). The site observations confirm that the concentrations of the majority of metals are a function of the pH conditions, overall salinity and mineral solubility constraints. From these observations the required geochemical mechanisms including pH determination, acid generation and neutralization, salinity calculation and solubility constraints have been built into the model (Strand *et al.*, 2010).

TSF solution chemistry was analyzed using PHREEQC to assess the precipitate phases most likely to govern solution chemistry and GWB to observe the potential speciation and the relationships between solubility, concentration and pH. Since the purpose of the IWBWQM is to simulate dynamic conditions, algorithms are used to assess how far the system is from the equilibrium condition. This is achieved by calculating the solubility product, K_{sp}, for a particular mineral at supersaturation and undersaturation. Equations 2 and 3 are examples, for gypsum, of the basis of the quantification of these non-equilibrium conditions:

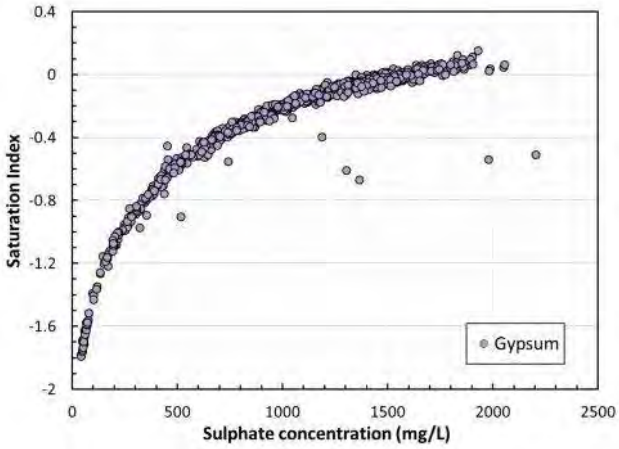

Figure 2 Saturation state of gypsum with increasing sulfate concentrations at the Antamina east waste rock dump

Undersaturated: $([Ca^{2+}] + \delta[Ca^{2+}]) \cdot ([SO_4^{2-}] + \delta[SO_4^{2-}]) = K_{sp(gypsum)}$ (2)

and

Supersaturated: $([Ca^{2+}] - \delta[Ca^{2+}]) \cdot ([SO_4^{2-}] - \delta[SO_4^{2-}]) = K_{sp(gypsum)}$ (3)

These calculate the change in the molar concentration (δ) that is required to bring the solution back to equilibrium. A series of these relationships is included in the model to move sensitive parameters in and out of solution as the pH and other variables change; those used in the TSF are shown in Table 1.

Table 1 Primary mineral controls used in the TSF section of the IWBWQM

Mineral	Formula	Mineral	Formula	Mineral	Formula	Mineral	Formula
Calcite	$CaCO_3$	Gypsum	$CaSO_4$		Cr_2O_3	Otavite	$CdCO_3$
Dolomite	$CaMg(CO_3)_2$	Anglesite	$PbSO_4$	Malachite	$Cu_2CO_3(OH)_2$		$Pb(OH)_2$
Siderite	$FeCO_3$	Brucite	$MgCO_3$	Manganite	MnO(OH)	Rhodochrosite	$MnCO_3$
Gibbsite	$Al(OH)_3$	Cerrusite	$PbCO_3$	Molybdate	Ca/Cu/Pb /$ZnMoO_4$	Smithsonite	$ZnCO_3$
Goethite	FeO(OH)						

Antamina site monitoring data and field kinetic testing suggests that sorption has an important control on metal concentrations at the TSF. This is taken into account in the model by calculating sorption of metal species to Fe-precipitates. The model assumes that the total iron in the TSF is the amount produced by pyrite oxidation; the dissolved iron is governed by solubility calculations. The iron precipitated at each time-step results from the total iron minus the dissolved iron. At a given pH and provided enough precipitated iron is present, the proportion of As, Mo and Se adsorbed to the precipitate is based on PHREEQC determined adsorption ratios. Although metals are typically

desorbed from other minerals present as pH decreases, this is not always the case. Figure 3 shows how the fraction of MoO_4^{2-} sorbed to a surface decreases as pH increases. In contrast, other Mo species, such as H_2MoO_4, remain sorbed at high pH.

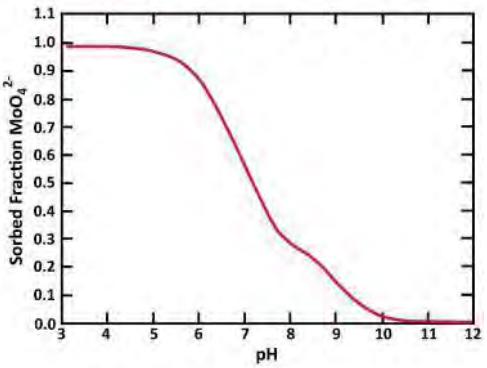

Figure 3 Sorption of MoO_4^{2-} with pH

Once the mass loss and gain and its effect on the TSF pond water dissolved solute has been determined in each time step, the dissolved solute mass for each parameter controlled by minerals/pH is assumed to be 'near' equilibrium in the pond. The concentration of solutes in the pond water is assumed to be the water quality in the pond for that time step. Any outflows from the system (barge pumped, seepage through the tailings-water interface, or other) are assigned this water quality.

RESULTS AND DISCUSSION

TSF IWBWQM model output was compared to TSF monitoring data provided by Antamina. Figure 4 shows the simulated output normalized to the site monitored data and expressed as a percentage above and below the monitored concentrations (set at 1). Simulated sulfate and chloride concentrations are within 20 % of the monitored values for the majority of the five year simulation period: this error is comparable to the analytical error associated with the monitoring data.

Figure 5 shows simulated pH levels normalized to those monitored at the TSF and expressed as percentages above and below the real values. For the majority of the simulated period, pH values are within 20 % of the real values (often within 10 %). This is comparable to analytical error. Figure 5 also shows the simulated TSF pond water volume normalized to water balance data provided by Antamina. The TSF IWBWQM produces a close calibration with the real water balance and is within 10 % of monitored values for the majority of the simulated period. In addition, Figure 5 shows the effect of deliberately 'stressing' the water balance; in this case adding an erroneous water flow of 50 L/s to the TSF pond. In this scenario the model rapidly loses the close calibration to the real data, indicating that the TSF IWBWQM is performing in close agreement to the observed water balance.

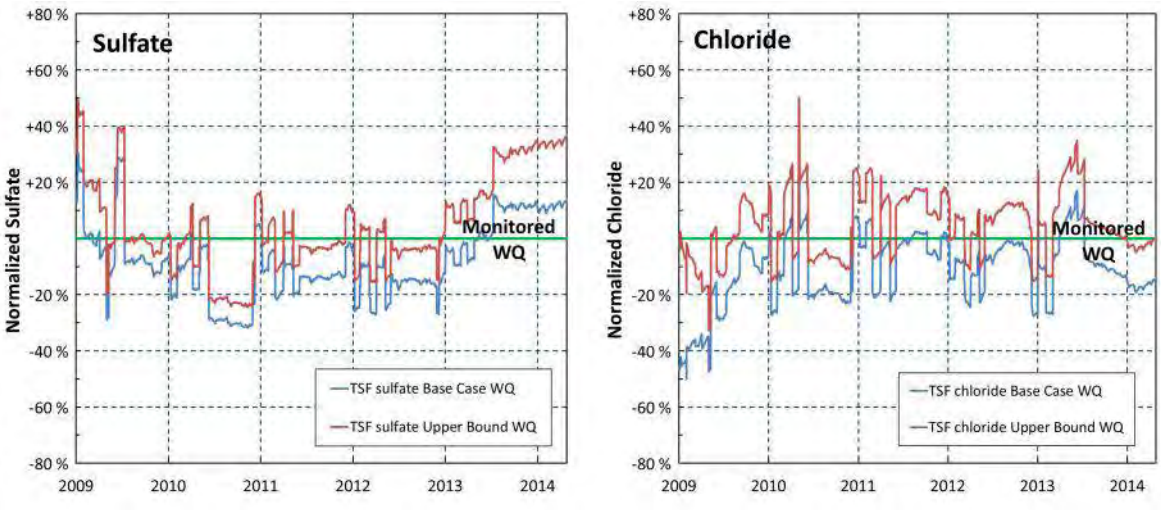

Figure 4 Simulated sulfate and chloride concentrations normalized to monitored concentrations at the TSF

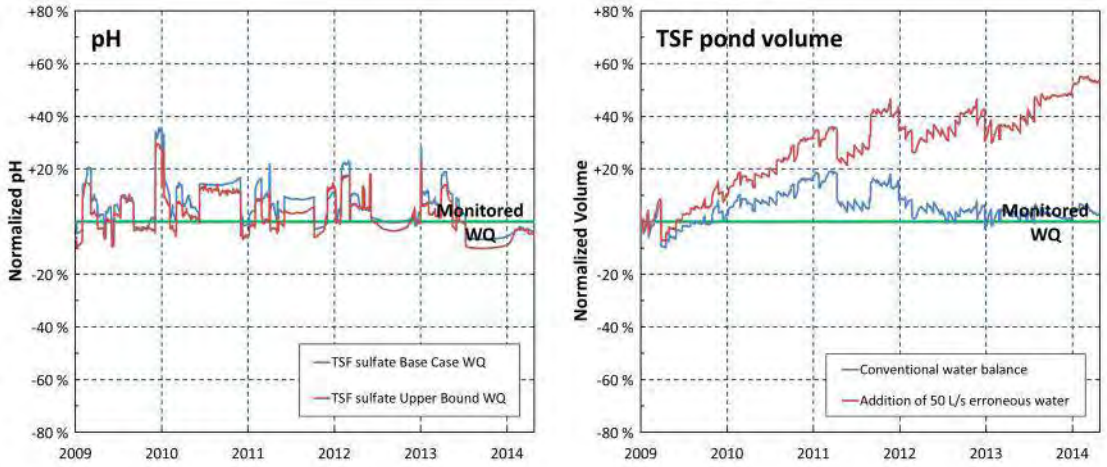

Figure 5 Simulated pH normalized to monitored pH values (LHS) and simulated TSF pond volume normalized to monitored values (RHS)

PHREEQC saturation assessment and the effect of increased sulfate to the TSF

Saturation indices of the IWBWQM mineral controls (Table 1) were calculated using PHREEQC, based on monitored TSF water qualities under the conditions of the mine site. Using PHREEQC in conjunction with the model is an iterative process and allows for continual adjustment of the controls as more data become available. Figure 6 shows that there is generally a good agreement between the TSF IWBWQM expected minerals (which, for equilibrium should be zero) and the saturation indices calculated in PHREEQC.

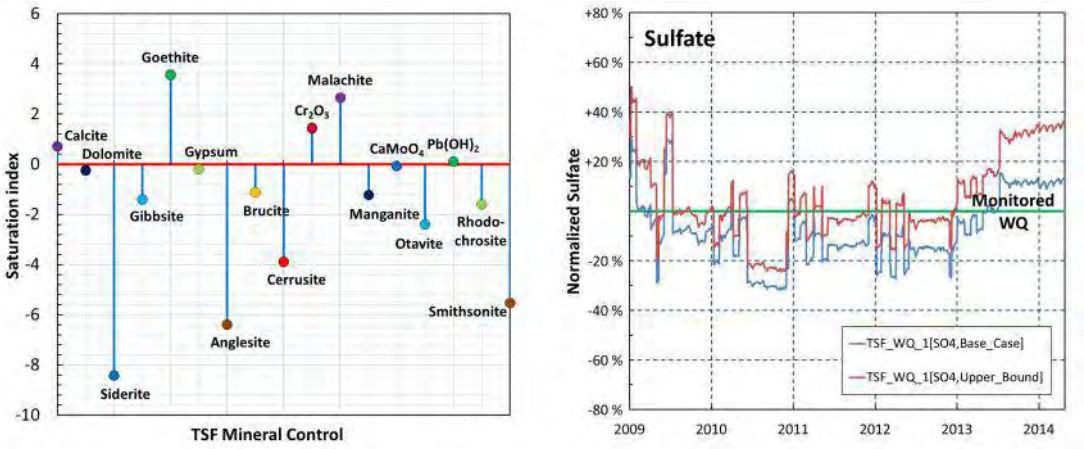

Figure 6 PHREEQC saturation indices using the water quality monitored in the TSF by Antamina (LHS) and normalized TSF sulfate concentrations after a 6-fold sulfate increase at 100 L/s (RHS)

The IWBWQM was tested for its robustness to changes in conditions by simulating an increased sulfate addition to the TSF. Figure 6 shows that, in spite of the increased sulfate input (here this is simulated as a 6-fold sulfate increase at 100 L/s), the TSF sulfate concentrations remain within 20 % of the monitored values (*cf.* Fig. 4) and suggests that the mineral control mechanisms built into the model can adjust to this influx; the IWBWQM moderates the impact of the additional sulphate by allowing oversaturated minerals to precipitate.

The Antamina site is ideal for applying the IWBWQM principles to other mine site facilities. Figure 7 compares the simulated normalized concentrations at the East Waste Rock Dump (EWRD). Although simulated sulfate is consistently lower than shown in the monitoring data, the values are, nonetheless, within 20 % for the majority of the simulation.

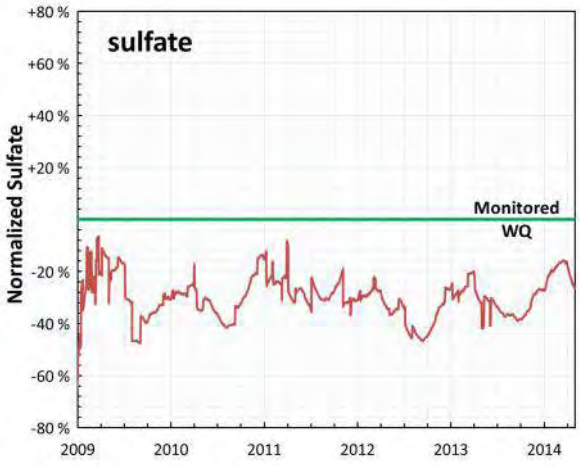

Figure 7 Simulated sulfate concentrations normalized to monitored concentrations at the EWRD, Antamina

CONCLUSIONS

This report outlines the infrastructure of the TSF IWBWQM and testing that has recently been conducted to check the mechanisms and controls within the model. The model is based primarily on site observations and fundamental geochemical principles: monitored water qualities are used provide the provisional model calibration and the water balance and water quality components of the model are continually updated as more information becomes available. Testing of the TSF IWBWQM has shown that the simulated water quality is within 20 % of that monitored at the mine site. The simulated TSF is closely calibrated with water balance data provided by Antamina.

Comparison with hydrogeochemical modelling programs, such as PHREEQC, shows that the TSF IWBWQM is operating as predicted by these programs. Nevertheless, the mechanisms built into the model are continually revised (with the aid of programs such as PHREEQC) to optimise the performance of the model. It is expected that this process will continue.

This paper has focused on the TSF facility at Antamina, but the mine site provides an ideal setting to test the application of the model to other facilities. Here we show examples applied to the East Waste Rock Dump.

ACKNOWLEDGEMENTS

Thanks are extended to all of the field technicians and staff for their hard work in data collection. Without their diligence, this model would not have the inputs and trends to support its calibration. We would like to acknowledge the collaborative efforts of UBC and the many consultants who have provided supporting studies to aid modelling of the various systems.

ABSTRACT

Water released from underground mine fissures is either pumped at the surface or accumulates in ponds underground. Fine particles of ore suspended in such solutions are susceptible to weathering under environmental conditions or through the effect of indigenous autotrophic microorganisms living in the ore. The leachability of the suspended solids determines the risk of water contamination underground and at the surface as well as the need of a pretreatment process. In this work environmental conditions are partly considered, as aggressive methods are also used for leaching. Water samples collected underground and at the surface of a mine, were filtered and the suspended particles were separated from the solution through filtration and analyzed by SEM-EDS, XRD and XRF. The solid was leached under simulated environmental conditions or ultrasonic acid digestion at various temperatures. The metal mobility test was carried out according to the German standard Norm DIN 19730. The XRD analysis revealed the presence of iron sulfide (pyrite) in underground samples and iron oxides (maghemite and mackinawite) and zeolite in samples collected at the surface, while the SEM-EDS and XRF results showed the presence of trace elements such as chrome, titanium, calcium, zinc, nickel, manganese, lead, copper, cobalt and magnesium. The amount of mobilized metals detected by ICP analysis indicates that the metal could be released from the suspended solids, however, further investigations are required to determine the extent and rate of metal leaching under environmental conditions.

The natural weathering of the suspended solids is possible and this could therefore contribute in the degradation of water quality by decreasing the pH and increasing metal concentration; this implies that pretreatment of mine water is required to mitigate the risk of contamination of water sources.

INTRODUCTION

Mining of ore as well as recovery of metals and other resources from the ores using mineral processing and hydrometallurgical processes generally results in the accumulation of suspended particle matters (SPM) also referred to as fluid fine mineral tailings. These particles often contain sulfide minerals which, if not properly stored can be oxidized, resulting in the formation of acid mine drainage (AMD), usually containing high concentrations of dissolved potentially toxic elements (PTE) and sulfate (SO_4^{2-}). According to several authors (Bird et al., 2008; Fuge et al., 1991; Allan, 1988; Helgen and Davis, 2000; Miller et al., 2007), the release of contaminant metals into the fluvial environment within mining-affected river catchments generally results from (1) acid mine drainage, (2) the release of waste slurries containing solute and particulate-associated metals, (3) dumping of mining and milling waste that is subsequently leached or dispersed downstream. Interaction of ground water and surface water with the suspended particle matters will result in the mobility of the trace elements from the solid phase after a time often determined by environmental conditions. Depending on the hydrogeochemical environment, the dissolution of SPM may give elevated concentrations of the trace elements and create potential contamination of associated ground water and surface water systems. The oxidation of sulfide minerals such as pyrite, chalcopyrite, arsenopyrite and pyrrhotite, will eventually result in the dispersion overtime of large amount of toxic metals into the ecosystem impacting the freshwater resources. From such sources, metal can easily move along the food chain causing genotoxicity among living organisms (Patra et al., 2004).

This study focuses on the investigation of the leachability of suspended particles in water from underground mine fissure and tailing ponds.

METHODOLOGY

Sampling

Water was collected from underground mine fissures and from tailings ponds at the surface. Suspended particles were collected from water samples by filtration through filter paper (Whatman 150 mm, Cat No 1440 150). The recovered suspended solid was dried at 50°C in the oven until constant weight.

Characterization of suspended particles

The suspended solid samples were ground in a mortar and for the determination of the mineralogical phase, they were subjected to X-ray diffraction (XRD) analysis using the Philips model X'Pert pro MPD, at a power of 1.6 kW used at 40 kV; Programmable divergence and anti-scatter slits; primary Soller slits: 0.04 Rad; 2θ range: 4-79.98; step size: 0.017°. The proportion of elements in the suspended solids was determined by X-ray fluorescence (XRF) using the MagiX PRO & SuperQ Version 4 (Panalytical, Netherland); a rhodium(Rh) anode was used in the X-ray tube and operated at 50 kV and current 125 mA; at power level of 4 kW.

Scanning Electrom Microscopy (SEM)

A FEI Quanta 200 ESEM Scanning Electron Microscope, integrated with an Oxford Inca 400 energy dispersive x-ray spectrometer was used for the analysis of the suspended particles.

Leaching experiments

The suspended solid samples were submitted to batch leaching with three different approaches aiming to test the mobility and rate of release of elements from the three suspended solid samples. The aggressive test using aqua regia aimed to approximate total metals not associated with silicate. In all experiments, about 0.1 g of samples was leached with 10 ml of lixiviant.

Leaching with synthetic acid rain

The Eastern Transvaal Highveld is the area in South Africa where large metal working industries and coal burning power stations are located; in this particular area acid rain can occur at an average pH of 4.2. To simulate the natural lixiviant, synthetic acid rain (SAR) was prepared by diluting the mixture of H_2SO_4 and HNO_3 to a pH of 4.2; this solution (SAR) was used in batch leaching at room temperature. Leaching was performed with simultaneous shaking on horizontal at a speed of 150 rpm and six shaking periods: 1, 2, 3, 4, 7 and 24 hours; a long term leaching test was performed without shaking over a period of nine weeks (simulation of environmental conditions).

Metal mobility test

The mobility of the elements was measured on the basis of the procedure described in the German Norm DIN 19730 (Deutsche-Norm DIN, 19730, 1997). The suspended solids were leached in deionized water without subsequent change of pH for 2 h at constant shaking speed of 20 rpm and at room temperature (~20°C).

Ultrasound assisted acid digestion method

To maximize the extraction of elements from the suspended solids, the leaching was performed using aquaregia; the mixtures in 250 ml flasks were immersed into the ultrasonic water bath and subjected to ultrasonic energy of 35 KHZ for 20 min. The three temperatures of the ultrasonic water bath considered were 30, 50 and 70°C.

ICP analysis

After the leaching process, the sample from each of the above test was collected into a 50 ml centrifuge tube, then centrifuged at 4000 rpm for 20 min and the supernatant carefully recovered without disturbing the pellet. The metal content of the supernatant was analyzed using the ICP-OES (ICP Expert II, Agilent Technologies 720 ICP-OES).

Leachability of elements

The leachability of an element was calculated by considering the approximate total metal (expressed in leached amount) and the percentage leached value for the element.

The leached amount was calculated using the following equation:

$$Ca = CL \times VL/S \quad (1)$$

Where Ca is the leached amount of an element in mg/g; CL is the concentration of an element in the leachate in mg/L; VL is the volume of the leachate in L, S is the mass of the suspended solid in g.

The percentage leached was calculated using the following equation.

$$Cp = Ca/Csp \times 100 \quad (2)$$

Cp is the percentage leached in %; Csp is the total concentration of an element in the suspended solid, estimated by XRF analysis.

RESULTS AND DISCUSSION

The susceptibility of suspended solids from mine ponds to release metals in the environment is investigated in this study with consideration of natural or environmental conditions impacting on the leachability of metals. **Minerals and elements in the suspended particles**

The chemical characteristic of the suspended particles may determine the rate of reaction with the lixiviant. The mineralogical composition as determined by the XRD showed (Table 1) higher content of pyrite (FeS_2) in underground suspended particles (SP). It is assumed that the lower content of pyrite in surface SP is associated with longer exposure to weathering and dissolution of pyrite, hence the presence of iron oxides such as maghemite and mackinawite. The zeolite was identified only in surface samples (B and C), while quartz (SiO2) was abundant in all the SPs.

Table 1 Mineralogical composition (XRD) of the suspended solids samples

Sample A		Sample B		Sample C	
Phase name	**Wt %**	**Phase name**	**Wt %**	**Phase name**	**Wt %**
Pyrite	12.74	Silicon Oxide	17.67	Calcium silicate	19.31
Potassium Iron Oxide	33.55	Clinoptilolite	27.46	Zeolite	12.59
Silicon Oxide	26.59	Mackinawite	24.42	Silicon Oxide	16.86
Magnetite	27.11	Maghemite	30.45	iron(III) oxide	24.45
				Iron Sulfide	26.79

Based on the consideration of Price et al. (1997), the above table shows that there will be negligeable clay or carbonate minerals neutralisation potential.

The SEM-EDS analysis (Figure 1) shows the abundance of elements such as Fe, Si, Ti, Cr, Al, K, Mg and S in all the samples which can be correlated to the presence of pyrite and aluminosilicates as revealed by the XRD results; the element composition was confirmed by XRF results in Table 2.

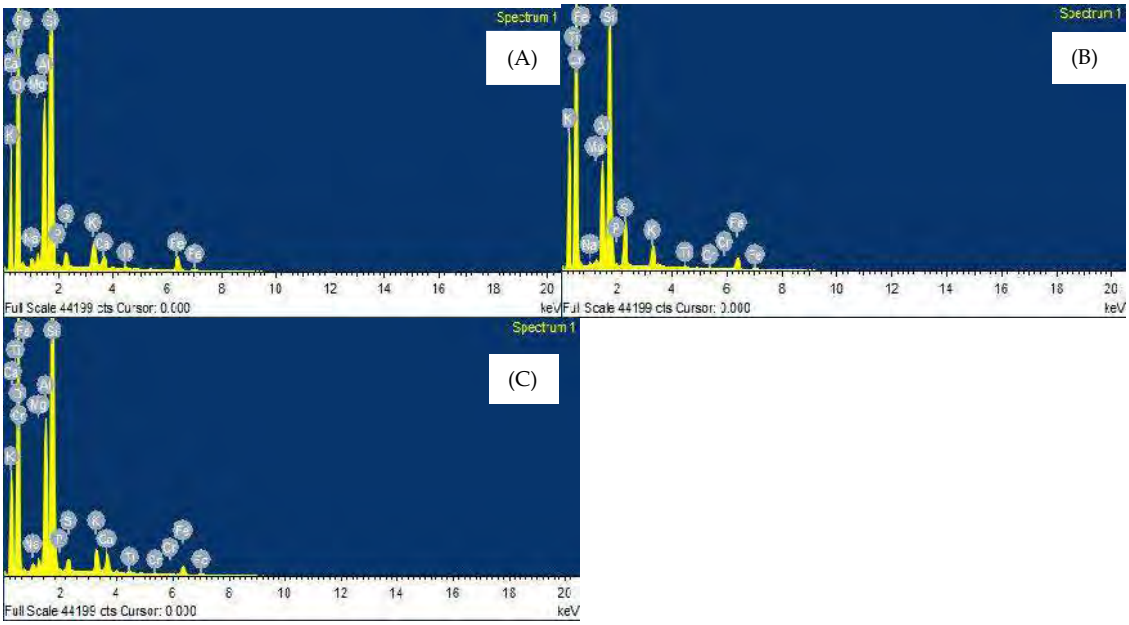

Figure 1 SEM-EDS analysis of suspended particles

Table 2 Chemical composition of suspended particles

Elements	Mass %		
	A	B	C
Na_2O	0.24	0.82	0.94

ZrO_2	0.05	0.04	0.03
BaO	nd	0.06	0.07
PbO	0.06	0.02	0.03
U_3O_8	0.03	0.01	nd

The Fe enrichment of the SPs is associated with Fe-rich sulfides and Fe oxides as observed with XRD analysis (Table 1) and also reported in the mine residues such as tailings (Hochella et al., 1999; CourtinNomade et al., 2003).

Mobility of elements under environmental conditions

The percentages of Al, Fe, Mn, Ni, Sr, Zn and Cr leached from the samples (A, B and C) are plotted in Figures 2a and b which correspond to metal release by long term leaching (simulation of environmental conditions) and mobility test, respectively. It is observed that the metals are easily leached from the SPA which has acidic tendency as revealed by the decrease of pH after nine weeks contributing to dissolution of the mineral. Furthermore the presence of zeolite in surface samples (B and C) reduces the mobility of metals due to its cation exchange and molecular sieving properties; it is reported (Jiwan et al., 2013) that zeolite if often used to reduce the leachability of metals in compost. The long term leaching was carried out without stirring in synthetic acid rain (SAR) which are similar to environmental conditions. The mobility test is carried out at the same pH as the original solution of the SP and could therefore reflect the dissolution likely to occur in mine water at the site; it is observed that (Figure 2B) under such condition all the metals were mobilized from the SPA and only Mn, Sr and Zn from SPB and SPC; overall Fe, Ni, Sr and Zn were found to be the elements with higher leachability.

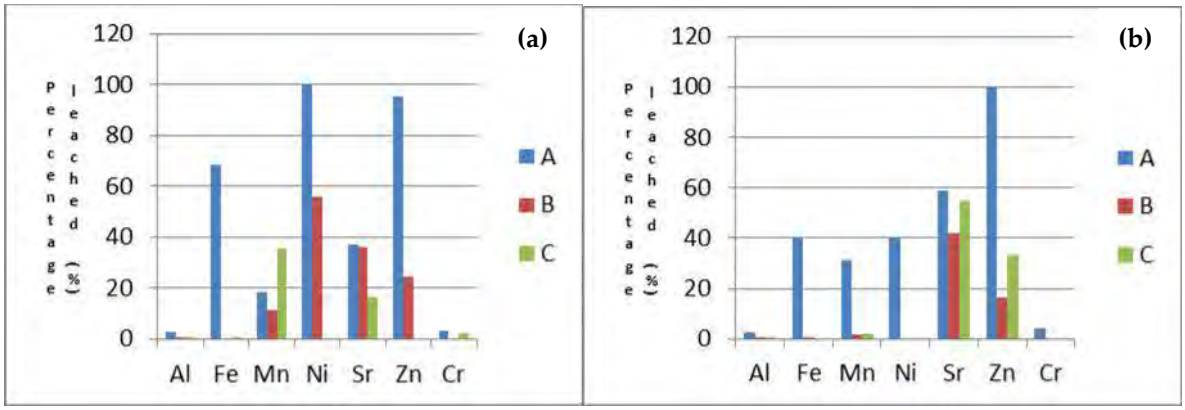

Figure 2 Percentage leached of metals from suspended particles following (a) long term leaching and (b) mobility test

To better understand the leachability of the element the correlation of their mobility and their concentrations in the SPs was evaluated; as shown in Table 2, the values of the coefficient of determination (R^2) were relatively low, implying very little correlation, therefore the mobility of the element is not strictly related to its concentration in the SP, similar results have been reported by Jankowski et al. (2006). Except for Fe and Zn, there was no obvious correlation between mobility of element and the long term leaching; trace elements may exist in different oxidation states in mineral matters and therefore respond differently to leaching (Wadge et al., 1987; Jackson and Miller, 1998).

Table 2 Correlation between mobility of elements, total concentration of elements and long term leaching

Elements	Mobility vs Total concentration	Mobility vs long term leaching
Al	-0.9792	0.9304
Fe	0.834	0.9998
Mn	0.9326	-0.4852
Ni	-0.8992	0.944
Sr	0.6583	-0.9435
Zn	0.74	0.99
Cr	0.9346	0.7551

This also implies in our study that the dissolution of the metal is mostly dependent on the chemical reactions given the distinctiveness with regard to the mineralogical composition of the samples.

Leachability of elements from suspended particles

Environmental monitoring often requires the determination of metal content of suspended particles, but most importantly the susceptibility of release by dissolution. Figures 3a, b and c below show the percentage of Al, Fe Mn, Ni, Sr, Zn and Cr released through ultrasonic digestion of SPs. The predominant factor during such leaching approach is the temperature which increased the reactivity between the lixiviant and the SP, but also important in this case, a very aggressive lixiviant namely aqua regia was used to ensure the maximum extraction of the metal from the SPs. This test is basically conducted to detect elements which can be a drainage chemistry concern but is not a direct measure of their threat to the environment (Price et al., 1997). It is observed that irrespective of the temperature, approximately all the metals were extracted from the SPs. The impact of temperature is however noticeable as for metals such Al, Sr and Cr there is significant increase of percentage of metal leached with increase of temperature.

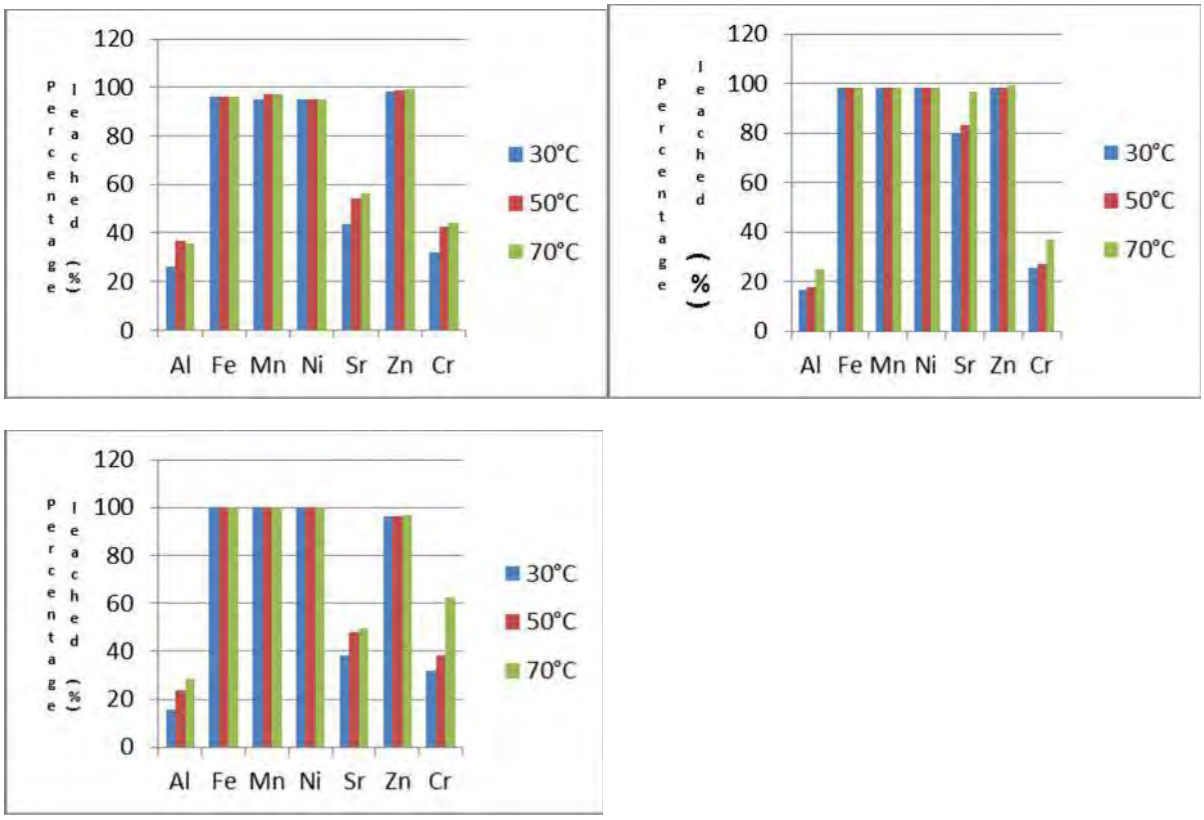

Figure 3 Percentage leached metals from ultrasonic assisted acid digestion of suspended particles

Maximum recovery close to 100% was achieved in most cases for Fe, Mn, Ni and Zn; Kazi et al. (2000) have also reported similar percentage recovery using ultrasonic acid assisted digestion for the recovery of Cd, Cr, Ni and Pb. This result indicates that weathering of the suspended particles over a relative long period of time will likely result in the release of most of the metals into the environment resulting in the pollution of water sources.

CONCLUSION

The suspended particles studied contained several metals in relatively high amounts with regard to environmental impact. The suspended particles collected underground were more likely to release the metals, the SP mineralogical propertyy is therefore and important parameter determining the mobility of the metals. The methods of metal extraction considered indicate that these metals will be released at various rates in the water system after short or long period of time. However, environmental conditions being only partly considered, the data could not be used for exact prediction of actual leachability at the mine site.

Release of Explosives Originated Nitrogen from the Waste Rocks of a Dimension Stone Quarry

Teemu Karlsson and Tommi Kauppila
Department of Land Use and Environment, Geological Survey of Finland

ABSTRACT

Emissions of nitrogen compounds, including $NH4^+$, $NO3^-$ and $NO2^-$, from mining areas can have detrimental effects on the environment through either eutrophication or direct toxicity. Besides environmental effects, contamination by nitrogen originated from explosives may be problematic, depending on definitions and classifications of inert waste. In certain jurisdictions, nitrogen contamination of otherwise mineralogically and chemically inert waste rocks of good technical quality may hinder utilization of these product streams. This is an important economic and environmental issue, especially at dimension stone quarries.

To study the amount of nitrogen contamination in waste rocks produced by these types of quarrying operations, two 1 m^3 lysimeters were installed at a selected quarry. The test units were filled with fresh waste rock immediately after the excavation of a block of dimension stone. The rainwater flowing through the test units was collected in separated plastic tanks and sampled regularly over a one year period.

The results indicate that the "first flush" of recharge water occurs rapidly, only after a few weeks, after which the nitrogen drainage settles to near natural rainwater levels. Calculations on the amount of nitrogen leached out of the test units and the remaining nitrogen detected on the rocks after the monitoring period suggest that a little more than half of the explosive residuals had remained within the waste rock material. The total amount of nitrogen derived from explosives in the waste rock material at a dimension stone quarry seems to be in the order of 0.1 mg/kg, which is well below the amounts commonly detected in waste rocks produced by larger scale mines and thus indicate that the environmental risks associated with these type of waste rocks are relatively low.

Keywords: Explosives, nitrogen, waste rock, dimension stone

INTRODUCTION

The presence of nitrogen compounds in mining areas can have detrimental effects on the environment through eutrophication or direct toxicity (Forsyth et al. 1995). Use of explosives is one of the main sources of nitrogen emissions in the mining industry (Morin & Hutt 2009). Besides environmental effects, contamination by nitrogen compounds derived from explosives may be problematic due to varying definitions and classifications of inert waste. Nitrogen contamination of otherwise mineralogically and chemically inert waste rocks of good technical quality may hinder the utilization of these product streams, which is an important economic and environmental issue at several quarries and mines.

To study the rate of dissipation and amount of nitrogen contamination on waste rock surfaces and to investigate the reactivity of the materials, a long term field study was conducted at a selected quarry.

METHODOLOGY

The study area was a dimension stone quarry located in Varpaisjärvi in the Lapinlahti municipality in the region of Northern Savonia (Figure 1).
The main stone extracted at the selected quarry is black diabase, with an average density of 3 080 kg/ m^3. The total amount of extraction is approximately 28 500 m^3/year, of which around 24 000 m^3 i.e. 73 920 tons is waste rock. The use of explosives, mainly nitroglycol and diatomite containing K-pipecharges by Forcit Oy, is roughly 5 700 kg/year, the specific charge (powder factor) being around 0.065 kg / t. The average nitrogen concentration of K-pipecharge is 4.2 % (Forcit Oy 2013). The water resistance of K-pipecharges is reasonable, but the unexploded agent dissolves gradually into water. The waste rocks consist mainly of the same diabase material as the final products.

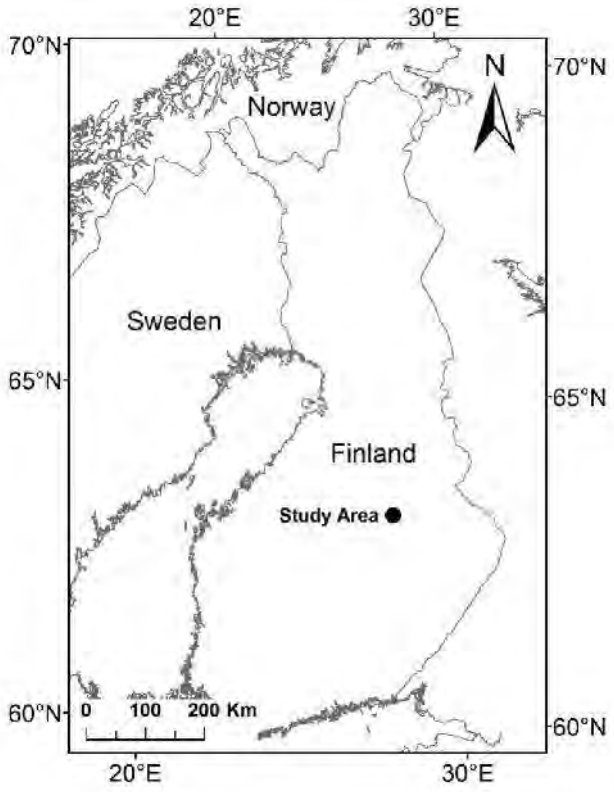

Figure 1 The test site (a dimension stone quarry) is located in Varpaisjärvi in the Northern Savonia region of Finland

To evaluate the temporal changes in the quality of water emanating from waste rock produced by the quarry, two lysimeters were installed at the quarry site, and filled with waste rock material collected immediately after the excavation of a large diabase block. The rock material in both lysimeters was identical and the purpose of setting up two units was to examine the repeatability of the test. Unit 1 contained approximately 1 970 kg of rocks with 38 % porosity, and Unit 2 contained approximately 1 790 kg of rocks with 44 % porosity. The test units are shown in Figure 2.

The rain water flowing through the lysimeters was collected in separate 70-liter plastic tanks and analysed frequently, 9 times in total, between the 10th of October 2012 and the 16th of October 2013, excluding the winter months when the test units were frozen. The sampling interval was 2 weeks during the first month and once a month during the rest of the monitoring period.

The monitored parameters included nitrogen species ($NO2^-$, $NO3^-$, $NH4^+$ and total-N), Cl^-, pH, Ec and temperature. Chloride (Cl^-) is present in rock dust and in the blasting residuals (as sodium chloride) and is considered as a good indicator of the first flush of water through the test units (Bailey et al. 2013).

At the end of the observation period, the test units were filled (washed) with tap water and sampled three times (Unit 2 only once) to remove the remaining nitrogen of explosive origin and to determine the porosity and approximate weight of the rocks inside the test units. The chemical composition of the tap water used for washing was analyzed as well.

Figure 2 The aging test units 1 (front) and 2 (behind). The rain water flowing through the units was collected in the green plastic tanks below. Photo: Lauri Solismaa / GTK

Field measurements and sampling

The untreated samples were collected into HDPE sample bottles that had been triple-rinsed with sample water. The sample bottles were sent to the laboratory in a cool box during the sampling day. The samples arrived at the laboratory next morning and were analysed as soon as possible, to minimize the alteration of the samples, especially the sensitive $NO2^-$.

The pH, temperature, electric conductivity, nitrite and ammonium were measured in the field. The pH was measured by the Mettler Toledo SevenGo pH-meter. The electrical conductivity and temperature were measured with the WTW-electric conductivity meter Cond 340i. The nitrite and ammonium concentrations were analyzed with a portable Hach Lange DR2800 spectrophotometer using Lange cuvette tests LCK342 (0.6-6 mg/l NO2-N) and LCK 304 (0.015-2 mg/l NH4-N). The amount of rain water accumulated in the tanks was measured and the tanks were emptied after every sampling occasion.

Besides field measurements, the nitrogen species were also analysed in a laboratory to estimate the accuracy of the spectrophotometric measurements and to investigate the effects of transportation of the water samples to the laboratory. The results seemed to be similar with both methods although the portable spectrophotometer gave lower concentrations when the weather was colder.

Laboratory measurements

The laboratory measurements included total nitrogen, nitrite, nitrate and chloride in an accredited laboratory (Labtium Oy). The $NO2^-$ was measured by spectrophotometry. The anions $NO3^-$ and Cl^- were measured using ion chromatography (IC) according to the standard SFS-EN-ISO 10304-1. $NH4^+$ was measured by the Aquakem analysator (salicylate-spectrophotometric method). Total nitrogen was measured by the peroxosulphate oxidation and Aquakem analysator (hydrazine reduction and spectrophotometric sulphanilamide method).

RESULTS AND DISCUSSION

The monitored concentrations and values followed similar trends in both test units, but the concentrations were somewhat lower in Test Unit 2. At first the electric conductivity and concentrations, e.g. of total-N and Cl^- were relatively high, but declined rapidly to the average local rain water values after the "first flush" (Figure 3). Cl^- declined more sharply and remained low for the remainder of the study. The nitrogen concentrations were more erratic, but the absence of Cl^- suggests that most of the nitrogen was delivered from rain water / atmosphere.

The most abundant nitrogen species was NO3-N, around 60 % of the total first flush N concentration. The NH4-N concentrations were relatively high during the first flush, around 40 % of the total N. Later, the proportion of the NO3-N increased to 67 – 94 % and the proportion of NH4-N decreased to 1 – 9 %. The field measurement values of $NH4^+$ and $NO2^-$ were mainly higher than those measured in laboratory, which may indicate the instability of these nitrogen species during transport.

The total-N concentrations in rainwater have been measured by the Finnish Environment Institute (SYKE) at the nearest weather station at Maaninka (about 40 km south west from Varpaisjärvi) during 2004 – 2012. The rainwater samples collected at the test units at Varpaisjärvi had similar total-N concentrations to Maaninka, around 0.6 mg/L. During two observation periods (30th of April 2013 and 20th of August 2013) the rainwater tanks were full and probably overflowed.

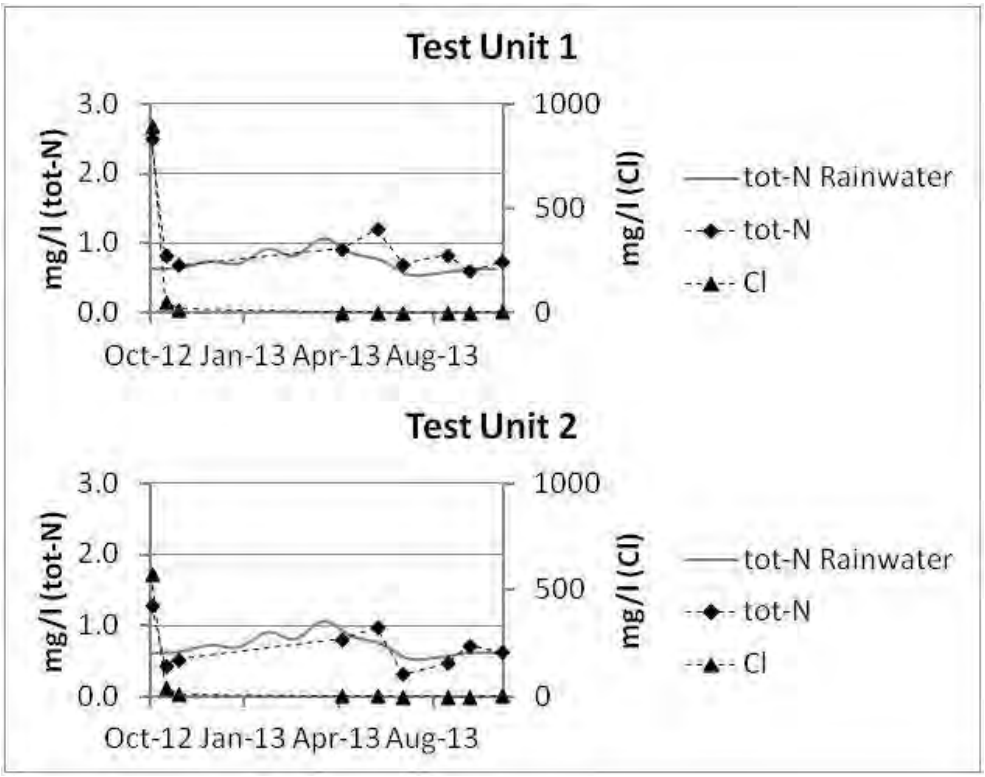

Figure 3 Total-Nitrogen and Chloride concentrations in the recharge waters of the Test Unit 2 and total-N of rainwater in Maaninka (monthly averages during the years 2004-2012) measured by the Finnish Environment Institute

The amount of water required to fill the Unit 1 was 380 litres and 440 litres for the Unit 2 (i.e. the porosities were 38 % and 44 %). The rock masses of the units were calculated by the volume and density of the diabase (in Unit 1 approximately 1 970 kg and in the Unit 2 approximately 1 790 kg).

The amounts of total nitrogen released from the test units were calculated by multiplying the amounts of water (litres) by the nitrogen concentrations (Table 1). The nitrogen concentrations of the first flush were determined by subtracting the background value (0.6 mg/L in October) from the measured concentrations. The first flush includes the first samplings in October 2012 when the concentrations were higher than the background values of rainwater (Unit 1 10th October 2012 and 25th October 2012, Unit 2 only 10th October 2012).

The amount of nitrogen originating from explosives was detected in Test Unit 1 was 138.8 mg i.e. 0.07 mg/kg Waste Rock and 32.5 mg i.e. 0.02 mg/kg Waste Rock in Test Unit 2. About half of the total nitrogen seemed to be left in the test units after one year of ageing. Presumably some traces of explosive nitrogen were also released after the first flush, but the nitrogen concentrations were so close to the average rain water values that assessment of exact numbers is difficult. Some small residual amounts probably also remained in the stone material after washing. Considering the uncertainty factors, the amount of nitrogen derived from explosives in the type of rock material used in this study is around 0.1 mg/kg or 0.1 g/t. Multiplying this by the annual average amount of waste rocks (24 000 m^3 i.e. 73 920 t) remaining at the test site results in blasting-related nitrogen load of around 7.4 kg/year from the waste rock pile.

Table 1 The amounts of total nitrogen released from the test units during first flush and washing. *NH4-N + NO2-N concentrations.

Sample	tot-N (mg/L)	Water (L)	Released N (mg)
Test Unit 1			
10.10.2012	1.9	28	53.2
25.10.2012	0.2	48	9.6
1st wash	0.1	380	38
2nd wash	0.1	380	38
3rd wash	0.0	380	0
Total N			**138.8**
Test Unit 2			
10.10.2012	0.7	27.5	19.3
1st wash	0.03*	440	13.2
Total N			**32.5**

Lysimeters used in this study were relatively small scale compared with the size fractions of normal waste rock material, which introduces a bias to the test setup. In addition, the residuals of explosives are heterogeneously distributed in a waste rock material as demonstrated by the differences between the test units. The rock material in the test units presented a ”worst case”; real waste rock contains also larger boulders, so it has less surface area / kg (= less explosives-N / kg)

than the finer material in the test units. This indicates that in practice, the amount of leaching from the waste rock material should be less.

Waste rocks produced by the natural stone industry seem to contain less explosives originated nitrogen than waste rocks produced by larger mining activities. For example waste rock at the Diavik diamond mine in Canada contains tot-N around 4.6 mg/kg (Bailey et al. 2013) and ore and waste rocks at the Kemi chromium mine around 20 mg/kg (Mattila et al. 2007).

The leaching tests conducted in this study apply to the K-pipecharge explosives used at the test quarry, which contain relatively low amounts of nitrogen, about 4.2 %. Different types of explosives exist for different purposes and their nitrogen contents and solubilities may vary. In general, the nitrogen content of different rock blasting explosives varies between 20 – 30 % of total weight (Chloth 2011).

CONCLUSIONS

Based on the observation period of more than a year the "first flush" of nitrogen occurs rapidly, during the first few weeks (or first rain events), after which the nitrogen drainage settles to natural rainwater levels. Based on the current results, the first flush removes approximately half of the total nitrogen, mainly in NO3-N and NH4-N forms.

Calculations on the nitrogen leached out of the test units during the observation period and the remaining nitrogen detected on the rocks after the test period indicate that some residuals of explosives remain within the test material. The remaining nitrogen is leached out fairly slowly, promoting loss to the atmosphere.

The two seemingly identical units had different nitrogen concentrations, which suggest that the undetonated explosives are heterogeneously distributed in a waste rock pile.

The total amount of nitrogen derived from explosives in the waste rock material of a dimension stone quarry seems to be on the scale of 0.1 mg/kg, which is well below the amount detected in waste rock produced by larger scale mines. The main reason for the difference is probably the moderate use of low nitrogen containing explosives in natural stone quarrying.

As the nitrogen contamination of dimension stone quarrying waste rock is relatively low to begin with and enhanced by the rapid flushing by rainwater, the residues of explosives should not be considered to prevent the utilization of otherwise mineralogically inert waste rocks of good technical quality.

ACKNOWLEDGEMENTS

This study was conducted as a part of the Finnish Green Mining project MINIMAN, which concentrated on the behaviour of nitrogen compounds in mining environments, and developing technologies for management of nitrogen discharges. The research project was realized during the years 2012-2014 as a cooperative project between the Geological Survey of Finland (GTK), Technical Research Centre of Finland (VTT) and Tampere University of Technology (TTY) together with several industrial and international partners.

ABSTRACT

AMEC Environment & Infrastructure (AMEC) was retained by M3 Engineering and Technology Corporation (M3) to provide an assessment of the acid rock drainage and metals leaching potential (ARD/ML) of waste rock and ore to be produced at an open pit copper mine located at high elevation (3,000 – 4,500 masl) in Peru. The mine is expected to produce about 573 Mt of ore for milling, 173 Mt of low-grade ore for heap leach, and about 1,360 Mt of waste rock over 25 years of operation. The current plan is to construct an on-site waste storage facility (WSF) by co-blending milled tailings with waste rock in an alpine valley. The WSF, which will also partially cover the heap leach residue pad located at the top of the valley, will contain underdrains directed to a single pond at the toe. Geochemical testing included analyses of 1000 samples from five major lithologies representing waste rock and ore for acid base accounting and content of total metals. Selected samples of waste rock, simulated tailings, and heap leach residue were submitted for mineralogical, humidity cell, and other geochemical testing. Geochemical results were modeled by considering the configuration of the WSF to predict water quality of the leachate at the toe. Leachate pH is expected to be mildly alkaline due to alkalinity generated primarily by the tailings. Although the heap leach residue is expected to contribute some acidity, alkalinity from the tailings will minimize the contribution. The results indicate that arsenic, chromium, mercury, and zinc may be of possible concern, requiring treatment prior to discharge.

Keywords: Tailings, Alpine, Waste Rock, Humidity Cells, ABA

INTRODUCTION

AMEC Environment & Infrastructure, a division of AMEC Americas Limited (AMEC), was retained by M3 Engineering and Technology Corporation to assess the acid rock drainage and metals leaching potential (ARD/ML) of waste rock and ore to be placed in a high elevation (3,000 – 4,500 masl) waste storage facility (WSF) in Peru. The WSF is designed to contain milled tailings from high-grade ore (573 Mt) co-blended with waste rock (1,360 Mt). The co-blended material is expected to partially cover a spent heap leach residue pad (total 173 Mt) when mining operations cease after 21 years. The WSF including the heap leach residue pad (total 2,106 Mt) will be located in an existing alpine valley with constructed underdrains directing leachate to a pond at the toe.

A geochemical testing program was conducted to enable prediction of potential water quality from the WSF to support mine planning activities. The objective of the program was to develop an integrated geochemical-hydrological loading model to predict water quality at the toe of the WSF using data derived from static and humidity cell testing of waste rock, simulated mill tailings, and heap leach residue as well as local meteorological data.

METHODOLOGY

Sample Selection

A total of 1000 samples were selected for static geochemical testing from available drill core from 205 diamond drill holes totaling 92,760 m spaced about 50 to 75 m apart. Preliminary estimates based on the block model for the mine identified six major rock types (lithologies) as listed in Table 1 with estimated proportions and number of samples selected for testing.

Table 1 Estimated Proportions of Major Identified Lithologies (Rock Types) and Sample Numbers

Lithology	Percentage of Waste Rock	WSF Weighted Proportion	Number of Waste Rock Samples	Number of High-grade Ore Samples	Number of Low-grade Ore Samples
Siltstone	18.2%	12.9%	178	13	4
Quartzite	32.1%	22.7%	494	49	24
Quartz Monzonite (fine-grained)	15.2%	10.7%	16	25	2
Quartz Monzonite (coarse-grained)	19.3%	13.6%	36	20	6
Feldspar-Megacrystic Quartz Monzonite (coarse-grained)	15.3%	10.8%	71	41	13
Monzodiorite	0.4%	Included	5	2	1
TOTAL	100.0%	100.0%	800	150	50

ABA Testing and Assay Database

The 1000 core samples were collected for acid base accounting (ABA) analyses to provide preliminary estimates for the potential acid generating (PAG), or non-PAG nature of the rock. Samples were analyzed for total sulfur, sulfate-sulfur, and pyritic-sulfur (sulfide-sulfur). Organic-sulfur was reported as the difference between total sulfur and the combination of the sulfate-sulfur

and pyritic sulfur. The Acid Generating Potential (AGP) was calculated based on sulfide analyses, whereas the. Acid Neutralization Potential (ANP) was determined following the State of Nevada Modified Sobek Procedure (2010). The potential for acid generation was assessed based on Neutralization Potential Ratio (NPR = ANP/AGP).

A metallurgical assay database for the 92,760 m of drill core, containing analyses for a total of 30,858 drill core samples, including concentrations of copper (Cu), molybdenum (Mo), iron (Fe), bismuth (Bi), antimony (Sb), arsenic (As), mercury (Hg), lead (Pb), and zinc (Zn), was reviewed to assess metal leaching (ML) potential prior to kinetic humidity cell testing.

In addition, composite samples representing simulated tailings and heap leach residue obtained from bench/pilot-scale metallurgical testing were submitted for the same ABA analyses used for waste rock and ore samples. The simulated tailings sample was derived from a blend of high-grade ore core samples and the simulated heap leach sample was derived from blended low-grade ore.

Humidity Cell Testing

Based upon results of static testing, kinetic testing (humidity cells) was initiated for nine of the waste rock samples and for single samples of simulated tailings and simulated heap leach residue obtained from bench/pilot-scale metallurgical tests. The nine samples of waste rock were selected to represent each major rock type (lithology), with two samples per lithology; one of either PAG rock (NPR<1) or uncertain (1<NPR<2) categories along with a non-PAG (NPR>2) sample from the same lithology. In addition, consideration was given to samples enriched in total contents of metals [copper (Cu), silver (Ag), molybdenum (Mo), bismuth (Bi), antimony (Sb), and arsenic (As)] based on assay analyses.

Humidity cell testing was conducted based on ASTM D5744-07 and EPA Method 1627. Testing for three of the nine waste rock samples was terminated after 20 weeks, because release rates of key parameters had stabilized. Humidity cell testing for the remaining six waste rock samples was continued for a total of 32 weeks. Humidity cell testing for the simulated tailings and heap leach samples was terminated after 20 weeks. Leachate samples were collected weekly for analysis of:

- pH, specific conductivity, total dissolved solids (TDS), alkalinity, and acidity;
- Concentrations of sulfate, chloride, fluoride, bicarbonate, and nitrate+nitrite nitrogen;
- Concentrations of calcium, magnesium, potassium, and sodium by inductively coupled plasma optical emission spectroscopy (ICP-OES); and,
- Concentrations of dissolved aluminum, antimony, arsenic, barium, beryllium, cadmium, chromium, copper, iron lead, manganese, mercury, nickel, phosphorous, selenium, silver, thallium, and zinc by inductively coupled plasma mass spectroscopy (ICP-MS).

Carbonate Analyses

The 11 humidity cell samples (nine waste rock, one simulated tailings and one simulated heap leach residue) were analyzed using a LECO C/S analyzer for (1) total carbon content and (2) carbon content of a subsample digested with hydrochloric acid to predict acid-insoluble carbon. The content of carbonate carbon (acid soluble carbon) was determined by difference and used to calculate carbonate NP. Although only a very limited number of samples were analyzed, the values were extrapolated to the remainder of the 800 sample waste rock database using linear regression to estimate carbonate NP for the entire waste rock database.

Other Analyses

The nine humidity cell waste rock samples were also submitted for X-ray diffraction using Rietveld refinement (RXRD) to provide a semi-quantitative estimate of mineral content. These waste rock samples and the two samples of metallurgical residues representing simulated tailings and heap leach residue were analyzed using the single addition net acid generation (NAG) test. On completion of humidity cell testing, the nine waste rock samples were submitted for particle size (grain size) analysis. Particle size data for composite bench/pilot-scale test samples were determined during metallurgical testing. Grain size analysis is typically used to estimate specific surface area of material in the humidity cells.

RESULTS AND DISCUSSION

Acid Base Accounting (ABA)

Methods for assessment of waste rock and ore as PAG or non-PAG vary depending on jurisdiction. As an initial PAG/non-PAG screening criterion for waste rock, MEND (2009) recommends NPR values greater than 2 to identify non-potentially acid generating (non-PAG) rocks; NPR values between 1 and 2 as having an uncertain acid-generating potential, requiring further testing for accurate assessment; and NPR values less than 1 as rock considered to be potentially acid generating (PAG). All samples with NPR values less than 2 are considered PAG until additional testing has been conducted. These criteria may also be applied to tailings; however, some jurisdictions recognize a lower NPR threshold for differentiating PAG and non-PAG tailings; however this requires site-specific studies. For this study, the MEND screening criteria (MEND, 2009) described earlier were applied to the ore/tailings as well as to the waste rock. It should be noted that the individual ore samples submitted for static testing were not subjected to metallurgical processing prior to analyses. The ABA characteristics and metal content of tailings derived from the ore could differ greatly from these analyses depending on the milling and heap leach processes. Average values for NPR, calculated from the ABA data (ANP/AGP) for the various lithologies where AGP is based on pyritic sulfur are summarized in Table 2.

Table 2 Proportion of 1000 Sample Database Based on NPR and Carbonate NPR (CNPR)

Lithology	Number of Samples	Sobek-NP		Avg.	Carbonate NP		Avg.
		NPR<2	NPR>2	NPR[1]	NPR<2	NPR>2	CNPR[1]
Low-grade Ore	50	48%	52%	1.8	72%	28%	0.6
High-grade Ore	150	48%	52%	1.4	79%	21%	0.4
Siltstone	178	14%	86%	2.8	22%	78%	1.1
Quartzite	494	20%	80%	1.6	56%	44%	0.2
Quartz Monzonite (fine-grained)	16	6%	94%	6.6	38%	63%	1.1
Quartz Monzonite (coarse-grained)	36	6%	94%	6.2	6%	94%	4.3
Feldspar-Megacrystic Quartz Monzonite	71	11%	89%	5.1	42%	58%	1.4
Monzodiorite	5	40%	60%	0.9	nd	nd	nd

Note: 1. Average for samples within a lithology or grade category
nd = not determined

Individually, the Siltstone, Quartz Monzonite (fine-grained), Quartz Monzonite (coarse-grained) and Feldspar Megacrystic Quartz Monzonite (coarse-grained) lithologies are non-PAG; collectively representing 67% of the waste rock. The Monzodiorite (<1% of the waste rock) was classified as PAG with an average NPR of 0.9, and the Quartzite (32% of the waste rock) was classified as uncertain with respect to ARD potential with an average NPR of 1.7. High-grade ore (feed stock for the mill) and low-grade ore (for use in the heap leach facility) had average NPR values of 1.4 and 1.8, respectively, indicating that the samples have uncertain ARD potential (1<NPR<2) with respect to the initial screening criteria. Overall, 52% of the ore samples were classified as non-PAG (NPR>2); 33% PAG (NPR<1) and 15% uncertain (1<NPR<2). Average values for Carbonate Neutralization Potential (CNPR) in Table 2 are discussed in the sections below.

Carbonate Carbon and NAG pH

The content of carbonate carbon for the nine waste rock humidity cell samples was used to calculate carbonate neutralization potential (CNP as $CaCO_3$ equivalent) for all samples in the database via linear regression. To calculate CNP, it is assumed that all neutralization potential (NP) is due to carbonate. For the waste rock and ore samples, CNP values represented between 15% and 70% of the Modified Sobek NP with an average of 26%. The values for carbonate content and the resulting carbonate NPR values (CNPR) show high variability with respect to acid generation potential and that the Quartz Monzonite (coarse-grained), Quartzite, and Feldspar-Megacrystalic Quartz Monzonite (coarse-grained) are either PAG (CNPR<1) or uncertain (1<CNPR<2) with respect to acid generation potential. Although the variability within each lithology (represented by only 2 samples each) was high, the CNPR values agreed with the NAG pH results. Comparison of NPR and CNPR values, NAG pH, and corresponding ARD classifications for the nine individual humidity cell samples is summarized in Table 3. Tailings and heap leach residue CNPR values and classification are compared to NAG pH classification in the same table. These values were used to calculate the average CNPR values for each lithology listed in Table 2.

Refinement of ABA Classification

Although the degree of variability for the CNP is higher than the Modified Sobek NP due to the limited number of samples, the amount of NP supplied by carbonate alone (CNP) provides a more conservative estimate of effective NP in the long term compared to modified Sobek NP values. Neutralization potential (NP) based on carbonate content (CNP) was used instead of Sobek NP as the primary means to assess ARD potential in these materials. Values for average CNPR, calculated as CNP/AGP, where AGP is based on pyritic sulfur, for the individual humidity cell samples with different lithologies is provided in Table 2 along with the average Sobek NPR values. Based upon the Sobek NP and the sulfide AP measurements, the waste rock had a weighted average NPR (based upon estimated percentages of the various lithologies in the waste facility; Table 1) of 3.9, indicating that overall the WSF is non-PAG. Based on the carbonate-carbon data, the weighted average of CNPR calculated for the waste rock overall based on the proportions of each lithology (Table 1) was 1.7, indicating that the waste rock, overall, has uncertain ARD potential. Based upon the CNPR data (Table 2), the quartzite waste rock was PAG with an average value of 0.2. The Siltstone, Quartz Monzonite (fine-grained), and Feldspar-Megacrystic Quartz Monzonite (coarse-grained) had CNPR values between 1 and 2, indicating uncertain ARD potential and the Quartz

Monzonite (coarse-grained) had an average CNPR of 4.3, indicating non-PAG material. Both the high-grade and low-grade ore had CNPR values less than 1, indicating that these materials are PAG. Note that these estimates for ARD potential for the site should be viewed as having a very high degree of variability, as the data were extrapolated to all 1000 samples using the original static data based on the carbonate analyses for the nine waste rock humidity cell samples, one tailings (cf. high-grade ore) sample, and one heap leach (cf. low- grade ore) sample.

The NAG test uses pH of 4.5 as a cutoff to differentiate between PAG and non-PAG rock. Based on this assessment, five of the nine waste rock samples were predicted to be PAG, including both samples of quartzite, and four samples were predicted to be non-PAG (Table 3). The simulated tailings sample had a NAG pH of 9.2, indicating it was non-PAG and the master composite sample (heap leach residue/low-grade ore) had a NAG pH of 3.4, indicating that it was PAG (Table 3).

Table 3 ABA and NAG pH Results for Individual Samples from Humidity Cells

Sample ID/Lithology	NPR ANP/AGP	ARD Class	CNPR CNP/AGP	ARD Class	NAG pH	ARD Class

Mineralogical Analyses

Results for mineralogical content of the nine samples, as determined by RXRD are as follows:

- The quartzite lithology was predominantly quartz (>95%) with some muscovite and metallic iron with one sample contained measurable quantities (0.5%) of pyrite.
- The siltstone samples contained quartz and muscovite (about 87%) with minor kaolinite and rutile. One sample also contained K-feldspar, andalusite, and detectable pyrite (0.4%).
- The quartz monzonite samples (fine-grained and coarse-grained) had similar mineralogy, containing quartz, feldspars, muscovite and kaolinite. The coarse-grained sample and one of

the fine-grained samples contained 2-3% jarosite, suggesting that the materials may have an acid generating source mineral in addition to sulfides (e.g., pyrite).

- The two Feldspar-Megacrystic Quartz Monzonite samples were very similar mineralogically, containing quartz, feldspars, muscovite, chlorite, pyrite, calcite, and siderite. Siderite ($FeCO_3$) is slow reacting compared to calcite, and estimates for carbonate NP were corrected in these two samples based on the mineralogical analyses.

Waste Rock Humidity Cells

After 20 weeks of waste rock humidity cell testing, leachate concentrations in three of the nine samples was terminated because release rates of key parameters had stabilized. The remaining six waste rock humidity cell samples were continued through 32 weeks. Based on humidity cell testing, preliminary estimates for exhaustion of sulfide-S (primary acid generation source) and carbonate NP (neutralization source) for waste rock samples in the nine humidity cells are summarized in Table 4. It should be noted that estimates for the humidity cells are based on best available data for the humidity cells, which may or may not have stabilized. Estimated rates of sulfate loss from the columns ranged from 0.25 to 26 mg/kg/week. Rates of alkalinity loss were similar for all columns at about 2.5 mg/kg/week with the exception of the Feldspar-Megacrystic Quartz Monzonite samples, which were 8.7 and 6.9 mg/kg/week. Using these values, predicted times required to exhaust sulfide and alkalinity in the humidity cells did not agree well with the original Sobek NPR values calculated from the static ABA testing. This indicates a high amount of variability within each lithology, particularly those samples containing low concentrations of sulfide and carbonate alkalinity. Note that these time estimates are for crushed samples under ideal laboratory conditions, whereas rates in the field are typically slower due to lower specific surface area values associated with larger rock fragments, ambient soil temperatures, and less contact with reactive surfaces as water flows among the larger rock fragments.

Table 4 Estimates of Years for Exhaustion of Sulfide and Carbonate in the Humidity Cells

Sample ID/ Lithology	CNPR CNP/AGP	Years to Exhaust Sulfide	Years to Exhaust Carbonate	Year to Acidification
015/Siltstone	8.1	23	19	19
198/Siltstone	0.0	14	0	Immediate
050/Quartzite	0.9	<1	38	Never
101/Quartzite	0.2	53	6	6
247/Quartz Monzonite (fine-grained)	0.0	4	6	Never
247b/Quartz Monzonite (fine-grained)	5.4	26	26	Never
017/Quartz Monzonite (coarse-grained)	1.0	157	5	5
142/Feldspar-Megacrystic Quartz Monzonite	1.5	<1	0	Never
164/Feldspar-Megacrystic Quartz Monzonite	0.2	11	13	Never

Tailings and Heap Leach Residue Humidity Cells

Humidity cell testing and analyses for the two metallurgical residue samples were completed through 20 weeks. Results indicated that the pH of the leachate from the Master Composite heap leach residue sample was 5.3 and the filtered tailings was 7.8. These data are assumed to represent long-term water quality for these materials, although they may or may not have stabilized during the 20-week testing. Based on the humidity cell leachate results, concentrations of metals released from the tailings are not anticipated to contribute high amounts of metals to the WSF leachate; however, it should be noted that the humidity cell data do not represent stabilized conditions; it is likely that metal leaching may not have been initiated due to the limited timeframe for leaching.

PROPOSED WASTE STORAGE FACILITY

Based on the mine plan, mill tailings derived from high-grade ore (about 573 Mt) are to be mixed with waste rock (about 1,360 Mt) for permanent storage in the on-site WSF. The WSF will also partially cover the heap leach facility (HLF; about 173 Mt), which will have been treated (surface irrigation) with about 2% H_2SO_4 for metal extraction. After mining operations cease (after 21 years) the entire WSF including the HLF not covered by co-mingled waste rock and tailings will be capped with a 2.5 m thick layer of tailings compacted to a dry bulk density of about 1.6 tonnes/m^3 and the compacted tailings will be covered with a 1 m thick layer of "inert" waste rock composed of roughly equal portions of Quartz Monzonite fine-grained; Quartz Monzonite coarse-grained and Feldspar-Megacrystic Quartz Monzonite coarse-grained lithologies. The waste rock layer will be covered with 0.5 m of growth media (soil) to support re-vegetation.

Water quality predictions for the leachate and ARD potential of the blended storage facility was based on the following assumptions:

- Release rates of acidity/alkalinity and metals from the co-mingled WSF at constant rates based on steady state data obtained from the humidity cells and on the proportion of materials during construction and after completion of mining;
- Instantaneous placement of the 2.5 m thick compacted tailings cover and 1 m of waste rock after 21 years of mining reducing the volume of infiltrating water. The volume and quality of water released at toe decrease and the results of the model presented herein represent worst case conditions;
- Ideal (perfect) mixing of rock types within the waste rock dump according to proportion of their lithologies (Table 1);
- Mill tailings are allocated to fill all pore space within the waste rock;
- The final configuration of the WSF covers an area of about 6,702,780 m^2 (6.7 km^2) receiving average annual precipitation of 963.8 mm, of which about 95% is received during the months of October to April. Evaporation from the surface of the WSF is assumed to be about 50% of precipitation. Losses from surface runoff and to groundwater are negligible.
- The HLF is assumed to be 100% PAG as it is leached with 2% H_2SO_4
- The proportion of PAG and non-PAG materials in the WSF are based on carbonate NP and a cut-off CNPR value of 2;
- Rates of releases for metals are based on the humidity cell data scaled up to field conditions.
- The waste rock is assumed to have an effective specific surface area of 13 m^2/tonne based on a total surface area of 20 m^2/tonne and 65% contact with water;

- Tailings and the heap leach residue are assumed to have specific surface areas the same as the respective humidity cell materials and will react to provide similar water quality.
- For the purposes of calculations, the internal temperature of the WSF is assumed to be constant at 15°C.

WATER QUALITY PREDICTIONS

Based on available data and assumptions, estimates for water quality of the WSF leachate are provided in Table 5. Leachate from waste rock will likely have a pH of approximately 4.6, calculated as weighted proportions of leachate contacting waste rock, tailings, and heap leach residue, at equal rates of flow through all materials, with equal contact. In reality, the majority of water flowing through the WSF is likely to be in contact with the larger pores of the waste rock with lesser contributions from the tailings and heap leach residue; however, estimates for water flow and proportions contacting each of the materials require a more detailed hydrological and hydrogeological assessment.

Table 5 Estimated Water Quality for WSF Leachate

Parameter	Units	Leachate	MPL[1] Liquid Effluent	NEQSW[2] Category 1
pH	su	4.6	6-9	6.5-8.5
Sulfate	mg/L	469		250
Calcium	mg/L	54		
Magnesium	mg/L	8

Notes: 1.Maximum Permissible Limits to unload liquid Effluents by Metallurgical Mining Activities.
2. National Environmental Quality Standards for Water Category 1: Potable Water

It is anticipated that water will flow through the much finer textured mill tailings at a much slower rate and consequently the volume of flow contributed from the tailings is expected to be less compared to flow and loadings from the waste rock; however, an estimate of the magnitude and proportions are beyond the current scope of this work.

The key parameters of concern appear to be pH, arsenic, copper, and iron. Some of the iron released from the WSF may precipitate from the leachate as it becomes more oxygenated by contact with the atmosphere. This may also reduce the concentrations of copper and arsenic due to co-precipitation or adsorption; however, concentrations may or may not be reduced to levels acceptable to Peruvian regulations, and thus may require active water treatment.

CONCLUSIONS

Based on static and humidity cell testing and the water quality model described herein, predictions indicate that leachate from the WSF is anticipated to contain elevated concentrations of iron, arsenic, and copper as well as acidic pH values less than the acceptable minimum required by Peruvian authorities for discharge to the environment. Water treatment measures may be required to reduce concentrations of metals as well as increase pH prior to discharge to the environment. Additional information on flow conditions, a detailed hydrological and hydrogeological assessment and water quality of downstream waters are required for further assessment.

Impacts of Artisanal Small-Scale Gold Mining on Water Quality of a Tropical River (Surow River, Ghana)

Karunia Macdonald, Mark Lund and Melanie Blanchette
Mine Water and Environment Research Centre, Edith Cowan University, Australia

ABSTRACT

Rivers in Ghana provide environmental and economic services such as fishery and farming, and are also the main sources of clean drinking water. Artisanal small-scale gold mining (ASGM), a significant industry in Ghana, typically occurs near streams and rivers in order to obtain a source of water for processing and waste discharge. ASGM is subsistence mining carried out by individuals or small collectives using rudimentary technologies for both extraction and processing of ore. Using small quantities of mercury for gold extraction, ASGM also releases high quantities of sediment, (along with metals and other contaminants) into local water bodies, posing environmental and downstream human health risks. In Ahafo, Ghana, we undertook a detailed assessment of the effect of ASGM on the water quality of the Surow River over one year (January 2013 to April 2014). Physico-chemical properties of the water at 11 sites along the river (above and below ASGM sites) were measured monthly. Our research indicates that the impacts of ASGM extend beyond Hg contamination, with the main effects of ASGM on river systems being changes in water conductivity, sediment loads, and metals, as well as alteration of river morphology. Dewatering water was responsible for significant increases in conductivity. We did not detect mercury above drinking water standards, with the exception being at the headwaters, presumably from natural sources. In general, we found that sites with associated ASGM activities had water qualities that did not meet Ghanaian national standards for drinking water, with manganese at particularly high concentrations. We also saw temporal variability in water quality parameters, likely due to the combination of fluctuating ASGM activities and the natural seasonal hydrology of tropical river systems.

Keywords: ASGM, sedimentation, mine dewatering, river ecosystems

INTRODUCTION

Rivers in Ghana provide not only environmental and economic services such as fishery and farming, but are also the main source of clean drinking water. Rural communities, particularly in areas where access to clean water is limited, often use untreated river water for domestic purposes including drinking. Where water is treated before consumption, declines in water quality within the rivers from pollutants and sediment loads from agriculture, industry, mining and forestry increase treatment costs (Fianko et al. 2010; Gyau-Boakye and Biney 2002). Coupled with declines in water quality, increasing demand (Gyau-Boakye and Biney 2002), and declining rainfall (Gyau-Boakye and Tumbulto 2000; Owusu and Waylen 2009), rivers in Ghana are under pressure.

Artisanal small-scale gold mining (ASGM) is a globally-significant industry, providing rural employment directly to at least 15 million people and indirectly to over 100 million in more than 70 countries (WHO 2013). Many ASGM operations occur near streams and rivers for easy access to alluvial ores, but also to supply water used in processing and as a receiving environment for mine waters. Although ASGM contributes to rural economies, it often results in degraded environmental, safety and social conditions due to the rudimentary mining and processing techniques used (Hilson 2002; Telmer and Veiga 2009). ASGM traditionally relied upon secondary and tertiary materials easily found near to the surface or river banks. However, due to depletion of alluvial resources and increased technical and financial capacities, contemporary operators are increasingly mining primary ore found underground, by manually digging vertical shafts or tunnels up to 30 to 35 m deep. These shafts and tunnels often require dewatering, with large volumes of untreated dewatering water often pumped out of these underground operations into nearby rivers and streams. Metal released from processing, dewatering or acid rock drainage can further degrade river water quality. Particularly concerning in ASGM is the widespread use of mercury amalgamation techniques in processing, although cyanide processing is increasingly being used in reprocessing of tailings (de Andrade Lima et al. 2008; Velásquez-López et al. 2011). Mercury processing emits toxic vapours, with predicted global mercury emission by ASGM to be 727 tonnes: 35% of the total world anthropogenic emission of mercury (UNEP 2013). The toxicity of mercury derived from ASGM operations to people and, to a lesser extent, the environment, has been well studied (Bose-O'Reilly et al. 2010; Castilhos et al. 2006; Donkor et al. 2006). However, the impact of AGSM operations on the broader water quality of these river and streams has been largely overlooked.

Previously, we identified a range of potential environmental impacts of ASGM on rivers, such as changes in hydrology and water quality (particularly increased turbidity), as a result of land clearing, erosion, mining and processing (Macdonald et al. 2014). Hydrological changes in rivers can alter available hydrological habitat for aquatic biota (Blanchette and Pearson 2013), and increased turbidity may lead to smothering of aquatic plants, habitats, and biota. Clearing of riparian vegetation, unregulated sewage from mining camps and rubbish disposal can impact on the rivers nutrient concentrations and habitats. In Ghana, these environmental impacts are temporally variable, with ASGM demands for water during dry seasons and excess water in wet seasons altering the flow of the river/stream (pers. obs.). Further, degradation of the river water quality and ecology can have flow-on impacts to cultural values associated with the river, as well as fishing and suitability for drinking.

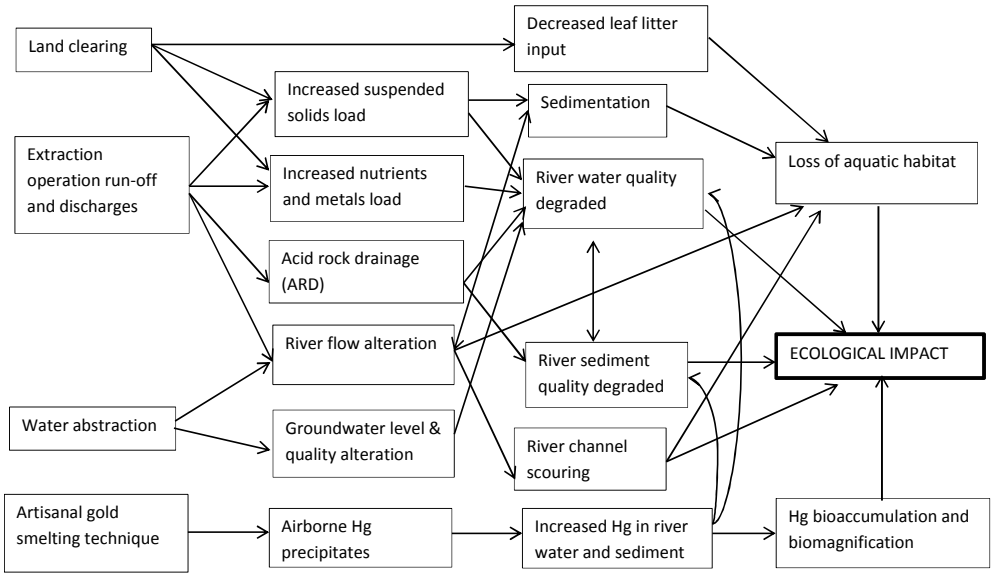

Figure 1 The impacts of artisanal small-scale gold mining (ASGM) on riverine systems (from Macdonald et al., 2014)

The impact of ASGM on tropical rivers has been investigated in Ghana, the Philippines, and Brazil, but the focus of these studies has been on elevated mercury concentrations and mercury cycling as a result of rudimentary processing techniques (Appleton et al. 2006; Bastos et al. 2007; Brabo et al. 2003). These studies were conducted on large river systems such as the Amazon in Brazil (Santos et al. 2000; Telmer et al. 2006) or the Pra (Donkor et al. 2005)and Ankobra Rivers in Ghana (Akabzaa et al. 2009) which have extensive and long-established ASGM operations with chronic mercury inputs. However, the scale and age of these systems prevents identification of other possible impacts besides mercury contamination. In contrast, ASGM activities in smaller rivers are easier to trace due to acutely concentrated nature of measurable impacts (see Webster et al. 1992). Therefore, this study is different from previously published research because of the focus on a smaller river, with the intention of more clearly defining the suite of impacts from ASGM operations.

The aim of this study was to identify the possible impacts of ASGM operations on water quality in the Surow River, a small tributary of the Tano River in Brong Ahafo, Ghana.

METHODOLOGY

Study site background

The Surow River catchment is located in the upper Tano River Basin in the Brong Ahafo region, Ghana, approximately 300 km northwest of the capital city of Accra (Figure 2). Major land uses in the Surow catchment are ASGM and agriculture among tracts of natural forest. Farming activities in the area include cash crop (cocoa), ranching and subsistence farming (vegetables and tubers). The Tano River (400 km long and 15,000 km^2 of catchment) is a major source of potable and domestic water for south west Ghana, and the Surow River is approximately 16 km long with a 3,500 ha. catchment. Located in a wet tropical region, the major rains occur during April to June (average

precipitation 294 mm/month) with minor rains from September to November (average precipitation 234 mm/month) and the driest months are from December to February (average precipitation 16 mm/month and evaporation 105 mm/month) (unpublished meteorological report NGGL, 2013). Therefore, rivers in the Tano Basin exhibit classical wet-dry hydrological patterns, driven by rainfall.

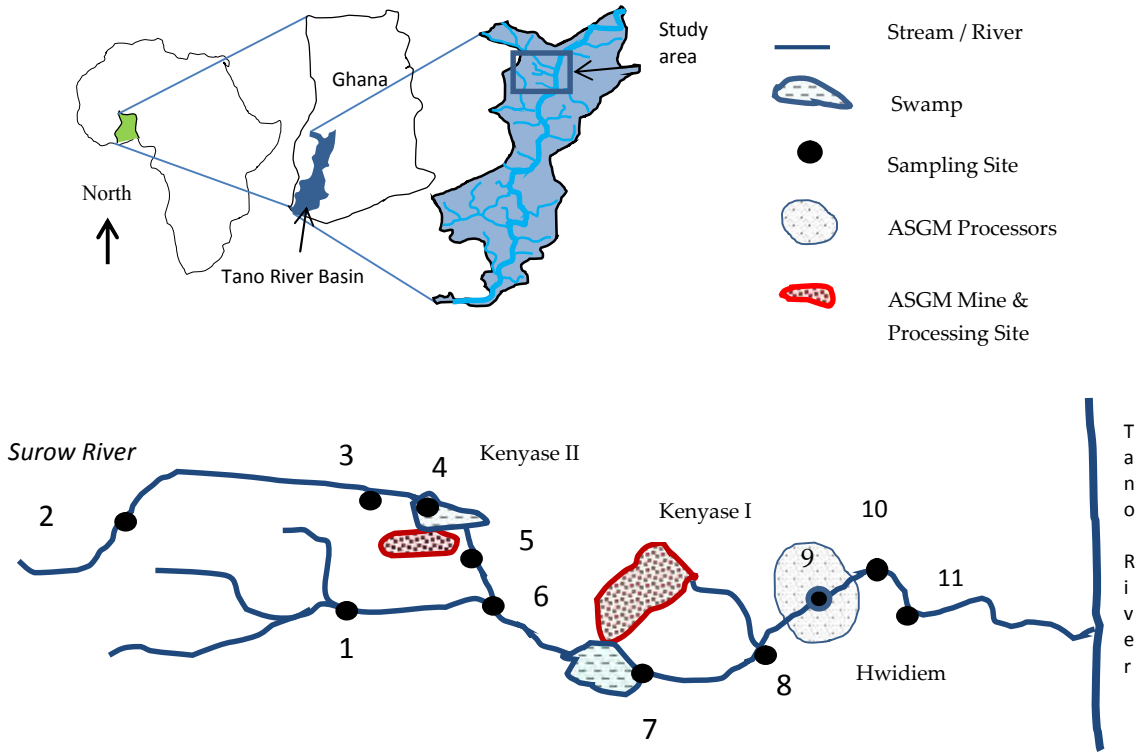

Figure 2 Location of sampling sites (1-11) along the Surow River, Ghana (not to scale)

ASGM has been practiced in many parts of Ghana for hundreds of years (Donkor, et al. 2005). However, operations are relatively new (9 years) to the Surow River catchment. ASGM in this area was started in 2005, following the commencement of a large multi-national gold mining project that discovered gold in the region. During the study period (February 2013 to April 2014), ASGM communities operated along the river at Kenyase I, Kenyase II and Hwidiem townships (Figure 2). At Kenyase I and II, small operators extracted secondary or tertiary alluvial ores easily found in the river banks, while larger operators extracted primary ore mined underground. Ores from these two sites are processed on site as well as sold to other processors mainly scattered near to the river at Hwidiem township. Loose gravel, sands and milled ores are processed via mechanical crushing, elutriation and, in most cases, mercury amalgamation followed by gold smelting and refining (see Macdonald et al. 2014).

Ghanaian legal provisions on mining exclude foreigners and foreign investments in ASGM operations. The sector, nevertheless, received foreign investments at least until March/April 2013 when the Ghanaian government deported as many as 4000 foreigners involved in the industry. As a result, many ASGM operators across the country (including those in Kenyase I and II) ceased most of their operations in May 2013, mostly due to lack of financial support previously provided by

foreign investors. Although underground mining activity was substantially reduced, dewatering of existing mine pits continued, especially during the wetter months. Smaller mining operators and processors, comprised of local citizens, continued to operate after the deportation.

Sampling program

Eleven sites on the Surow River were sampled monthly for 14 months from February 2013 to April 2014, typically within a 12 h period. Sites were chosen based on access, safety, and representativeness of catchment land use (Table 1). In addition, direct sampling of dewatering water at the Kenyase I ASGM site (sample site 8) was conducted once in April 2014.

Table 1 Hydrology and land use of sites (numbered upstream to downstream) on the Surow River, Ghana (February 2013-April 2014)

Sample site	Dominant site hydrology	Major land use
1	Riffle/run	Minimal use
2	Riffle/run	Minimal use
3	Pool/slow run	Minimal use, rural dwelling
4	Swamp	Mining, processing waste
5	Riffle/run	Minimal use
6	Run	Minimal use
7	Swamp	Mining, processing waste
8	Rifle/Run	Dewatering water
9	Riffle/Run	Processing
10	Riffle/Run	Cattle, cocoa farming
11	Pool/slow run	Rural dwelling

On each sampling occasion, and at each site, water depth and velocity (Marsh-McBirney Flowmeter, USA) were measured. Physico-chemical parameters of pH, oxygen reduction potential, dissolved oxygen (DO), temperature, electrical conductivity (EC), and turbidity were measured *in situ* using a Quanta Multimeter (Hach, USA). Water samples were collected 0.1 m below water surface and immediately divided into unfiltered and filtered (through 0.5 μm GF/C; Pall Ltd Metrigard) aliquots. All samples were stored at <4°C prior to analysis.

Aluminum, As, Cd, Cu, Cr, Mn, Pb, Zn in filtered water was analyzed using inductively coupled plasma mass spectrometry (ICP-MS) following USEPA Method 200.8; Fe and Mg were analyzed using ICP (USEPA Method 200.7), and Hg was quantified using cold vapour atomic absorption (CVAA; USEPA Method 245.1,detection limit of 0.0002 mg/L). Dissolved organic carbon was analyzed following USEPA Method 5310B. On unfiltered samples, total Kjeldahl nitrogen (TKN)

was analyzed via block digester method (USEPA M351.2); and total phosphorus was analysed with an auto ascorbic acid method (USEPA M365.1). The above samples were airfreighted to ACZ Laboratory in Colorado, USA.

Analysis of ammonia/ammonium (NH_3-N), nitrate/nitrite (NOx-N) and sulfate (SO_4) on filtered water were performed at the Newmont Ghana Ltd. environmental laboratory at Ahafo using a Hach DR 2800 spectrophotometer following APHA (2005) methods 4500B&C, USEPA Method 375.4; and USEPA Method 365.2 respectively.

Data Analysis

Water quality data was ordinated using principal components analysis (PCA) to illustrate patterns in the data, then compared among sites using permutational ANOVA (PERMANOVA). Data were prepared for ordination and analysis by selecting parameters where more than half of the samples were above detection; values below detection were replaced with half the detection limit, missing data were replaced by the average of any other data for that time and treatment, and auto-correlated parameters were reduced to a single representative parameter. Data were also normalized in Primer v6 prior to ordination and analysis. Significance testing of the multivariate data among sites was undertaken on PERMANOVA, using a two-way, unreplicated design with time (fixed) and site (random) as factors, followed by pairwise comparisons between sites. All analyses were performed on Primer v6 (Primer-E; Clarke and Gorley 2006).

RESULTS AND DISCUSSION

Water quality varied among sites (pseudo-F 2.36, $P<0.01$) and over time (pseudo-F 3.92, $P<0.01$), reflecting stochastic events, seasonal trends, and anthropogenic impacts. A PCA of water quality data, separated by month, illustrates the effect of seasonal trends on the data is presented in Figure 3 (note different axis scales). On most occasions, water quality at the headwater sites (1, 2, 3), and minimal land use sites (5, 6) were closely associated with each other, with the exception of site 6 in September and October 2013. Water quality at sites 1, 2 and 6 were not significantly different to each other, but were different to 5 (Table 2). Water from sites 1, 2 and 3 (headwaters) had low EC (0.11-0.35 mS cm^{-1}), turbidity levels generally below the Ghanaian EPA standard of 75 NTU (except on one occasion at site 2, and six occasions for site 3 where turbidity peaked at 247 NTU), and pH levels between 6.03 to 7.81. Water quality at the headwater sites reflects catchment mineralization (NGGL 2005), with silicate and carbonate mineral weathering, precipitation, and agricultural activities the most significant processes influencing the water quality in the area (Banoeng-Yakubo et al. 2009; Yidana 2009).

In March 2013, Hg concentrations at sites 1 and 3 exceeded the Ghanaian drinking water standards of 0.002 mg L^{-1}, reaching 0.003 mg L^{-1} – at no other time or site were standards exceeded. Mean (±SE) Fe concentrations declined downstream from 1.07±0.35 at site 1, to 0.25±0.10 by site 9. The Ghanaian drinking water standard for Fe is 0.3 mg L^{-1} and the EPA standard is 1 mg L^{-1}; essentially, exceedances occurred at headwater sites. Manganese exceeded the Ghanaian drinking water standards (0.05 mg L^{-1}) in 93 out of 130 samples, and the EPA standard (0.1 mg L^{-1}) in 67 samples across all sites and times (Figure 4). Although there were exceedances of both standards at sites 1 and 2, at site 3 every sample exceeded the drinking water standard. Sites 4, 5 and 6 (further downstream) had progressively fewer exceedances of the drinking water standard for Mn.

Therefore, Hg, Fe, and Mn concentrations in the Surow River do not appear to be directly related to ASGM operations, instead reflecting local geologies.

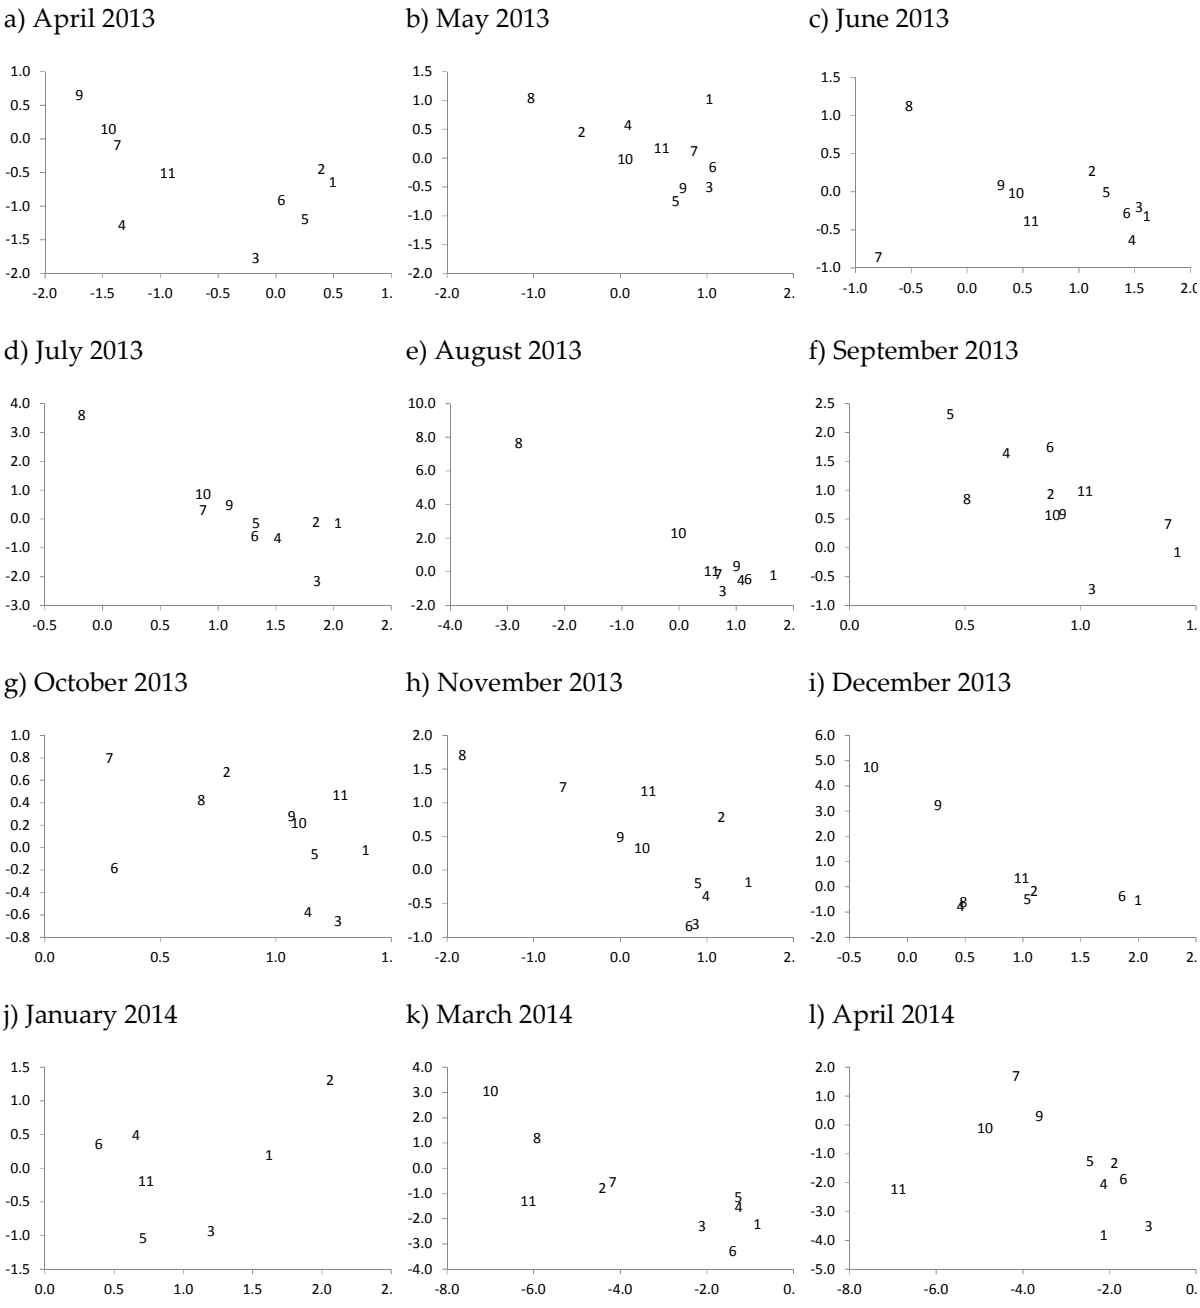

Figure 3 PCA of water quality data per sampling month (a-l) showing each site. Each graph is a subset of a single PCA on all available data. Note different axis scales

Sites 5 and 6 were similar to 1, 2, and 3 on most occasions (Figure 3), even during the period of highest ASGM activity (prior to May 2013) at site 4. At sites 5 and 6, EC ranged between 0.14—0.31

mS cm^{-1}, turbidity was 30—247 NTU and pH was 6.57—7.69, with metal concentrations similar to that of the upstream sites, except for Mn concentrations, which were among the highest of all sites at site 5 ranging between 0.03—3.11 mg L^{-1} (mean 0.8±0.3 mg L^{-1}). The similarity of sites above and below site 4, a site of intense ASGM activity, suggests that the impacts of ASGM, as measured, are highly localized.

Site 4 was separated from headwater sites (1-3) in April 2013 at the height of AGSM operations. Pairwise comparisons between all sites (across all times) show no significant differences between the two main ASGM sites 4 and 7, with 5 similar to 7 but not to 4. The start of the wet season in September 2013 altered the relationship among all sites. Although ASGM activity partially returned to site 4 in April 2014, the impact on overall water quality was not pronounced (as indicated by a lack of separation from other sites; Figure 3), possibly due to the heavy rainfall and high flows at this time. Magnitude and timing of flows appeared to have a variable impact on how different site 4 was from the rest of the data set.

At site 4, accumulation of sediment from processing at Kenyase II turned the defined river channel into a broad swamp. The site had a wider range of water temperatures (23.4-31.6 ^{o}C) than other sites - possibly due to its lack of canopy cover. The site had EC similar to the headwater sites (0.11—0.24 mS cm^{-1}) despite its proximity to an ASGM site, although underground mining activities were not significant during the study period (i.e., highly conductive groundwater was not being discharged into the river) Surface mining and ore processing were the main activities, resulting in high turbidity (peak >2000 NTU; mean 277±141 NTU) and sedimentation at site 4 (Figure 4). The number of exceedances of the Ghanaian EPA standard for turbidity was the same as site 3, although values were lower at site 3. Although the impact of ASGM operations on increasing turbidity are clearly visible before April 2013, after this time turbidity was also being generated at site 3. Higher flows during the wet seasons are naturally high in turbidity, with the sedimentation generated at site 3 washed downstream to site 4, and then carried further downstream to site 7. With the exception of Mn, dissolved metal concentrations were also similar at up- and downstream sites (5 and 6). Mean Mn concentrations at site 4 (0.51±0.24 mg L^{-1}) were higher than at site 3 (0.21±0.03 mg L^{-1}), indicating that ASGM activity was a source of the metal. Further, the only times that Mn concentrations were higher at site 4 than at site 3 was during periods of mining activity (April 2013, 2014, and December 2013). Mn is a hematological toxicant in fish, mammals and human (Crossgrove and Zheng 2004). Over discharge of manganese into aquatic ecosystems may affect the survival of natural fish population (Agrawal and Srivastava 1980).

In addition to site 4, sites 7 and 8 were highly impacted by ASGM activities, and tended to separate from other sites, particularly in June, July August, and November 2013 (Figure 3). Site 7 was highly turbid (up to 2000 NTU), particularly in comparison to headwater sites (Figure 4). At site 7, EC ranged from 0.20-0.95 mS cm^{-1}, pH ranged between 6.7—8.2, and occasionally had very high concentrations (and consequently mean concentrations) of NOx-N, TKN, Ca, and P compared to site 6 (site 6 being directly upstream of site 7, and unimpacted by mining). At site 7, metals were similar in concentration to site 6, with the exception of Mg which between December 2013 and April 2014 has concentrations at least an order of magnitude higher than site 6. There was a marginal increase in Mg seen at site 4 during April 2013.

a) Manganese b) Turbidity

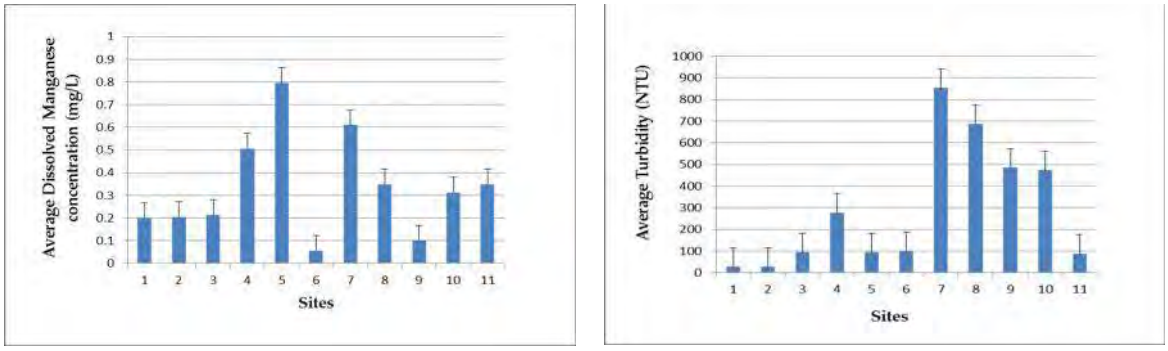

Figure 4 Mean (+SE) of a) manganese and b) turbidity at sites in the Surow River between February 2013 and April 2014. Sites are ordered upstream (1) to downstream (11)

The occasional spikes seen in nutrient concentrations at site 7 might be related to surrounding farming activities (cocoa plantation and cattle). Alternatively, in a forested stream, following a disturbance such as deforestation in the catchment, vegetative nutrient uptake is reduced while mineralization of organic matter is accelerated, which can result in elevated concentrations of NOx-N, Ca, Mg, K and Na (Webster et al. 1992). Site 7 is a swamp resulting from the deposition of sediment that came with the run-off from the exposed land, elutriation boxes, unregulated tailing, and waste material disposal at Kenyase I site. The size of ASGM operations at Kenyase I (site 7, 8) was larger than Kenyase II (4) this was also reflected in the relative size of the two swamps and mean turbidity values (Figure 4). River sediment is a sink of many pollutants and a medium for bio-geological processes including methylation of mercury; the quality of river water and habitats can strongly be influenced by quality of sediment (Chon et al. 2012; Kehrig et al. 2003).

Table 2 Significance of pairwise comparisons between sites from PERMANOVA (ns = P>0.05, t<1.3; s= P<0.05, t>1.3). See Table 1 for site details

	2	3	4	5	6	7	8	9	10	11

5	-	-	-	-	s	ns	s	s	s	ns
6	-	-	-	-	-	s	s	s	s	ns
7	-	-	-	-	-	-	s	s	ns	ns
8	-	-	-	-	-	-	-	s	ns	s
9	-	-	-	-	-	-	-	-	s	ns
10	-	-	-	-	-	-	-	-	-	ns

Site 8 was significantly different to all other sites except 10 (Table 2), and was characterized by high EC (0.58±0.08 mS cm^{-1}; peak 1.02 mS cm^{-1} in April 2013) for the duration of the study, particularly during the height of ASGM operations (February-April 2013). Five out of 13 times EC exceeded the

Ghanaian drinking water standard (0.5 mS cm^{-1}) but not the EPA standard of 1.5 mS cm^{-1}. Site 8 received dewatering water from the underground mines at Kenyase I via a drain. Dewatering water at the Kenyase I mine was sampled directly in April 2014 and had an EC of 1.3 mS cm^{-1}, suggesting this as the most likely source of the high EC at site 8. Calcium, Mg and Zn concentrations were generally similar to site 7; and higher than sites 1 to 6, particularly during the dry seasons (although the reason for this pattern was unclear). Site 8 had a pH between 6.7—8.5 (the highest recorded pH at any site during the study); turbidity was high between 19—2000 NTU, with the low turbidities occurring during the wet season when discharge of a large amount of dewatering water occurred.

Sulfate concentrations were substantially higher at site 8 than at all other sites (108.3±46.4 mg L^{-1} compared to <13 mg L^{-1} at sites 1—6), except for in December 2013 when sulfate at site 7 was 281 mg L^{-1}. Sulfate concentrations exceeded the drinking water standard of 250 mg L^{-1} on four occasions. Dewatering water appears to be source of the sulfate obtained from the mineralization of the ores in the area, which mostly contain sulfide composites (NGGL 2005) typical of the Sefwi belt of the Birimian host rocks, the main source of gold and diamonds that extends across Ghana (Akabzaa, et al. 2009). Similarities between sites 7 and 8 were not observed in May, July and August 2013, where site 7 had water quality similar to the headwater sites, possibly reflecting the downturn in ASGM activity at this time.

Site 9 is surrounded by ASGM processors, but no mining activities, and water quality at site 9 was significantly different from all other sites except site 11 (Table 2). Although the high turbidity recorded at sites 7 and 8 also occurred at site 9, values at site 9 were generally lower (Figure 4). The high EC at site 8 did not persist at site 9, and concentration of most metals at site 9 were lower than at sites 7 and 8 –below the Ghanaian drinking water standard with exceptions of Fe (2 occasions) and Mn (8 occasions). Broadly, water quality at sites 9, 10 and 11 tended to be similar (Figure 3, Table 2), with the exception of after December 2013 where 11 separated from 9 and 10 (although water quality overall at site 11 was not significantly different to sites 9 and 10; Table 2). Although overall water quality at sites 9, 10 and 11 tended to be significantly different to upstream sites (Table 2), this distinction was not reflected in the PCA ordinations for May, June, October and November 2013, possibly due to increased hydrological connectivity during the times of highest rainfall.

Water quality at site 11 was only significantly different to sites 1, 3 (headwaters) and 8 (ASGM dewatering), likely because as the most downstream site, site 11 represents the cumulative impacts of land use within the catchment.

CONCLUSIONS

Previously, we identified a range of possible environmental impacts of ASGM on riverine systems. In the Surow River, Ghana, ASGM activities increased sedimentation, altered river morphology, and elevated Mn concentrations. As evidenced by high pH across all sites and times, we did not observe acid mine drainage, although the mineralogy of the area made it unlikely because it contains low levels of pyrite. Mercury was only detected in headwater sites, presumably from natural rock sources. Dewatering water discharges were found to substantially increase EC in the river, although, as with most observed parameters, impacts were local. During the wet seasons, we observed that higher flows in the river tended to reduce the differences between sites. Overall, water quality in the river at many sites did not meet the standards set for the environment by the Ghanaian EPA and for drinking water. Future work will investigate the effect of ASGM activities on river ecology.

ACKNOWLEDGEMENTS

The authors wish to acknowledge support and assistance received from various institutions and individuals, including but not limited to: (1) Mr Anthony Loh and Ms Rita Lebene-Tibu of Newmont Ghana Gold Limited (NGGL) at Ahafo for their assistance in airfreighting the samples to be analysed at ACZ in the USA, (2) the NGGL Environment Laboratory staff at Ahafo, (3) Mr. Mumin Zakaria and Mr. Yakubu Ibrahim of Hwidiem, Ghana, (4) Nana Osuodumgya Berima Apiedwaa, Chief of Hwidiem Town (5) Dr Clint McCullough of Golder Associates (Perth) for his contributions to project design, and (6) Kenyasi I Galamsey (ASGM) Committee, Brong Ahafo, Ghana.

ABSTRACT

In catchments affected by diffuse mining-related pollution, the effectiveness of future remediation efforts at point discharges (e.g. mine drainage adits) may be severely limited as diffuse sources persist in elevating instream contaminant concentrations. This paper aims to systematically map potential diffuse mining pollution sources across catchments in England and Wales through (1) undertaking a risk-based classification of all waste rock mining features mapped between 1840 and the present (e.g. waste rock, tailings and processing plants), and (2) screening national datasets of fluvial metal(loid) concentrations in mine-affected catchments. A total of 2402 waste rock features (total surface area: 91 km^2) are identified in mining catchments, which in 11 priority catchments accounts to >10% of the catchment area. Many of these waste rock features are located in steep, upland catchments where risk for ongoing contaminated sediment delivery to watercourses is highlighted by topographic analyses (e.g. distance from stream features, slope and drainage areas) for each feature. There also appears to be a considerable inventory of within-stream potential diffuse pollution sources. In 69% of mine-affected catchments with available fluvial sediment concentration data, lead (Pb) exceeds the Probable Effects Level (PEL), above which potential negative effects on sediment dwelling organisms would be anticipated. The data highlight the ubiquity of diffuse-mining related pollution, and data presented for one catchment in north east England illustrate the importance of diffuse source mining pollution to overall metal export from such river systems. Such information will be of use for managers in catchment scale source apportionment studies and remedial planning for point discharges.

Keywords: diffuse pollution; metal mine; zinc; lead; geographic information system

INTRODUCTION

The persistent environmental legacy of abandoned metal mine discharges on the aquatic environment has long been recognised (e.g. Lewin et al. 1977). There has been a considerable associated growth in research in recent decades to try and address these legacy pollution issues, through the development of passive treatment systems requiring modest maintenance and running costs (e.g. Gandy and Jarvis, 2012). In catchments affected by metal mine pollution, the long term effectiveness of remedial action at point discharges (i.e. discrete discharges from mine adits or drainage levels) needs to be considered in the light of the broader controls on water quality within the wider catchment. Environmental regulators have increasingly focussed management on the catchment scale as a result of legislative drivers (e.g. the Water Framework Directive in Europe) that recognise that investment in remedial action must lead to demonstrable improvements in water quality and ecology at a catchment scale. As such, an awareness of the transient influence of different polluting sources on water quality at downstream regulatory compliance points is required. In catchments affected by abandoned metal mining, there are often multiple point discharges contributing to any instream water quality failure in addition to a range of diffuse metal inputs, the significance of which (and subsequent mobility of metals) will vary under differing hydrological conditions.

Where studies on the nature and extent of diffuse mining pollution have been undertaken, diffuse inputs into river systems have been found to be ubiquitous (e.g. Mighanetara et al., 2009; Byrne et al., 2013; Jones et al., 2013). These diffuse pollution mechanisms range from direct diffuse input of contaminated groundwater into surface waters to runoff from waste rock heaps, through to the remobilisation of weakly associated sediment-bound metals from instream sediments into the water column (for example during a fall in stream pH that may occur after heavy rainfall in peatland-rich upland catchments). The latter mechanism has been highlighted as important by several workers (e.g. Banks et al., 2010, Gozzard et al., 2011) as a significant portion of metals are typically found in sediment fractions that are either readily exchangeable or remobilised with change in pH or redox (Environment Agency, 2006). Studies have shown that these diffuse inputs are also visible from scales ranging from individual reaches (10s of metres) around mine sites (e.g. Gozzard et al. 2011) through to river basin scale (100s of km^2: e.g. Mayes et al., 2013). Indeed, in catchments with large inventories of metal-contaminated sediments in floodplain deposits, modelling studies have suggested it may take centuries for sediment metal concentrations to return to pre-mining levels (e.g. Dennis et al. 2009).

In the UK, national metal mine water management strategies have been focussed on catchment-scale management, with exercises to identify water bodies impacted by metal mining pollution (both point and diffuse) and subsequently prioritise them for potential remedial action (Jarvis and Mayes, 2012; Mayes et al. 2009). These large scale exercises have also provided detailed inventories for metal flux arising from point metal mine discharges (e.g. Mayes et al., 2010). However, no systematic assessment of potential diffuse metal mine pollution sources has yet to be established. Diffuse pollution issues were cited as a common occurrence at 187 of 256 mine sites in national surveys of environment managers (Jarvis and Mayes, 2012), however no specific detail on the nature and extent of these issues were provided.

This paper provides an overview of national scale GIS-based analysis to systematically identify potential diffuse metal mining pollution sources across England and Wales. By using a range of spatial resources (e.g. topographic maps, national geochemical atlases) we: (1) identify the extent of potential diffuse sources in priority mine-impacted catchments (e.g. extent of waste rock; establish

sediment metal concentrations), and (2) undertake a risk-based assessment of individual waste rock features based on physical attributes. These resources will be useful to river basin managers to help inform operational catchment-scale management, for example in terms of identifying potential locations for monitoring diffuse pollution inputs (e.g. upstream and downstream of waste rock) in catchment scale remedial planning investigations. A case study of the River South Tyne catchment, in north east England, concludes the paper. It highlights the importance of effective monitoring of both aqueous and particulate metals to quantify diffuse pollution, and also illustrates the challenges involved in managing such diffuse sources.

METHODOLOGY

Catchment descriptors

All spatial analyses were undertaken in Arc GIS v.10, with statistical analyses undertaken in Minitab v.15. Sediment metal concentration data were normally distributed after log transformation (Kolmogorov Smirnov $P>0.05$) so parametric methods are used. Spatial analyses focussed on the 264 water bodies in England and Wales deemed to be impacted or probably impacted by abandoned metal mine pollution (see Mayes et al., 2009 for detailed description of impact categories), which account for around 6% of all streams and rivers. In these priority water bodies, a range of physical and chemical environmental characteristics were derived to assist in the interrogation of catchment-scale water quality studies (e.g. Gozzard et al., 2011). The characteristics generated are detailed in Table 1 and utilise a range of datasets such as national topographic layers, Landmark waste rock data (from national Ordnance Survey mapping – see below) and GBASE stream sediment data. The latter is a geochemical atlas collated by the British Geological Survey (BGS) of individual sediment analyses at roughly 1km^2 grid square resolution nationally (Lister and Johnson 2005).

Waste rock heap mapping

Waste rock heaps are mapped digitally in the UK by the Ordnance Survey under the Historic Landmark dataset and provide a potential basis for systematic mapping of waste rock (e.g. waste rock, tailings) associated with abandoned metal mines. The Landmark data consists of shapefiles (polygons of areas) marked as waste rock or potential mining wastes digitised from historic OS maps (from 1st Edition c. 1840 to present). The datasets contain many features that may not be related to metal mining, so the first process was a manual check as to the likelihood of individual mapped features being related to historic metal mining (and not for example, due to aggregate extraction). This was done through combining the shapefiles from different mapping dates then:

- Screening for only those features that fell within a 1000m radius of a mineral vein (buffer analysis).
- Clipping the Landmark dataset to only the priority catchments identified by Mayes et al. (2009).
- Manually comparing remaining features against aerial photography (ESRI World Imagery) to assess whether features could be readily discounted as not being related to metal mining - for example, if aerial photography showed the feature to be a limestone quarry in a mineralised district. Features clearly related to other non-metal mining extractive activities were filtered from subsequent analyses.

These screening procedures reduced the number of features from an initial 85,478 features to 2,402.
